Weiyuan Huang (*Abstract Co-Author*)
Feng Chen, MD, PhD (*Abstract Co-Author*)

PURPOSE

Recurrence after radiofrequency ablation (RFA) for atrial fibrillation (AF) is common, with traditional models mainly relying on clinical factors, often overlooking imaging features. Epicardial adipose tissue (EAT) plays a role in AF recurrence. This study aims to develop three predictive models—radiomics, clinical, and combined—to enhance prediction accuracy for post-ablation recurrence.

METHODS AND MATERIALS

This retrospective study included 168 AF patients who underwent RFA between January 2020 and October 2024. Preoperative contrast-enhanced cardiac CT images and clinical data were collected. Patients were divided based on recurrence within two years or the first late recurrence (=30 seconds of atrial arrhythmia). The radiomics model involved manually delineating the EAT region using 3D Slicer, followed by feature extraction with PyRadiomics, selecting 1218 features through LASSO regression. The clinical model was based on baseline clinical and laboratory data, including BMI and HbA1c levels. The combined model integrated radiomics and clinical features, analyzed through LASSO regression. The dataset was split into a training set (70%) and a test set (30%), with model performance evaluated using AUC, sensitivity, specificity, F1 score, and decision curve analysis (DCA).

RESULTS

The radiomics model identified 13 significant features, showing that EAT's 3D morphology and texture complexity influenced recurrence risk. The AUC for the training set was 0.878 (95% CI: 0.810-0.934) and 0.846 (95% CI: 0.733-0.939) for the test set. The clinical model identified three key predictors: early recurrence history, HbA1c = 6.0 %, and BMI > 25 kg/m². The AUC for the training set was 0.809 (95% CI: 0.723-0.888) and 0.824 (95% CI: 0.695-0.941) for the test set. The combined model, merging radiomics and clinical factors (early recurrence history, HbA1c, BMI), had an AUC of 0.935 (95% CI: 0.887-0.972) for the training set and 0.884 (95% CI: 0.775-0.974) for the test set. Decision curve analysis showed the combined model provided the highest clinical net benefit in the 0.05-0.20 risk threshold range.

CONCLUSION

The combined model, integrating radiomics and clinical features, outperformed the individual models, showing the highest AUCs (testing set :0.884). This model offers a more reliable method for predicting AF recurrence, improving post-ablation management.

CLINICAL RELEVANCE/APPLICATION

The combined radiomics-clinical model improves prediction accuracy, aiding clinicians in making more informed decisions and reducing recurrence risks post-ablation. This approach enhances patient management and outcomes.

M5A-SPCA-10 HEAD-TO-HEAD COMPARISON OF CORONARY ARTERY PLAQUE ANALYSIS USING SPECTRAL PHOTON-COUNTING CT VERSUS HD-IVUS IN PATIENTS WITH CHRONIC TOTAL OCCLUSION

Magdalena Dobrolinska, MD (*Presenter*)
Marcel Greuter, PhD (*Abstract Co-Author*)
Niek Prakken (*Abstract Co-Author*)
Tim Leiner, MD, PhD (*Abstract Co-Author*)
Maksymilian Opolski (*Abstract Co-Author*)

PURPOSE

To assess the accuracy of photon-counting computed tomography (PCCT) for characterizing coronary artery plaque morphology, using high definition intravascular ultrasound (HD-IVUS) as the reference standard.

METHODS AND MATERIALS

This retrospective study included patients with chronic total occlusion of a coronary artery who underwent coronary CT angiography (CCTA) on a photon counting CT (PCCT, NAEOTOM Alpha, Siemens Healthineers) before undergoing percutaneous coronary intervention (PCI) for revascularisation. High definition intravascular ultrasound (HD-IVUS) imaging was performed immediately following successful intraplaque recanalization of the coronary occlusion and before stent implantation. A total of 99 matched cross-sectional slices from CCTA and IVUS were analyzed. Plaque morphology was classified on IVUS as: calcified (hyperechoic plaques with acoustic shadowing), fibrous (echogenicity similar to adventitia without attenuation), lipid-rich (echo attenuation), calcium-lipid, calcium-fibrous, and fibro-lipid (mixed acoustic features). CCTA images were reconstructed at six monoenergetic (monoE) levels: 40, 55, 70, 90, 120, and 140 keV. Plaques were manually segmented on each monoE image, and mean and minimum Hounsfield Units (HU) were recorded.

RESULTS

At 70 keV, calcified plaques exhibited the highest mean HU values (calcified: 1200±362HU; calcium-fibrous 514±49HU; calcium-lipid 154±68HU), while non-calcified plaques, namely fibrous (92±30HU), fibro-lipid (76±32HU), and lipid-rich (73±24 HU), had significantly lower values. There were no significant differences between fibrous and fibro-lipid, and fibrous and lipid-rich plaques ($p = 0.436$ and $p = 0.99$, respectively). For fibro-lipid and fibrous plaque, both mean and minimum HU values

decreased with increasing monoE level. Importantly, minimum HU values for lipid-rich plaques increased with higher monoE levels, a pattern opposite to that observed in fibrous and fibro-lipid plaques.

CONCLUSION

Monoenergetic reconstructions improve differentiation among non-calcified coronary plaque types. Notably, lipid-rich plaques display a distinctive HU spectrum that facilitates their identification.

CLINICAL RELEVANCE/APPLICATION

PCCT shows promise for enhanced identification and characterization of non-calcified coronary plaques, with particular focus on lipid-rich plaques related to the vulnerable plaque concept, potentially improving risk stratification and guiding personalized treatment strategies.

M5A-SPCA-12 T2 PARAMETRIC MAPPING INHOMOGENEITY IN PATIENTS WITH CARDIAC SARCOIDOSIS: A SIGN OF ACTIVE INFLAMMATION

Arzu Canan, MD (*Presenter*)
Mauricio Barbosa, MD, PhD (*Abstract Co-Author*)
Yin Xi, PhD (*Abstract Co-Author*)
Vlad Zaha (*Abstract Co-Author*)
Kartik Agusala (*Abstract Co-Author*)
Asha Kandathil, MD (*Abstract Co-Author*)
Suhny Abbara, MD (*Abstract Co-Author*)
Ronald M. Peshock, MD (*Abstract Co-Author*)
Orhan K. Oz, MD,PhD (*Abstract Co-Author*)
Fernando U. Kay, MD, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate diagnostic potential of T1 and T2 parametric mapping sequences and increased focal T2 inhomogeneity for identifying active inflammation in cardiac sarcoidosis.

METHODS AND MATERIALS

Patients with cardiac sarcoidosis who had both CMR and PETCT before Dec 2022 were screened for eligibility. After excluding ineligible patients, 28 patients with cardiac sarcoidosis and 28 age- and sex-matched controls were included. Based on PETCT findings, patients with cardiac sarcoidosis were categorized into two groups: PET-positive and PET-negative. Native T1 and T2 parametric mapping images were segmented using the AHA16-segment model in 3D Slicer (slicer.org).Two independent readers analyzed all cases, while one reader segmented control group.For each patient, max segmental values, standard deviation(SD), mean absolute deviation(MAD) of segmental values, MAD of SD(MAD-SD), and log-transformed MAD-SD, were calculated for both native T1 and T2 parametric mapping. MAD values were used to assess increased tissue inhomogeneity. Pairwise Wilcoxon test was used with Holm correction for each parameter. ICC was used to assess reader agreement.

RESULTS

Among 107 patients, 79 were excluded (63-absent,9-incomplete,and 7-non-diagnostic parametric mapping).Final cohort consisted of 28 patients:13 in PET-positive and 15 in PET-negative group. Median interval between CMR and PETCT was 44 days. No significant differences in age, LV and RV EDV or EF between groups were noted(Table 1).Individual comparisons of T1 and T2 values between groups are listed in Table 2.For native T1, max segmental value, SD, and MAD of segmental values were significantly higher in PET-positive group compared to both PET-negatives and controls. Although max segmental T2 and SD values were higher in PET-positive group than in PET-negative group, the differences were not statistically significant. When comparing PET-positive group to controls, max mean, max SD and mad mean showed statistically significant elevation. No significant differences in T1 or T2 parameters between PET-negative group and controls was found. Inter-reader agreement for T1 parameters was moderate, whereas for T2 parameters was good, with highest agreement for T2-SD (ICC=0.88).

CONCLUSION

MAD-T2 values provide an assessment of T2 inhomogeneity, which may be useful in identifying active myocardial inflammation, such as edema, especially when maximum T2 values are below upper normal thresholds in patients with cardiac sarcoidosis.Attention to these parameters may offer improved reproducibility and enhanced detectability of active inflammation.

CLINICAL RELEVANCE/APPLICATION

MAD-T2 may enhance detection of active myocardial inflammation in cardiac sarcoidosis, even when T2 values appear normal.

M5A-SPCA-14 DIAGNOSTIC ACCURACY OF CORONARY ARTERY CALCIUM CT IN INDIA AND PAKISTAN: A META-ANALYSIS

Anna Newman, MD (*Presenter*)
Jeremy R. Burt, MD (*Abstract Co-Author*)
Shannon J. Zhou, MD (*Abstract Co-Author*)
Reham M. Ellessy, MBBCh (*Abstract Co-Author*)
Amr M. Salem, MBChB (*Abstract Co-Author*)
Anujin Baljinnyam, MD (*Abstract Co-Author*)
Naim Qaqish, MD (*Abstract Co-Author*)
Gilberto J. Aquino, MD (*Abstract Co-Author*)
Ismail M. Kabakus, MD, PhD (*Abstract Co-Author*)
Dhiraj Baruah, MBBS, MD (*Abstract Co-Author*)

PURPOSE

Though Coronary Artery Calcium Scoring (CACS) is recognized as an effective tool to guide risk stratification and avoid downstream testing in at-risk patients in high-income countries, little data exists on applicability of this tool in countries with developing economies. In this systematic review and meta-analysis, we examined the use of CACS in predominantly low-intermediate risk patients in India and Pakistan to determine its diagnostic performance compared to gold-standard CT or conventional coronary angiography.

METHODS AND MATERIALS

The authors searched the PubMed, SCOPUS, and World of Science databases for peer-reviewed studies evaluating populations in India and Pakistan between 2003-2024 in accordance with PRISMA guidelines. We examined the relationship between CACS and obstructive (=50% stenosis) coronary artery disease diagnosed by angiography among patients at risk for coronary artery disease.

RESULTS

In India and Pakistan, 11 studies included 4105 patients who met inclusion criteria. Some studies included symptomatic patients (5/11, 45.4%), other studies included asymptomatic patients with =1 risk factors (4/11, 36.4%), or all-comers (2/11, 18.2%). Mean age was 51.91 ± 10.97 with 70.4% male. Most studies (81.82%) used CT scanners with = 64 detector rows, and all studies used the Agatston method for CACS. Overall, 47.7% (95%CI=30.2-65.3%) had CACS = 0. The pooled negative predictive value (NPV) for CACS = 0 to rule out obstructive CAD was 90.9% (95% CI=84.1-95%) (see Figure of Forest Plot). The prevalence of CACS > 0 was 52% (95%CI=38.6-65.3%). Prevalence of CACS 1-99, 100-399, and = 400 was 25.09%, 19%, and 8.7%, respectively. Compared to gold-standard angiography, sensitivity, specificity, and positive predictive value (PPV) of CACS > 0 for CAD were 89.1% (95% CI=73.8-96%), 85.2% (95% CI=71.7-92.9%), and 88% (95% CI=77-0.94.2%). Of the five studies with reported data, 12.54% (±10.31%) of patients had noncalcified atherosclerotic plaque.

CONCLUSION

Among mostly low- to intermediate-risk patients in India and Pakistan, the absence of CAC was associated with a low prevalence of obstructive CAD on angiography. However, the pooled NPV was lower than previously published in high-income countries. Randomized studies are needed to assess the utility of CAC testing as a large-scale gatekeeper in this setting.

CLINICAL RELEVANCE/APPLICATION

The results of this study support the efficacy of CACS for risk stratification in India and Pakistan. High NPV supports the use of CACS to rule out obstructive CAD and act as a gatekeeper for subsequent testing in non-acute coronary syndrome patients. Additional research is required to understand why the pooled NPV was lower in India/Pakistan than previously published in high-income countries.

M5A-SPCH-1 ASSOCIATIONS OF AIRWAY RESPIRATORY MECHANICS WITH LUNG HEALTH, SMOKING, AND PHYSICAL ACTIVITY PARAMETERS

Punam K. Saha, PhD (*Presenter*)
Syed Ahmed Nadeem, PhD (*Abstract Co-Author*)
Xinyu ZHANG (*Abstract Co-Author*)
Xiaoliu Zhang (*Abstract Co-Author*)
Kung-Sik Chan (*Abstract Co-Author*)
Elizabeth A. Regan, MD,PhD (*Abstract Co-Author*)
R. Graham Barr (*Abstract Co-Author*)
Eric A. Hoffman, PhD (*Abstract Co-Author*)
Sean B. Fain, PhD (*Abstract Co-Author*)
Alejandro Comellas, MD (*Abstract Co-Author*)

PURPOSE

Respiratory lung function is compromised in chronic obstructive pulmonary disease (COPD). Radiographic markers of emphysema, air-trapping, and small airway disease have been established as signs of compromised lung health in COPD. We retrospectively study associations of multi-volume CT-based respiratory mechanical biomarkers of lobar airways with lung health, smoking, and physical activity.

METHODS AND MATERIALS

Automated algorithms were applied to total lung capacity (TLC) and residual volume (RV) CT images to compute breathing-related measures of airway radial expansion (? air-R) and along-the-length stretching (? air-S) (Figure 1(a)). ? air-R is computed as the change (%) in cross-sectional area (CSA) at a matching airway between TLC and RV, while ? air-S is computed as the change (%) in path-length from the carina to a matching airway between TLC and RV. For each ?-metric, lobe-specific mean value over segmental airways was computed for each participant of the Genetic Epidemiology of COPD (COPDGene) study Iowa cohort at baseline visits; exclusion criteria: never-smokers, BMI <20kg/m 2 or >35kg/m 2 , and missing data. Pearson correlation values of ?-metrics with spirometry, emphysema, airway wall thickness (pi10), air trapping, smoking pack-years, and six-minute walk distance (6MWD) were computed.

RESULTS

The correlation (r-values) heat map of lobar airway ?-metrics with lung health, smoking, and physical activity parameters is presented in Figure 1(b) (n = 853; age (mean±SD): 64.2±8.3 years; 384 females; BMI: 27.9±3.6 kg/m 2). In general, stronger associations were observed for ? air-S as compared to ? air-R and at lower lobes than upper lobes. Spirometric lung function measures positively correlated with both ?-metrics, while radiographic lung health markers of emphysema, air trapping and pi10 were negatively associated. The associations with spirometric and radiographic measures were significant at lower lobes for ? air-R and at both lobes for ? air-S . Smoking pack-years showed a significant negative association only with ? air-S at upper lobes, while significantly positive association was observed for the physical ability metric 6MWD for ? air-R at lower lobes and ? air-S at both lobes.

CONCLUSION

Spirometric and radiographic lung health parameters as well as physical activity were correlated with respiratory airway mechanical measures; these associations were stronger for along-the-length airway stretching and at lower lobes. Smoking showed significant negative association with along-the-length airway stretching at upper lobes.

CLINICAL RELEVANCE/APPLICATION

Understanding regional interactions of breathing-related mechanical properties of airways with lung health, smoking, and physical activity parameters in COPD.

M5A-SPCH-3 ASSESSMENT OF PULMONARY VENTILATION FUNCTION IN COPD PATIENTS WITH PHASE-RESOLVED FUNCTIONAL LUNG (PREFUL) MRI

Yu Zhang (*Presenter*)
Ting Yin (*Abstract Co-Author*)
Robert Grimm, PhD (*Abstract Co-Author*)
Chunchao Xia (*Abstract Co-Author*)
Zhenlin Li (*Abstract Co-Author*)

PURPOSE

Lung magnetic resonance imaging based on the phase-resolved functional lung(PREFUL) technique allows assessment of pulmonary ventlation function. Previous studies are limited to Asian populations and COPD populations. To assess the feasibility and accuracy of PREFUL MRI in Asian patients with chronic obstructive pulmonary disease (COPD), especially with different COPD severity.

METHODS AND MATERIALS

39 COPD patients (age 41-75 years, 23 males and 16 females) were examined at 3T MRI. Subjects were scanned during free-breathing in a supine position with the following imaging parameters: TE/TR = 1.86/0.74ms, flip angle = 4°, slice thickness = 15mm, field of view = 500x500mm, matrix size = 256x256. A total of 6-10 slices were obtained to cover the whole lung and 500 images per slice were acquired in 60 seconds duration. The images were processed using the research Software MR Lung. Pixel-wise ventilation parameters were extracted from the respiratory cycle, which included: regional ventilation (RVent), flow-volume loop correlation (FVLc), regional ventilation defect percentage (RV DP) and FVLc defect percentage (FVLc DP). Pulmonary function tests (PFT) were performed within one month of the MRI. Forced expiratory volume in 1 s (FEV1), FEV1% predicted (FEV1 %), and forced vital capacity (FVC) were measured in accordance with guidelines. COPD severity was

defined according to the Global Initiative for Chronic Obstructive Lung Disease (GOLD). The relationship between PREFUL-derived ventilation parameters, PFT parameters and GOLD stage were evaluated using Spearman's correlation (r) analyses.

RESULTS

Among the lung function parameters derived from PREFUL MRI, FLVc, RV DP and FLVc DP showed good to strong correlation with the GOLD stages, FEV1, FEV1 %, and FEV1/FVC values obtained from PFT results, while RVent only showed mild correlation with GOLD stages and PFT results. Detailed correlations were summarized in Figure 1. Figure 2 presented representative images of patients with different GOLD stages. As the GOLD stage became more severe, PREFUL MRI images showed more ventilation-related defects, with areas of exacerbation occurring predominantly in the lower lungs, consistent with the greater susceptibility of the lower lobe to damage in patients with COPD.

CONCLUSION

In conclusion, our results suggest that functional information derived from PREFUL MRI allows the assessment of the ventilatory function of the lungs by means of ventilatory parameters and could be used to assess lung function in COPD patients.

CLINICAL RELEVANCE/APPLICATION

The results suggest that PREFUL MRI-related parameters can effectively differentiate between different grades of COPD and may assist in diagnosing and monitoring COPD.

M5A-SPCH-4 ULTRA-LOW-DOSE CHEST CT WITH DEEP LEARNING RECONSTRUCTION FOR LUNG CANCER SCREENING: COMPARISON WITH STANDARD-DOSE FOR LUNG-RADS ASSESSMENT

Siqi Qu (*Presenter*)
Zhiming Xiang (*Abstract Co-Author*)
Qiuxing Chen (*Abstract Co-Author*)
Kun Ma (*Abstract Co-Author*)

PURPOSE

To explore the feasibility of different reconstruction algorithms in ultra-low-dose chest CT (ULDCT) based on BMI grouping, focusing on image quality and Lung Imaging Reporting and Data System (Lung-RADS) assessment.

METHODS AND MATERIALS

In this prospective study, patients with suspected pulmonary nodules underwent both standard-dose CT (SDCT; 100 kVp/smart MA) and ultra-low-dose CT (ULDCT). ULDCT scans were divided into two groups (UL-A and UL-B) based on different dose settings. SDCT, reconstructed with adaptive statistical iterative reconstruction-Veo (ASIR-V50%), served as the reference. ULDCT images were reconstructed using ASIR-V50%, filtered back projection (FBP), and deep learning image reconstruction (DLIR) at medium (DLIR-M) and high (DLIR-H) strengths. Lung-RADS classifications were assigned using computer-aided detection (CAD) software. Image quality was analyzed using Kruskal-Wallis one-way analysis. The agreement of Lung-RADS classification with the reference was assessed using weighted kappa (Kw) statistics.

RESULTS

A total of 193 patients (mean age ± standard deviation, 58 ± 14 years; 99 men) with 869 pulmonary nodules were included. The effective dose (ED) was 3.62 ± 1.40 mSv for standard-dose CT (SDCT), 0.88 ± 0.19 mSv for UL-A, and 0.48 ± 0.11 mSv for UL-B, corresponding to dose reductions of 73.58% and 85.96%, respectively ($P < 0.001$). Compared to ASIR-V50% and FBP, DLIR significantly reduced both lung tissue and background noise (standard deviation, SD) and improved SNR and CNR ($P < 0.001$). Among DLIR methods, DLIR-H outperformed DLIR-M in reducing SD and increasing SNR and CNR ($P < 0.001$). Additionally, Image quality was significantly better in the UL-A group compared to UL-B ($P < 0.001$). Lung-RADS agreement (weighted kappa, Kw) between SDCT and ULDCT reconstructions showed no significant difference between the two dose groups ($P > 0.001$): UL-A group—ASIR-V50% (0.971), DLIR-M (0.971), DLIR-H (0.957), FBP (0.957); UL-B group—ASIR-V50% (0.981), DLIR-M (0.981), DLIR-H (0.975), FBP (0.970).

CONCLUSION

ULDCT showed high concordance with SDCT in Lung-RADS categorization, with no significant impact of dose differences on nodule risk classification. DLIR enhanced image quality at ultra-low doses, with a positive correlation between radiation dose and image quality. Among the reconstruction methods, DLIR-M outperformed DLIR-H and FBP in Lung-RADS assessment.

CLINICAL RELEVANCE/APPLICATION

Lung-RADS standardizes CT-based lung cancer screening and helps monitor outcomes. ULDCT greatly lowers radiation while keeping high consistency in Lung-RADS classification, highlighting its clinical value for routine screening.

M5A-SPCH-5 ULTRA-HIGH RESOLUTION CT PULMONARY ANGIOGRAPHY WITH PHOTON-COUNTING DETECTOR CT: LOW DOSE, HIGH IMPACT

Pauline Pannenbecker, MD, BA (*Presenter*)
Philipp Gruschwitz, MD (*Abstract Co-Author*)
Jan P. Grunz, MD (*Abstract Co-Author*)
Alena Kollmann, MD (*Abstract Co-Author*)
Thorsten A. Bley, MD (*Abstract Co-Author*)
Henner Huflage, MD (*Abstract Co-Author*)

PURPOSE

To assess image quality (IQ) in CT pulmonary angiography (CTPA) with ultra-high resolution (UHR) photon-counting detector (PCD) CT at two clinically relevant dose levels compared to standard resolution (SR) energy-integrating detector (EID) CTPA.

METHODS AND MATERIALS

In this retrospective IRB-approved study, 227 CTPAs acquired between April and October 2024 were analyzed (75 EID-CT; 76 PCD-CT at IQ level 50, 76 at IQ level 25). UHR scans were acquired on a dual-source PCD-CT scanner using flash mode and reconstructed at 55 keV, while dual-source dual-energy SR EID scans served as reference. Objective IQ (vessel attenuation) was assessed using standardized ROIs. Subjective IQ - including pulmonary artery visibility, iodine map IQ and self-reported diagnostic confidence - was rated by three blinded radiologists using dedicated 5-point scales. For all exams, radiation dose parameters were documented.

RESULTS

Peripheral vessel visibility and overall subjective IQ were rated higher in both UHR groups, with no relevant differences between IQ25 and IQ50. Self-reported diagnostic confidence was higher with UHR CTPAs, particularly when combined with iodine maps: after viewing both, CTPA and iodine maps, readers (R) gave the two highest confidence scores in 100% (R1/R3) and 92.1% (R2) of IQ50 scans, and 100% (R1), 96% (R3) and 94.6% (R2) of IQ25 scans. For SR EID scans, highest or second-to-highest confidence levels were reported in only 73.3% (R3), 66.7% (R1) and 66.6% (R2) of cases. Median HU values in the pulmonary trunk were higher in both UHR groups (623.3 HU for IQ25, 567.8 HU for IQ50) compared to the SR EID group (397.2 HU), all $p < 0.001$. Mean radiation dose was highest in the UHR IQ50 group (CTDIvol 6.7 mGy), lowest in the UHR IQ25 group (3.0 mGy) and intermediate in the SR EID group (4.7 mGy).

CONCLUSION

Subjective IQ and diagnostic confidence in CTPA were significantly improved with UHR PCD-CT compared to conventional SR EID-CT. Readers consistently rated vascular detail, iodine map quality and overall diagnostic confidence higher with UHR imaging. Notably, even at substantially reduced radiation dose levels, UHR at 3.0 mGy achieved IQ and diagnostic performance comparable to UHR at 6.7 mGy.

CLINICAL RELEVANCE/APPLICATION

UHR PCD-CTPA offers improved image quality, increased pulmonary artery visibility and higher diagnostic confidence in reporting pulmonary embolism, while enabling significant dose reduction compared to conventional EID-CT systems.

M5A-SPCH-6 EVALUATING CHANGES IN REGIONAL STATIC LUNG COMPLIANCE VIA PORCINE BLEOMYCIN LUNG INJURY MODEL

Anna Fuss (*Presenter*)
Sun-Joo Jang (*Abstract Co-Author*)
Albert Sinusas, MD (*Abstract Co-Author*)
Stephanie Thorn (*Abstract Co-Author*)

PURPOSE

To study developing methodology to evaluate lobar-level static lung compliance (SLC) through analysis of a porcine unilateral bleomycin-induced lung injury model, extracting changes in lobar SLC as a measure of lung function in various regions.

METHODS AND MATERIALS

Yorkshire pigs (n=5) were anesthetized, intubated, and placed in supine and head up tilt (30 degree) position. Bleomycin sulfate (2.5 U/kg) diluted in 1ml/kg normal saline solution was delivered using image guidance into left lower lobe bronchus during balloon occlusion to avoid contralateral spillage. End-inspiratory ECG-gated chest CT was acquired immediately thereafter with 64-slice CT (Verizon-CT 400, Spectrum Dynamics) at baseline (A), 7 days post lung-injury (B), and 14 days post lung-injury (C). At each time interval, lungs were subjected to and imaged at 0, 10, 20, and 30 cmH2O pressure respectively. Images were analyzed using MIM Encore Software (Version 7.3.6), combining semi-automatic workflows, manual inclusion of lung consolidation, and lobar segmentation. Lobar volumes were extracted from each scan and used to compare ?SLC across "A-B" (7 days), and "A-C" (14 days) time intervals.

RESULTS

The whole lung ?SLC across interval A-C, averaged across 5 pigs, measured from 0-30 cmH2O, was -3.64 (ml/cmH2O). Comparatively, over the same intervals, the injured left and right lungs experienced an average -3.38 (ml/cmH2O) and -0.15 (ml/cmH2O) ?SLC, respectively. Lobar level analysis showed the left lower lobe had the greatest average decrease in SLC over the total time interval. A significant difference was found in the A-C interval ?SLC values ($p = 0.024$), specifically demonstrating a significantly greater decrease in the left lower lobe than the right lower lobe ($p = 0.049$). Interestingly, the left lower lobe experienced a -4.07 (ml/cmH2O) ?SLC over interval A-B, yet a -3.65 (ml/cmH2O) overall ?SLC over interval A-C, indicating some lung recovery in latter half of experimental time interval.

CONCLUSION

CT imaging over a range of inflation pressures provides an index of changes in regional SLC in porcine bleomycin regional lung injury model. The injured left lower lobe experienced the greatest decrease in SLC. Therefore, lobar lung segmentation of non-contrast CT images has been established to measure changes in regional lung compliance.

CLINICAL RELEVANCE/APPLICATION

Establishing a non-invasive means of assessing changes in SLC can be used to evaluate the efficacy of radiotracer-based theranostics targeted at inhibiting fibroblast activation protein in clinical conditions the result in lung fibrosis.

M5A-SPCH-7 THE APPLICATION OF PHOTON-COUNTING DETECTOR CT IN A LUNG CANCER COHORT: A COMPARATIVE STUDY OF VIRTUAL NON-CONTRAST AND PURECALCIUM IMAGES VERSUS TRUE NON-CONTRAST IMAGES

Xiaoxu Guo, MD (*Presenter*)
Yuhan Zhou, MD (*Abstract Co-Author*)
Limin Lei, MD (*Abstract Co-Author*)
Zhihao Wang (*Abstract Co-Author*)
Yi Fan Guo (*Abstract Co-Author*)

PURPOSE

To determine the effectiveness of photon-counting detector CT (PCD-CT) using virtual non-contrast (VNC) and PureCalcium (PC) images for the reliable evaluation of lung cancer lesions compared to true non-contrast (TNC) images.

METHODS AND MATERIALS

A total of 100 patients were prospectively enrolled in this study between September and December 2024, and all underwent chest plain and contrast-enhanced scans on PCD-CT. The TNC, VNC, and PC images were reconstructed with slice thicknesses of 5.0 mm, 1.0 mm, and 0.4 mm, respectively, and were labeled as TNC, VNC-AP, VNC-VP, PC-AP, and PC-VP. Objective parameters, including CT attenuation, image noise, signal-to-noise ratio (SNR), and contrast-to-noise ratio (CNR), were assessed. Additionally, subjective evaluations of image noise, delineation of anatomical structures, lesion sharpness, and overall image quality were scored on a 5-point Likert scale.

RESULTS

Among the 100 patients (58 males), no significant differences were observed between the objective parameters of PC-VP and TNC images ($P > 0.05$). Compared to TNC, VNC-AP and PC-AP showed higher CT attenuation for vessels, subcutaneous fat, and muscle, with similar results for vessels (pulmonary artery and descending aorta) in VNC-VP ($P < 0.05$). The largest absolute error in attenuation between TNC and VNC images were observed in subcutaneous fat (29.60 ± 10.11 for VNC-AP and 32.50 ± 12.23 for VNC-VP). No significant differences were found between PC-VP and TNC images in terms of image noise, anatomical structure delineation, lesion sharpness, and overall image quality ($P > 0.05$). Regarding image noise, TNC images exhibited superior scores compared to VNC images. The scores for anatomical structure delineation and lesion sharpness in VNC-AP and PC-AP were both lower than those of TNC, with statistically significant differences.

CONCLUSION

PC-VP images obtained from PCD-CT demonstrated accurate and high-quality imaging comparable to TNC images, offering a reliable approach for reducing radiation dose in patients with lung cancer.

CLINICAL RELEVANCE/APPLICATION

By selecting appropriate VNC or PC images to replace TNC images, the accumulation of radiation dose during the follow-up process of tumor patients can be reduced

M5A-SPCH-8 DEEP LEARNING-GUIDED QUANTITATIVE TUMOR SIGNATURES EVALUATE IMMUNOTHERAPY RESPONSE: A MULTICENTER VALIDATION STUDY

Leilei Shen, MD (*Presenter*)
Zicheng Zhao (*Abstract Co-Author*)

Mengsu Zeng, PhD (*Abstract Co-Author*)
Xiaodan Ye, MD (*Abstract Co-Author*)

PURPOSE

This study aims to evaluate the response of immunotherapy in advanced non-small cell lung cancer derived from deep learning-guided quantitative analysis of tumor signatures, and to compare the manual assessment with conventional RECIST criteria.

METHODS AND MATERIALS

In this multicenter study, 97 patients (55 from Center A and 42 from Center B) undergoing immune checkpoint inhibitor therapy were retrospectively analyzed. Baseline and post-treatment CT scans (after 2-3 therapy cycles) were recorded. A deep learning-guided 3D segmentation model was developed and externally validated to quantify tumor signatures, including tumor volume, long diameter, and short diameter, which were used to assess the immunotherapy response in advanced non-small cell lung cancer. The U-Net-based convolutional neural network, trained on a publicly available dataset, generated full 3D tumor masks with a "one-click" within the approximate lesion location. Quantitative parameters were automatically extracted from the model masks and compared to physician-derived measurements. Changes between baseline and follow-up diameters were classified per RECIST1.1 into complete response (CR), partial response (PR), stable disease (SD), or progressive disease (PD). Model-based classifications were compared to radiologist calls for concordance.

RESULTS

The model achieved mean Dice coefficients of 0.78 ± 0.15 (pre-treatment) and 0.67 ± 0.21 (post-treatment), indicating good agreement with manual contours. Automated diameters correlated strongly with manual measurements ($r = 0.92$, $p < 0.001$) and showed minimal bias (mean difference: 1.8 mm; 95% limits of agreement: -4.5 to 8.1 mm). Overall agreement between model-predicted and radiologist-assigned response categories was 88% (? = 0.81). Discrepancies (12% of cases) occurred primarily in borderline SD/PR calls and lesions with necrotic or heterogeneous features.

CONCLUSION

The deep learning-guided semi-automatic segmentation approach enables rapid, reproducible tumor quantification and immunotherapy response assessment that closely matches expert radiologists. This tool holds promise for streamlining clinical workflows and reducing interobserver variability.

CLINICAL RELEVANCE/APPLICATION

This semi-automatic segmentation software for quantitative analysis of advanced lung tumors post-immunotherapy serves as a valuable adjunct in clinical assessment. Automating tumor delineation reduces physicians' workload and delivers objective efficacy metrics, supporting more personalized treatment decisions.

M5A-SPCH-9 INFLUENCE OF RADIATION DOSE REDUCTION AND RECONSTRUCTION ALGORITHMS TO QUANTITATIVE COPD EVALUATIONS ON HIGH-DEFINITION CT WITH SUPER-HIGH-RESOLUTION MODE IN SMOKERS

Yoshiyuki Ozawa, MD, PhD (*Presenter*)
Yoshihiro Ikeda (*Abstract Co-Author*)
Tatsuya Kimoto (*Abstract Co-Author*)
Kota Aoyagi (*Abstract Co-Author*)
Hirona Kimata (*Abstract Co-Author*)
Yuya Ito (*Abstract Co-Author*)
Kenji Fujii (*Abstract Co-Author*)
Naruomi Akino (*Abstract Co-Author*)
Takahiro Ueda, MD, PhD (*Abstract Co-Author*)
Masahiko Nomura, MD, PhD (*Abstract Co-Author*)
Takeshi Yoshikawa, MD (*Abstract Co-Author*)
Daisuke Takenaka, MD (*Abstract Co-Author*)
Yoshiharu Ohno, MD, PhD (*Abstract Co-Author*)

PURPOSE

High-definition CT (HDCT) with energy integrated detector is clinically available and can provide higher spatial resolution images by high-resolution (HR: 0.5 mm×80 rows/1792 channels) and super-high-resolution (SHR: 0.25 mm×160 rows/1792 channels) modes as compared with conventional multi detector row CTs. The purpose of this study was to determine the influence of radiation dose and reconstruction algorithms to quantitative chronic obstructive pulmonary disease (COPD) evaluation on HDCT with SHR mode in smokers.

METHODS AND MATERIALS

49 smokers underwent HDCT with SHR mode at standard- (CTDI vol : 9.0±1.8mGy), reduced- (1.7±0.2mGy) and ultra-low-dose (0.8±0.1mGy) levels. All HDCT data were reconstructed with hybrid-type iterative reconstruction (IR), model-based IR and deep learning reconstruction (DLR). Standard protocol in this study was standard-dose HDCT with hybrid-type IR. According to pulmonary function test results, all smokers were divided into five groups as follows: 'non-COPD', 'GOLD I', 'GOLD II', 'GOLD III' and 'GOLD IV' groups. In each smoker, percentages of low attenuation volume within lung (%LAV) and wall area at sixth level bronchi (%WA) were automatically measured by means of our proprietary software. To determine the influence of radiation dose reduction and reconstruction algorithm to quantitative COPD evaluation, each index was correlated between each HDCT and standard protocols by Pearson's correlation. Moreover, paired t-test was performed to compare each index between each HDCT and standard protocols. Furthermore, both indexes on each HDCT protocol were compared among all groups by Tukey's HSD test.

RESULTS

With each reconstruction methods, %LAV ($0.97=r$, $p<0.0001$) and %WA ($0.92=r$, $p<0.0001$) had excellent correlations between each HDCT and standard protocols. At each HDCT protocol, both indexes of 'non-COPD' and 'GOLD I' groups had significant differences with those of others ($p<0.05$). Moreover, both indexes of 'GOLD II' group had significant difference with that of 'GOLD III' or 'GOLD IV' groups ($p<0.05$).

CONCLUSION

HDCT with SHR mode has little influence of radiation dose reduction and reconstruction algorithm to quantitative CT evaluation of COPD in smokers.

CLINICAL RELEVANCE/APPLICATION

Quantitatively assessed HDCT with super-high-resolution mode has little influence of radiation dose reduction and reconstruction algorithm to quantitative CT evaluation of COPD in smokers.

M5A-SPCH-10 TUMOR RIM-SPECIFIC CT RADIOMICS IMPROVES PREDICTION OF PATHOLOGICAL COMPLETE RESPONSE TO NEOADJUVANT IMMUNOTHERAPY IN NSCLC

Yanbo Li (*Presenter*)
Jingyi Yang (*Abstract Co-Author*)
Fangyuan Qu, MD (*Abstract Co-Author*)
Qiliang Wang (*Abstract Co-Author*)
Xiaoting Cai (*Abstract Co-Author*)
Yicai Zhang (*Abstract Co-Author*)
Fan Liu (*Abstract Co-Author*)
Jiahui E (*Abstract Co-Author*)
Ying Liu (*Abstract Co-Author*)

PURPOSE

This study aims to enhance pathological complete response (pCR) prediction to neoadjuvant immunotherapy in non-small cell lung cancer (NSCLC) patients by using radiomics analysis across various volumes of interest (VOIs) of the primary tumor on CT images.

METHODS AND MATERIALS

A total of 229 NSCLC patients who received neoadjuvant immunotherapy between August 2018 and May 2024 were retrospectively analyzed. Pre-treatment CT images were used to construct radiomics models based on four tumor-related volumes of interest (VOIs): gross tumor volume (GTV), tumor rim volume (TRV) which included 3mm inward contraction and 3mm outward expansion of the tumor boundary, 3 mm peritumoral region (PTV3), and 6 mm peritumoral region (PTV6). Radiomics signature was constructed using linear discriminant analysis (LDA), with 10-fold cross-validation. Model performance was assessed using area under the curve (AUC), calibration, and decision curve analysis (DCA). SHapley Additive exPlanations (SHAP) were used to interpret and visualize the prediction process of the optimal model. In addition, radiogenomic analysis was performed in 36 patients from the TCIA database with available RNA-sequencing data to explore the biological relevance of radiomics features.

RESULTS

Ninety-seven patients (42.4%) achieve pCR after neoadjuvant immunotherapy. The TRV radiomics model demonstrated the highest accuracy for the prediction of pCR in the testing cohort (AUC: 0.827, 95% CI: 0.742-0.913), significantly outperforming GTV (0.631, 95% CI: 0.516-0.746), PTV3 (0.658, 95% CI: 0.546-0.770), and PTV6 radiomics models (0.689, 95% CI: 0.580-0.798) (all $p < 0.05$). Calibration curves of all radiomics models showed good agreement between predicted and observed outcomes. DCA revealed higher net clinical benefit of the TRV model compared to others. Further radiogenomic analysis showed that higher TRV radiomics score correlated with increased antitumor immune cell infiltration and upregulation of immune regulatory and cellular metabolism pathways.

CONCLUSION

The proposed TRV radiomics model provides superior predictive performance for assessing pCR in NSCLC patients undergoing neoadjuvant immunotherapy compared to conventional tumor or peritumoral regions radiomics models.

CLINICAL RELEVANCE/APPLICATION

TRV-based CT radiomics provides a noninvasive and robust approach for early identification of NSCLC patients likely to benefit from neoadjuvant immunotherapy, supporting precision medicine by tailoring treatment strategies and potentially sparing non-responders from unnecessary interventions.

M5A-SPCH-11 DEVELOPING AND VALIDATION OF A MULTIMODAL-BASED MACHINE LEARNING MODEL FOR DIAGNOSIS OF USUAL INTERSTITIAL PNEUMONIA: A PROSPECTIVE MULTICENTER STUDY

Hongyi Wang (*Presenter*)
Min Liu (*Abstract Co-Author*)
Huaping Dai (*Abstract Co-Author*)

PURPOSE

Usual interstitial pneumonia (UIP) indicates poor prognosis and is frequently misidentified, necessitating an auxiliary diagnostic tool. This study was to establish and validate a machine learning (ML) classifier using radiomics features and clinical data to identify UIP from other ILD patterns.

METHODS AND MATERIALS

We conducted a prospective cohort study with chest high-resolution chest computed tomography (HRCT) scans from ILD patients across three medical centers. Using multidisciplinary diagnosis-determined UIP as the reference, we extracted multimodal data including whole-lung radiomics features on HRCT and demographics, smoking, lung function, and comorbidity data. An eXtreme Gradient Boosting (XGBoost) classifier predicted UIP likelihood was used to design a nomogram that was tested in a multicenter ILD clinical cohort. An area under the receiver operating characteristic curve (AUC) and Kaplan-Meier plots with multivariable cox regression were used to assess the performance of the established model.

RESULTS

The study included 5213 HRCT image datasets in training (n=3639), internal (n=785), and external (n=789) validation datasets in 3433 male ILD patients (average age 61.7 ± 10.8 years). UIP prevalence was 43.7% across the whole dataset with 42.7% and 41.3% for internal validation set and external validation set. The radiomics-based classifier had an AUC of 0.790 in the validation set, and 0.786 for the test dataset. Integrating multimodal data improved AUCs to 0.802 and 0.794, respectively. The integration model was comparable to doctors with over 10 years of experience in ILD. Predicted UIP status was associated with high all-cause mortality risk ($p<0.001$, hazard ratio: 3.108 and 95% confidence interval: 2.162 - 4.466).

CONCLUSION

The classifier combining radiomics and clinical features showed strong performance across varied UIP prevalence. This automated tool efficiently classifies UIP in ILD patients undergoing chest HRCT, enabling early antifibrotic intervention.

CLINICAL RELEVANCE/APPLICATION

We developed and validated a robust classification diagnostic model for UIP diagnosis by integrating radiomics and clinical data. The nomogram demonstrated superior performance and clinical utility, offering a reliable and interpretable tool for UIP detection which could improve the homogenization of ILD diagnosis.

M5A-SPCH-12 PATHOLOGIC FIBROBLASTIC FOCI CORRELATE WITH CT-QUANTIFIED FIBROTIC PROGRESSION IN INTERSTITIAL LUNG DISEASE

Akira Haga, MD, PhD (*Presenter*)
Tae Iwasawa, MD, PhD (*Abstract Co-Author*)
Tomoe Sawazumi (*Abstract Co-Author*)
Koji Okudela, MD (*Abstract Co-Author*)
Tomohisa Baba (*Abstract Co-Author*)
Takashi Ogura, MD (*Abstract Co-Author*)

PURPOSE

To test whether larger fibroblastic foci (FF) and hepatocyte nuclear factor-4a (HNF4a) expression are associated with faster interstitial-lung-disease (ILD) progression on CT quantified with QZIP-ILD.

METHODS AND MATERIALS

Between October 2018 and August 2023, 100 ILD patients with baseline and follow-up thin-section CT (median interval = 322 days) and surgical lung biopsy were retrospectively reviewed.CT: QZIP-ILD classified voxels into eight patterns; the yearly percent change in each pattern was the progression score.Pathology: Whole-slide images were analyzed in QuPath. Annotated FF, stroma and air trained slide-specific random-forest models. FF was recorded as the percentage of tissue area occupied by fibroblastic foci; HNF4a-positive area was measured in mm^2. Outputs were verified by a board-certified pathologist.Statistics: Two-sided Pearson correlations with Benjamini-Hochberg correction ($a = 0.05$). Sample sizes after missing data: FF vs CT change - upper 100/lower 94; HNF4a vs CT change - 71/71; FF vs HNF4a - upper 71/lower 68.

RESULTS

Higher FF percentage correlated with yearly increases in upper-lobe honeycombing ($r = 0.27$, $p < 0.01$) and traction bronchiectasis ($r = 0.24$, $p < 0.05$). In lower lobes, it correlated with consolidation + fibrosis ($r = 0.21$, $p < 0.05$) and traction bronchiectasis ($r = 0.24$, $p < 0.05$). Upper-lobe HNF4a area correlated with honeycombing ($r = 0.42$, $p < 0.001$) and traction bronchiectasis ($r = 0.35$, $p < 0.01$); no significant HNF4a correlations were seen in lower lobes. FF percentage and HNF4a were also correlated only in upper samples ($r = 0.45$, $p < 0.01$).

CONCLUSION

QZIP-ILD progression rises in proportion to FF burden and, in upper lobes, to HNF4a expression, identifying both as quantitative markers of rapid ILD fibrosis progression.

CLINICAL RELEVANCE/APPLICATION

Automated CT progression metrics combined with digitally quantified histology provide reproducible biomarkers for risk stratification, guide imaging follow-up, and can enrich patient selection and endpoints in future antifibrotic trials.

M5A-SPCH-13 CORRELATION OF PROGRESSION PREDICTION, AND EXTENT SCORES FROM HIGH-RESOLUTION CT, FAPI-PET WITH PATHOLOGY SPECIMEN WITH INTERSTITIAL LUNG DISEASE TREATED BY LUNG TRANSPLANT: PRELIMINARY RESULTS OF A PROSPECTIVE EXPLORATORY STUDY

Grace Hyun Kim, PhD, MS (*Presenter*)
Ji Yeon Kim (*Abstract Co-Author*)
Pangyu Teng, PhD (*Abstract Co-Author*)
Masatoshi Hotta, MD, PhD (*Abstract Co-Author*)
Gregory A. Fishbein, BS (*Abstract Co-Author*)
Vilasinee Rerkpichaisuth (*Abstract Co-Author*)
Andrea Oh, MD (*Abstract Co-Author*)
Jeremie Calais, MD (*Abstract Co-Author*)

PURPOSE

Recent studies suggest that machine learning algorithms and quantitative interstitial lung disease (ILD) patterns on high-resolution CT (HRCT) may help predict a progressive fibrosing ILD phenotype. This study aimed to test whether a predictive score and ILD patterns on HRCT are associated with fibrosis extent in pathological specimens from ILD patients who underwent lung transplantation.

METHODS AND MATERIALS

This preliminary post-hoc analysis used data from a single-center, open-label, single-arm, prospective exploratory biodistribution study of 68Ga-FAPI-46 PET imaging in ILD. Patients confirmed by HRCT and scheduled for lung transplantation were included. The most recent volumetric HRCT prior to PET was analyzed. Quantitative ILD (QILD) scores were computed using machine learning-based radiomic features. QILD includes fibrotic reticular patterns (quantitative lung fibrosis, QLF) and inflammatory ground-glass opacities (QGG). A single time point prediction (STP) score representing predicted progressive ILD was also calculated. Imaging findings were aligned with pathology samples. Formalin-fixed, paraffin-embedded lung tissues were stained with hematoxylin and eosin and digitized. Fibrosis and honeycombing, markers of irreversible damage, were delineated using QuPath. Quantitative analysis measured fibrosis extent across the tissue. Matched regions of interest (ROIs) were identified between pathology and HRCT. Associations were tested using mixed-effects models.

RESULTS

Between Nov 2021-Apr 2022, four ILD patients underwent HRCT and FAPI PET/CT before lung transplant. Two patients (with NSIP and IPF) had 19 usable pathology slides. Mean (±SD) pathology fibrosis extent was 71.1% (±21.7), range 41.5-99.5%. Matched HRCT ROIs (6 and 2 months pre-transplant) had mean QLF of 48.0% (±34.9), QGG of 20.8% (±21.4), STP of 62.9% (±16.0), and combined maximum QLF or STP of 90.4% (±21.8). Matched pathological fibrosis extent was positively associated with max HRCT scores ($p = 0.033$), and QLF ($p = 0.019$) after adjusting for SUVmax. QGG showed a negative trend ($p = 0.11$).

CONCLUSION

Fibrotic and predicted progressive regions on HRCT were positively associated with fibrosis in pathology. These findings support further development of predictive CT and FAPI-PET biomarkers for stratification and monitoring of progressive ILD.

CLINICAL RELEVANCE/APPLICATION

Imaging-based identification of progressive fibrosing ILD phenotype may improve prediction of disease progression and guide patient management.

M5A-SPER-1 VIRTUAL CONTRAST-ENHANCED CTA FOR THORACIC AORTIC DISSECTION USING A REGISTRATION-GUIDED GAN

Motohiko Yamazaki, MD, PhD (*Presenter*)
Yuma Fuzawa, MD (*Abstract Co-Author*)
Masaki Tominaga (*Abstract Co-Author*)
Takuya Yagi (*Abstract Co-Author*)
Hiroyuki Ishikawa, MD, PhD (*Abstract Co-Author*)

PURPOSE

CT angiography (CTA) is the gold standard for diagnosing aortic dissection but may be omitted in patients with contraindications to contrast media or when clinical suspicion is low. Non-contrast CT often lacks sufficient contrast between the true and false lumens, complicating diagnosis. This study aimed to generate virtual contrast-enhanced CTA from non-contrast CT using a registration-guided generative adversarial network (Reg-GAN) and evaluate its utility in diagnosing thoracic aortic dissection.

METHODS AND MATERIALS

In this retrospective study, the training dataset included 110 aortic dissection and 100 non-dissection cases, selected from emergency department patients who underwent contrast-enhanced CTA between 2015 and 2023. The test dataset consisted of 63 consecutive cases from 2024 at the same institution and 25 emergency cases from an external institution. An additional 700 non-dissection CTA cases from a non-emergency cohort were used for pretraining. The Reg-GAN model was trained to generate virtual contrast-enhanced CTA while compensating for spatial misalignment between non-contrast CT and true contrast-enhanced CTA. Training used 3D patches (384×256×8), a batch size of 1, and the Adam optimizer (learning rate = 0.0001) for 20 epochs. The diagnostic performance and image quality of the virtual contrast-enhanced CTA were evaluated.

RESULTS

In the internal test set (n = 63), the virtual contrast-enhanced CTA achieved a sensitivity of 91.4% (32/35) and a specificity of 100% (28/28) for detecting aortic dissection. In the external test set (n = 25), the virtual contrast-enhanced CTA achieved a sensitivity of 100% (9/9) and a specificity of 87.5% (14/16). The contrast-to-noise ratio between the true lumen and the thrombosed false lumen was significantly higher in the virtual contrast-enhanced CTA than in the original non-contrast CT (154.06 ± 215.61 vs. 0.79 ± 0.92, $p < 0.001$). However, discontinuous depiction of the intimal flap in the virtual contrast-enhanced CTA made it difficult to identify the entry and re-entry sites. The image similarity between the virtual and true contrast-enhanced CTA was relatively good in both the internal and external test sets (mean structural similarity index ± standard deviation: 0.793 ± 0.046 and 0.833 ± 0.028, respectively).

CONCLUSION

The virtual contrast-enhanced CTA generated using the Reg-GAN model improved the visualization of thoracic aortic dissection compared to non-contrast CT and demonstrated good diagnostic performance.

CLINICAL RELEVANCE/APPLICATION

Although virtual contrast-enhanced CTA cannot fully replace true CTA, it may serve as a valuable adjunct to assist radiologists in interpreting non-contrast CT for the evaluation of thoracic aortic dissection.

M5A-SPER-2 AI-DRIVEN TRIAGE OF INTRACRANIAL HEMORRHAGE ON ED HEAD CT IMPROVES RADIOLOGIST TURNAROUND TIME

Emily Mungovan, BA (*Presenter*)
Samantha A. Furlong, MD (*Abstract Co-Author*)
Owen Donnelly, RT (*Abstract Co-Author*)
Debra Desmarais, MBA (*Abstract Co-Author*)
Daniel Sacchetti (*Abstract Co-Author*)
John A. Mungovan, MD (*Abstract Co-Author*)

PURPOSE

The purpose of this study is to evaluate whether radiologists use AI-generated notifications to prioritize new cases of intracranial hemorrhage (ICH) on noncontrast head CTs in the emergency department (ED), as measured by turnaround time (TAT). It was hypothesized that AI allows radiologists to effectively prioritize new true positive (TP) ICH over follow-up, false positive (FP), and negative studies.

METHODS AND MATERIALS

All noncontrast head CTs flagged as positive for ICH by a commercial AI platform across a multi-hospital integrated health system over 12 months were reviewed. Studies read between 10 PM and 7:30 AM were excluded, as overnight radiologists did not have access to the AI. Sites included three hospital-based EDs: one is a Level II trauma center and all three are primary stroke centers. All positive studies were reviewed and categorized as TP or FP. Mean TATs were calculated for TP, FP, and negative cases. TAT was defined as the time from scan availability to first radiologist access. Follow-up scans of known hemorrhage were identified and analyzed separately to isolate new ICH.

RESULTS

Out of 14,707 ED head CTs at this institution in 2024, 632 (4.3%) had positive AI notifications. Of these, 383 were TP (61%) and 243 were FP (39%). Fifty-four TP cases (8%) were follow-ups of known ICH. Average TAT for new ICH (TP excluding follow-ups) was 12.9 minutes. FP cases averaged 16.2 minutes, and negative cases 15.7 minutes. TAT for all TP was 13.8 minutes. The difference in TAT between TP and FP cases was statistically significant ($p=0.02$), and greater when analyzing new ICH only ($p=0.001$). The difference between new TP and negative studies was also significant ($p<0.0001$). Radiologists accessed AI alerts via a Picture Archiving and

Communication System (PACS)-integrated widget showing key images and follow-up status. This allowed rapid triage without opening full studies. Shorter TAT for new ICH suggests radiologists leveraged the widget to identify and prioritize rapid turnaround of new ICH reports.

CONCLUSION

Radiologists at this institution effectively used AI notifications to prioritize review of new ICH cases, improving reporting speed. This has the potential to improve patient outcomes by decreasing wait time to diagnosis.

CLINICAL RELEVANCE/APPLICATION

AI can improve time-to-diagnosis for new intracranial hemorrhage in the ED by helping radiologists efficiently triage and report true positives more quickly.

M5A-SPER-3 DEEP LEARNING-DERIVED XP-AGE: A NOVEL CHEST RADIOGRAPH-BASED BIOMARKER TO IMPROVE ICU MORTALITY PREDICTION

Yasuhito Mitsuyama (*Presenter*)
Ryo Deguchi (*Abstract Co-Author*)
Hirotaka Takita, MD, PhD (*Abstract Co-Author*)
Shannon Walston (*Abstract Co-Author*)
Yukio Miki, MD, PhD (*Abstract Co-Author*)
Daiju Ueda, MD, PhD (*Abstract Co-Author*)

PURPOSE

This study aimed to determine whether "Xp-age"—a newly developed, deep learning-based biomarker of biological aging derived from chest radiographs—could enhance the accuracy of established ICU mortality prediction scores (SAPS II, APACHE II, and SOFA). By directly integrating an imaging-based measure of aging, this work introduces a novel approach to refining risk stratification in critically ill patients.

METHODS AND MATERIALS

We retrospectively analyzed adult ICU admissions at a single center who had both chest radiographs and complete data for SAPS II, APACHE II, or SOFA. The Xp-age model, previously trained on radiographs from healthy individuals, was applied without additional fine-tuning. We replaced the age component in SAPS II and APACHE II with Xp-age and compared standard SOFA with versions that included either chronological age or Xp-age. Predictive performance for ICU mortality was assessed via 10-fold cross-validation with XGBoost.

RESULTS

Among 8,177 ICU admissions, incorporating Xp-age improved predictive performance across scoring systems. In SAPS II, replacing chronological age with Xp-age increased the AUROC from 0.79 to 0.81 ($p=0.015$). APACHE II showed an AUROC increase from 0.77 to 0.81 ($p<0.001$). For SOFA, adding Xp-age raised the AUROC from 0.83 to 0.85 ($p=0.012$), whereas adding chronological age offered no substantial gain. Survival analyses revealed distinct high- and low-risk groups of Xp-age models ($p <0.001$).

CONCLUSION

Replacing or supplementing chronological age with Xp-age, a novel biomarker captured from chest radiographs, boosts the predictive accuracy of ICU mortality scores. These findings suggest that Xp-age captures physiologic dimensions of aging beyond chronological age, offering a new avenue for more precise prognostic assessment in critical care.

CLINICAL RELEVANCE/APPLICATION

By incorporating an innovative, imaging-based aging biomarker into conventional ICU scoring tools, clinicians may achieve enhanced risk stratification and more targeted patient management, ultimately improving outcomes and resource allocation in critical care settings.

M5A-SPGI-1 DIAGNOSTIC ACCURACY OF FULL VS. ABBREVIATED GADOXETATE-ENHANCED MRI IN COLORECTAL CANCER: PRELIMINARY RESULTS FROM A PROSPECTIVE RCT

Harry R. Marshall, MD, PhD (*Presenter*)
Karen Dunn (*Abstract Co-Author*)
Vibhuti Kalia, MD, FRCR (*Abstract Co-Author*)
Darryl W. Ramsewak, MD (*Abstract Co-Author*)
Shelby Champion (*Abstract Co-Author*)
Natalie Grindrod (*Abstract Co-Author*)
Zahra Kassam, MD, FRCPC (*Abstract Co-Author*)

PURPOSE

Colorectal adenocarcinoma is a leading cause of cancer mortality, with liver metastases in up to 50% of patients. Accurate detection is essential for staging and treatment planning, with gadoxetate-enhanced MRI playing a central role. Abbreviated MRI protocols are emerging alternatives due to reduced scan time, cost, and improved throughput. Although prior studies suggest similar diagnostic performance to full protocols, most are small and retrospective. We report preliminary results from a prospective, randomized trial comparing abbreviated versus standard gadoxetate-enhanced liver MRI in patients with colorectal cancer.

METHODS AND MATERIALS

Sixty patients with histologically confirmed colorectal cancer and suspected or known liver metastases were randomized 1:1 to either an abbreviated or standard gadoxetate-enhanced MRI protocol. Randomization used variable block sizes (4, 6, or 8) with concealed allocation. The abbreviated protocol included T2-weighted, diffusion-weighted, and hepatobiliary phase sequences. The full protocol additionally included T2 fat-saturation, T1 in-phase/out-of-phase, and dynamic contrast-enhanced sequences. Three abdominal radiologists independently reviewed all MRIs in a blinded fashion, without access to clinical data or prior imaging. Readers marked up to 10 lesions per case and assigned a suspicion score (1-5) for each. Ground truth was based on pathology when available, or follow-up/prior imaging. Performance was evaluated using AUC, sensitivity, specificity, and accuracy. Final statistical testing will occur upon full enrollment (n=200).

RESULTS

Fifty-eight patients completed the study (one withdrew; one excluded for protocol deviation). Of 367 lesions, 342 had reference standards (72 pathology-confirmed, 270 by imaging follow-up). Of these, 173 were metastatic and 169 benign; most common benign diagnoses were cysts (n=106), ablation zones (n=28), and hemangiomas (n=9). Average AUC across readers was 0.94 (range: 0.92-0.97) for abbreviated MRI and 0.95 (range: 0.89-0.98) for full MRI. At fixed 90% sensitivity, mean specificity and accuracy were 90% and 90% for abbreviated MRI, and 92% and 91% for full MRI.

CONCLUSION

Radiologist performance in detecting liver metastases was comparable between abbreviated and full MRI protocols. These findings support the potential of abbreviated MRI as a resource-efficient alternative.

CLINICAL RELEVANCE/APPLICATION

Abbreviated gadoxetate-enhanced liver MRI may deliver diagnostic performance similar to full protocols while reducing scan time, interpretation time, and cost. These results support broader adoption in oncologic imaging workflows.

M5A-SPGI-2 THE VALUE OF SPECTRAL CT DERIVED SPLENIC EXTRACELLULAR VOLUME FRACTION COMBINED WITH CT VOLUME RELATED PARAMETERS IN IDENTIFYING HIGH RISK VARICES IN CIRRHOTIC PATIENTS

Yiming Yang (*Presenter*)
Yupin Liu (*Abstract Co-Author*)
Dongjing Zhou (*Abstract Co-Author*)

PURPOSE

This study aims to evaluate the value of spectral-CT derived splenic extracellular volume fraction (ECV) combined with CT volume-related parameters in identifying high-risk varices (HRV) of cirrhotic patients.

METHODS AND MATERIALS

This study recruited a total of 89 cirrhotic patients, who underwent spectral-CT scanning in the equilibrium phase. Using upper gastrointestinal endoscopy as the reference standard, the patients were divided into the HRV group (n=40) and the non-HRV group (n=49). Spectral-CT derived ECV of liver (L-ECV) and spleen (S-ECV), as well as normalized iodine concentration of the liver (L-NIC) and spleen (S-NIC) were measured based on the iodine concentration (Fig 1a). Total liver volume (TLV), volume ratio of Couinaud segments I-III to segments IV-VIII (LSVR) and splenic volume (SV) were measured in the viewer workstation(Fig 1b). The spectral-CT quantitative parameters and CT volume-related parameters were compared between the HRV and the non-HRV cirrhotic patients using univariate analysis. The multivariate logistic analysis was used to build a model for diagnosing HRV. Receiver operating characteristic curve (ROC) analysis was performed to determine the performance of the combined model, spectral-CT quantitative parameters and CT volume-related parameters in diagnosing HRV.

RESULTS

Univariate analysis showed statistically significant differences in S-ECV, L-ECV, S-NIC, TLV, LSVR, SV between the HRV and the non-HRV cirrhotic patients ($p<0.05$)(Table 1). The combined CT model, developed based on S-ECV, SV and LSVR was built by multivariate logistic analysis (Table 1). The areas under the curve (AUCs) of the combined model, S-ECV, SV and LSVR for diagnosing HRV were 0.863, 0.794, 0.800 and 0.793 respectively (all $p < 0.05$)(Fig 2, Table 2).

CONCLUSION

The model including spectral-CT derived splenic ECV, splenic volume and liver segmental volume ratio could effectively identify high-risk varices of cirrhotic patients.

CLINICAL RELEVANCE/APPLICATION

Noninvasive identification of HRV in cirrhotic patients is of significant value because it could help avoid some unnecessary upper gastrointestinal endoscopy. Splenic ECV combined with CT volume-related parameters added clinical value in diagnosing HRV for patients with liver cirrhosis, which may provide helpful and reliable evidence for clinical diagnosis and treatment.

M5A-SPGI-4 CONTEXT-AWARE DEEP LEARNING ENABLES EXPERT-LIKE BOWEL INFLAMMATION DETECTION IN MRE IMAGES

Hansang Lee, PhD (*Presenter*)
Chaelin Lee (*Abstract Co-Author*)
Seohyun Lee (*Abstract Co-Author*)
Nieun Seo, MD, PhD (*Abstract Co-Author*)
Joonseok Lim, MD (*Abstract Co-Author*)
Helen Hong, PhD (*Abstract Co-Author*)

PURPOSE

Accurate detection of bowel inflammation in Magnetic Resonance Enterography (MRE) is critical for evaluating disease severity in Crohn's disease (CD). However, conventional deep learning models often operate on single slices, neglecting valuable contextual information, resulting in suboptimal performance. We investigated whether incorporating spatial context into detection models not only improves detection accuracy but also increases the correlation of automated lesion count/area with human annotations, reflecting more human-like assessment.

METHODS AND MATERIALS

We retrospectively analyzed MRE scans from 208 patients (training: 104, validation: 52, test: 52). Expert radiologists annotated inflammatory lesions (bounding boxes), providing ground truth for lesion count and total area per patient. We developed and compared two context-aware methods against their corresponding baselines: (1) A YOLOv4-based method incorporating spatial context via multi-slice input, and (2) A Mask R-CNN (MRCNN)-based method employing FocalNet as a backbone for hierarchical contextual feature learning. Detection performance was evaluated using slice-level mean Average Precision (mAP), precision, and recall. To assess models' similarity with human annotations, we measured Spearman correlation coefficients between model-predicted lesion statistics (count and area per patient) and expert annotations.

RESULTS

The proposed context-aware YOLOv4 model achieved the highest detection performance across all metrics (mAP@50 = 74.5%, precision@50 = 70.7%). The proposed FocalNet-enhanced context-aware MRCNN also outperformed baseline MRCNN, showing improvements in both mAP and recall. In terms of similarity with human annotation, the proposed context-aware MRCNN showed Spearman correlations of 0.70 ($p<0.05$) for lesion count and 0.63 ($p=0.05$) for area. The proposed context-ware YOLOv4 achieved correlations of 0.65 ($p<0.01$) for count and a strong 0.68 ($p<0.01$) for area, outperforming its vanilla baseline. These findings suggest that context-aware methods not only detect lesions more accurately but also better align with expert assessment patterns.

CONCLUSION

Incorporating contextual information into deep learning methods improves both detection accuracy and similarity with human expert behavior. The proposed context-aware YOLOv4 showed particularly strong alignment with human assessment, suggesting its potential utility in supporting assessment of CD activity. (This work was supported by grants from NRF (RS-2024-00336063) and KHIDI (HI22C1496).)

CLINICAL RELEVANCE/APPLICATION

By providing expert-like lesion quantification, the proposed context-aware methods may assist radiologists in objective sMARIA scoring in CD.

M5A-SPGI-5 AVOIDING PATIENT RE-SCANS: DEEP LEARNING-BASED SYNTHESIS OF ABDOMINAL CONTRAST ENHANCED CT FROM AVAILABLE SERIES

Tejas Sudharshan Mathai, PhD, MS (*Presenter*)
Xinya Wang (*Abstract Co-Author*)
Praveen Thoppey Srinivasan Balamuralikrishna, MBBS (*Abstract Co-Author*)
Vivek Batheja (*Abstract Co-Author*)
Ronald M. Summers, MD, PhD (*Abstract Co-Author*)

PURPOSE

Radiologists routinely use abdominal contrast-enhanced CT (CECT) to diagnose a variety of diseases. However, a patient's clinical indication dictates the specific CT protocol used for imaging. This obviates the acquisition of certain CECT series, e.g., portal-venous (PV) phase during lung cancer screening. Yet for opportunistic screening purposes, these unacquired CECT series are important for organ, fat, and muscle volumetry. In this work, an automated tool was developed to synthesize a CECT given a non-contrast CT and a desired phase condition.

METHODS AND MATERIALS

First, to learn features of various phases in a CT study, the publicly available MAISI model was trained on the public DeepLesion (4460 patients, 10,649 studies, 42,851 series) and WAW-TACE (233 patients, 233 studies, 854 series) datasets. Next, given a non-contrast CT and desired portal-venous condition, a diffusion model extracted features from MAISI to synthesize the required CECT. Four diffusion models were tested: VCM, Adapter, ControlNet, and STControl (ours). The pancreas segmentation task assessed the PV CECT synthesis quality using the public TotalSegmentator (TS) tool. Our framework was tested on an internal Institution-A dataset (63 patients, 63 studies, 63 non-contrast and 63 PV series) and external Vin-Dr dataset (46 patients, 46 studies, 46 non-contrast and 46 PV series). Two clinicians (2+ years of experience) annotated the pancreas in the PV CTs in these test datasets. Segmentation metrics, such as Dice Similarity Coefficient (DSC) and Normalized Surface Distance (NSD), were computed. Statistical analysis was done using one-way repeated measures Analysis of Variance (ANOVA) and Tukey's post-hoc test.

RESULTS

On Institution-A dataset, our STControl model obtained 67.8+/- 14.2 DSC and 35.8 +/- 12.0 NSD. On Vin-Dr dataset, our model obtained 57.8 +/- 16.0 DSC and 29.1 +/- 11.7 NSD. Across all segmentation metrics, STControl was statistically significantly better compared to Adapter ($p = 0.001$) and VCM ($p < 0.001$) on both internal and external datasets.However, no difference was observed ($p = 0.92$) between STControl and ControlNet.

CONCLUSION

With our model, TS closed the segmentation performance gap between the synthesized PV and reference PV series. To our knowledge, we are the first to develop a 3D diffusion model for 3D abdominal CECT translation.

CLINICAL RELEVANCE/APPLICATION

Our framework is generalizable and can synthesize any CT from the available series in a study. This may be of value when organ morphology rather than focal lesions is critical, as in body composition analysis. Moreover, patient re-scans are reduced, and patients are not exposed to extra radiation doses or subject to contrast agent hypersensitivity.

M5A-SPGI-6 ACCURACY OF MULTIPARAMETRIC ULTRASOUND WITH FAT FRACTION FOR THE ASSESSMENT OF HEPATIC STEATOSIS IN MASLD PATIENTS: AN INTERIM ANALYSIS

Antonino Andrea Blandino, MD (*Presenter*)
Roberto Cannella, MD (*Abstract Co-Author*)
Giordana Mattana, MD (*Abstract Co-Author*)
Tommaso V. Bartolotta, MD,PhD (*Abstract Co-Author*)

PURPOSE

To investigate the performance of quantitative ultrasound with US Fat Fraction (USFF) in patients with metabolic dysfunction-associated steatotic liver disease (MASLD).

METHODS AND MATERIALS

Patients with MASLD prospectively underwent same-day MRI (3T), using the mDixonQuant sequence for fat fraction quantification, and quantitative ultrasound, consisting of Tissue Attenuation Imaging (TAI), Tissue Scatter-distribution Imaging (TSI), and USFF, performed by a radiologist and a radiology resident to assess inter-reader reliability.Spearman's rank-order correlation was calculated between USFF and MRI fat fraction. The diagnostic performance was investigated with the area under the receiver operating characteristics curve (AUC), sensitivity and specificity according to the optimal cutoff.

RESULTS

One hundred and three (103) patients (67 males, median age: 60 years) were enrolled. Among them, 82 (79.6%) had grade=1 steatosis and 37 (35.9%) had grade=2 steatosis. There was a high positive correlation between USFF and MRI fat fraction (rho 0.815, p<0.001). For the diagnosis of grade=1 steatosis the AUCs were 0.886 (95%CI: 0.823, 0.949) for TAI, 0.797 (95%CI: 0.706, 0.889) for TSI, and 0.896 (95%CI: 0.834, 0.959) for USFF. An USFF >6.47 had a sensitivity of 91.5% and a specificity of 76.19% for grade=1 steatosis. For the diagnosis of grade=2 steatosis, the AUCs were 0.913 (95%CI: 0.854, 0.973) for TAI, 0.863 (95%CI: 0.791, 0.934) for TSI, and 0.928 (95%CI: 0.876, 0.980) for USFF. An USFF >11.94 had a sensitivity of 89.2% and a specificity of 84.85% for grade=2 steatosis. Reproducibility of USFF was excellent (ICC: 0.952; 95%CI: 0.930, 0.968).

CONCLUSION

USFF provides excellent performance and reproducibility for quantifying hepatic steatosis in patients with MASLD.

CLINICAL RELEVANCE/APPLICATION

By providing noninvasive, cost-effective quantification of liver fat with high accuracy and reproducibility, USFF facilitates early detection, risk stratification and management of steatosis in MASLD.

M5A-SPGI-8 DIAGNOSTIC PERFORMANCE OF MACHINE LEARNING MODELS FOR PREDICTING ADVANCED LIVER FIBROSIS: A BIVARIATE META-ANALYSIS

Bruno Ishizuka (*Presenter*)
Victor Arthur Ohannesian (*Abstract Co-Author*)
Luciano Falcao (*Abstract Co-Author*)
Karina De Lima Andrade (*Abstract Co-Author*)
Ricardo Suruagy-Motta (*Abstract Co-Author*)
Mariana Lee Han (*Abstract Co-Author*)
Mariana Leticia De Bastos Maximiano (*Abstract Co-Author*)
Carlos Tudino (*Abstract Co-Author*)
Fernanda Fleming (*Abstract Co-Author*)
Miguel J. Francisco Neto, MD, PhD (*Abstract Co-Author*)

PURPOSE

To systematically assess the diagnostic accuracy of machine learning (ML) models for detecting advanced liver fibrosis in patients with chronic liver disease, using histopathology or elastography-based imaging as reference standards.

METHODS AND MATERIALS

A systematic review and bivariate diagnostic meta-analysis were conducted in accordance with PRISMA-DTA guidelines. Databases searched included PubMed, Embase, Scopus, Web of Science, and CENTRAL (through April 2025). Studies were eligible if they evaluated the performance of ML models in classifying advanced liver fibrosis (=F3 or F4) using liver biopsy or two-dimensional shear wave elastography as reference standards. The main outcomes were pooled sensitivity, specificity, area under the receiver operating characteristic curve (AUROC), positive and negative likelihood ratios (LR+, LR-), and diagnostic odds ratio (DOR). Between-study heterogeneity and threshold effects were assessed, and publication bias was evaluated using Deeks' funnel plot asymmetry test. Statistical analyses were performed using Stata v15 and the MIDAS module.

RESULTS

Sixteen studies were included, comprising 3,558 reference-positive and 10,052 reference-negative patients. The pooled sensitivity of ML models for detecting advanced fibrosis was 0.90 (95% CI: 0.82-0.94), and specificity was 0.82 (95% CI: 0.71-0.90). The positive likelihood ratio (LR+) was 5.1 (95% CI: 3.0-8.6), and the negative likelihood ratio (LR-) was 0.13 (95% CI: 0.07-0.22). The diagnostic odds ratio was 40 (95% CI: 17-93), with an AUROC of 0.93 (95% CI: 0.90-0.95). Heterogeneity was considerable (I^2 = 99%), but threshold effects were negligible (R = -0.12; proportion due to threshold = 0.01). Between-study variance was moderate for both sensitivity (ICC = 0.27) and specificity (ICC = 0.34). Deeks' test did not reveal evidence of publication bias (p = 0.461).

CONCLUSION

ML-based models demonstrate high diagnostic accuracy for detecting advanced liver fibrosis, with excellent sensitivity and strong discriminatory performance (AUROC > 0.90). Despite high heterogeneity, the low negative likelihood ratio supports their potential utility in ruling out advanced fibrosis in clinical practice.

CLINICAL RELEVANCE/APPLICATION

Machine learning algorithms represent promising noninvasive tools for the identification of advanced hepatic fibrosis, especially in settings where liver biopsy is contraindicated or unavailable. Given their high sensitivity and ease of deployment in routine clinical imaging workflows, these models may support early risk stratification and management of patients with chronic liver disease, particularly in large-scale screening or resource-limited scenarios.

M5A-SPGI-10 DEEP LEARNING FOR AUTOMATED EVALUATION OF SARCOPENIA, MYOSTEATOSIS AND PROGNOSIS IN PATIENTS WITH LOCALLY ADVANCED RECTAL CANCER USING BASELINE CT: AN EXTERNAL VALIDATION STUDY

Kui Sun, MMedSc, PhD (*Presenter*)

PURPOSE

Sarcopenia, assessed by skeletal muscle index (SMI), and myosteatosis, quantified through muscle density (MD), are critical prognostic determinants in locally advanced rectal cancer. Current CT-based manual measurements of SMI and MD remain labor-intensive. This two-center study developed a deep learning using baseline CT to facilitate the evaluation of muscle biomarkers and validated their prognostic value in locally advanced rectal cancer (LARC).

METHODS AND MATERIALS

A two-center retrospective analysis was conducted on 408 patients (329 patients from center1, 79 patients from center2). ResNet-50 was trained using five-fold cross-validation on L3-level CT images to classify MD and SMI. The generalizability of the well-trained model was evaluated on the external validation cohort. Additionally, three junior physicians were enlisted to perform independent visual evaluations. The results of these manual assessments were compared with the diagnostic outputs generated by the model. Evaluation metrics included the area under the receiver operating characteristic curve (AUC), and Kaplan-Meier survival analysis for disease-free survival (DFS) and overall survival (OS).

RESULTS

The model achieved a higher performance for MD compared to SMI in both the development (mean AUC, 0.929 vs. 0.884) and external validation cohorts (0.875 vs. 0.737, p<0.01). Subgroup analysis demonstrated the stability of MD-AI with AUC ranging from 0.851 to 1.000. MD significantly stratified DFS (p<0.05 in the overall and development cohorts) and OS (p<0.05 across all cohorts). Visual assessments by junior physicians were inferior to the AI model (MD, AUC: 0.683-0.723 vs. AI: 0.918; SMI, AUC: 0.549-0.565 vs. AI: 0.786).

CONCLUSION

An artificial intelligence effectively and automatically assessed skeletal muscle status in LARC.

CLINICAL RELEVANCE/APPLICATION

By integrating MD-AI into routine CT workflows, clinicians can objectively predict survival outcomes (DFS/OS) and tailor treatment strategies to mitigate skeletal muscle abnormalities-related complications.

M5A-SPGI-11 PREDICTIVE VALUE OF MRE-MEASURED INFLAMMATORY BURDEN AND SEVERITY FOR ASSESSING TREATMENT RESPONSE IN SMALL BOWEL CROHN'S DISEASE

Jordi Rimola, MD, PhD (*Presenter*)
Julia M. Saidman, MD (*Abstract Co-Author*)
Agnes Fernandez-Clotet (*Abstract Co-Author*)
Josep Puig, MD,PhD (*Abstract Co-Author*)
Ingrid Ordas (*Abstract Co-Author*)

PURPOSE

Identifying predictors of therapeutic response is the cornerstone of personalised medicine. Changes in intestinal lesion severity have received much attention, but the value of changes in inflammation length has not been properly analysed. We aim to identify findings on MR Enterography (MRE) 46 weeks after initiating biological treatment in small bowel Crohn's disease (SBCD) that predict adverse long-term outcomes.

METHODS AND MATERIALS

Post-hoc analysis of a prospective longitudinal single-centre study included patients with SBCD requiring biological treatment. MRE data were obtained at baseline and at week 46 after treatment initiation. Patients were followed two years afterwards. Severity of SBCD lesions was assessed by the segmental MaRIA score. The length of the inflammation was made using a 3D curved multiplanar reconstructions (Horos®). A logistic regression analysis was performed to assess the prognostic value of different radiologic findings, including length of inflammation (inflammatory burden) and severity of lesions for disease modifying events.

RESULTS

Among the 65 patients included, 39 (60%) had =1 adverse outcome during the follow-up: 29 (44.6%) had clinical recurrence; 20 (30.76%) required surgery, and 12 (18.46%) hospitalization. At week 46, healing of severe lesions (defined as MaRIA<11) was found in 23/65 (35.4%).In the multivariate analysis, persistence of severe lesions at week 46 predicts higher risk of surgery (OR=7.44 [95%CI1.84-50.5] p=0.013) and has a trend to increase the risk of any event (OR=7.88 [95%CI1.12-159] p=0.07), whereas improvement of radiological severity (reduction of MaRIA) has protective effect over any modifying disease events (OR=0.89 [95%CI0.82-0.96] p=0.003) or treatment discontinuation (OR=0.92 [95%CI0.85-0.98] p=0.01). In contrast, changes in the length of inflammation or severe inflammation did not predict any adverse events.

CONCLUSION

Improvement in radiological severity of SBCD as measured by MaRIA has a positive impact on clinically relevant disease outcomes. Continued investigation by increasing the sample size in relation to the reduction of inflammatory burden is needed.

CLINICAL RELEVANCE/APPLICATION

Identifying MR parameters that predict clinically relevant outcomes helps to define therapeutic endpoints.

M5A-SPGI-13 EARLY CHANGE IN SKELETAL MUSCLE DENSITY PREDICTS RECURRENCE FOLLOWING CURATIVE RESECTION OF WELL-DIFFERENTIATED PANCREATIC NEUROENDOCRINE TUMORS

Yu Li (*Presenter*)
Yuqi Wang (*Abstract Co-Author*)
Jing Zhu (*Abstract Co-Author*)
Yan Deng (*Abstract Co-Author*)
Haopeng Yu (*Abstract Co-Author*)
Zixing Huang (*Abstract Co-Author*)
Bin Song (*Abstract Co-Author*)

PURPOSE

This study aimed to establish the prognostic impact of early changes in skeletal muscle index (SMI) and density (SMD) in patients with well-differentiated (G1/G2) pancreatic neuroendocrine tumors (pNETs).

METHODS AND MATERIALS

Sixty-eight patients with G1/G2 pNETs who underwent curative resection between August 2013 and December 2022 were retrospectively analyzed. Skeletal muscle area (SMA) and SMD were measured at the L3 level using preoperative and 1-year postoperative abdominal CT scans. Changes in skeletal muscle index (?SMI) and density (?SMD) were calculated, with a decrease of >5% defined as a significant decline. Patients were stratified into decreased and stable groups based on ?SMI and ?SMD, respectively. Recurrence-free survival (RFS) was evaluated using Kaplan-Meier curves and Cox regression models.

RESULTS

Among the 68 patients (median age 51 years; 39 [57.4%] female), histopathology confirmed G1 disease in 24 (35.3%) and G2 in 44 (64.7%). With a median follow-up of 44.5 months, 18 patients (26.5%) experienced disease recurrence. The decreased ?SMD group showed significantly poorer RFS compared to the non-decreased group ($p < 0.01$). However, no significant difference was found between ?SMI groups ($p > 0.05$). Multivariate analysis indicated that ?SMD (decreased vs. stable; HR = 6.245, 95% CI: 1.377-28.323, $p < 0.01$) and tumor size (=3 cm vs. <3 cm; HR = 0.284, 95% CI: 0.080-1.017, $p < 0.05$) were independently associated with RFS.

CONCLUSION

Early postoperative decline in SMD is an independent prognostic biomarker for recurrence in patients with G1/G2 pNETs, supporting its clinical utility in risk stratification and guiding postoperative surveillance.

CLINICAL RELEVANCE/APPLICATION

Quantitative CT-based assessment of muscle density provides an objective imaging biomarker to assess recurrence risk. Early detection of SMD decline may facilitate intensified follow-up or consideration of adjuvant therapy in high-risk pNET patients.

M5A-SPGI-14 CONTRAST-ENHANCED CT-DERIVED EXTRACELLULAR VOLUME FRACTION PREDICTS SURVIVAL IN POSTOPERATIVE PANCREATIC CANCER PATIENTS

Shuai Ming (*Presenter*)
Wei Wei (*Abstract Co-Author*)

PURPOSE

To evaluate the prognostic value of extracellular volume (ECV) fraction derived from contrast-enhanced computed tomography (CECT) in predicting survival outcomes of patients with resectable pancreatic ductal adenocarcinoma (PDAC).

METHODS AND MATERIALS

The study cohort included a total of 166 patients with resectable PDAC who underwent CECT before operative excision between Jan 2018 and Mar 2021. The CT-derived tumor ECV fractions were calculated from the unenhanced and equilibrium-phase CT images. The effects of patient clinical factors, CECT image parameters, and tumor ECV fractions on overall survival (OS) and progression-free survival (PFS) were assessed by univariate and multivariate analyses using Cox proportional hazards models. In addition, to verify the reliability of ECV, Masson's trichrome staining was performed on surgically resected specimens from a subset of patients to quantify intratumoral collagen content. Pearson correlation was used to analyze the relationship between CT-derived ECV and collagen ratio (CR).

RESULTS

The median value of CT-derived tumor ECV was 32% (21% - 41%). Increased ECV fractions were positively associated OS and PFS. Age and CT-derived ECV fraction was an independent predictor of OS ($p = 0.012$; $p = 0.001$), while tumor size and CT-derived ECV fraction was an independent predictor of PFS ($p = 0.016$; $p = 0.001$) in patients with resectable PDAC. In addition, ECV was determined to be strongly correlated with CR ($r = 0.860$, $p < 0.001$).

CONCLUSION

CECT-derived ECV fraction is strongly correlated with collagen ratio and is positively related to OS and PFS of patients with resectable PDAC.

CLINICAL RELEVANCE/APPLICATION

CECT-derived ECV fraction could be used as a reliable noninvasive biomarker for predicting survival in patients with resectable PDAC.

M5A-SPGI-15 DEEP LEARNING-BASED CONTOURING OF HEPATIC COUINAUD SEGMENTS ON CT: UTILITY FOR VOLUMETRIC ANALYSIS OF FUTURE LIVER REMNANT

Tejas Sudharshan Mathai, PhD, MS (*Presenter*)
Praveen Thoppey Srinivasan Balamuralikrishna, MBBS (*Abstract Co-Author*)
Vivek Batheja (*Abstract Co-Author*)
Cathleen Hannah (*Abstract Co-Author*)
Mike Kassin (*Abstract Co-Author*)
Ifechi Ukeh (*Abstract Co-Author*)
Jonathan Hernandez (*Abstract Co-Author*)
Ronald M. Summers, MD, PhD (*Abstract Co-Author*)

PURPOSE

Hepatocellular carcinoma (HCC) is a common primary liver tumor, and the liver is a frequent site of metastasis of other cancers. High tumor burden, proximity to hepatic vessels, and other comorbidities mean only 30% of patients are candidates for treatment. However, surgical resection requires a 20 - 40% future liver remanent (FLR) to avoid post-operative complications. The purpose is to develop an automated tool that delineates hepatic Couinaud segments for pre-surgical treatment planning and FLR volumetry.

METHODS AND MATERIALS

Two CT datasets were used for training: 1) 442 patients from the public Medical Segmentation Decathlon (MSD) Hepatic Vessels dataset, and 2) 77 patients imaged at Institution-A with ascites, splenomegaly and those who underwent hepatic arterial embolization. Two CT datasets were used for testing: 1) 14 patients from Institution-A (internal): 8 of whom underwent right-sided portal vein embolization with pre- and post-surgical CT exams available, and (2) 197 patients in the public TCIA Colorectal Liver Metastasis (CRLM) dataset. A senior radiologist annotated the FLR in the CRLM dataset, while the Couinaud segments were annotated by two physicians in the remaining datasets. Segments 2,3,4 in the internal test dataset was considered as the FLR. A 3D nnU-Net was trained with default hyperparameters to outline the Couinaud segments. Metrics, such as Dice Similarity Coefficient (DSC), Hausdorff Distance (HD) error (in mm), and volume error (in cc) were calculated. The performance was compared to a previously described 3D U-Net developed to quantify liver segmental volume ratio (LSVR) in patients with cirrhosis.

RESULTS

For the internal test dataset, compared against 3D U-Net, our 3D nnU-Net obtained a DSC of 0.89 +/- 0.2 vs. 0.75 +/- 0.35 ($p = 0.014$), HD error of 10.6 +/- 10.9 vs. 28.5 +/- 42.5 mm ($p = 0.019$), and volume error of 3.8 +/- 45.6 vs. 11.3 +/- 106.1 cc ($p = 0.35$). For the external CRLM dataset, our 3D nnU-Net obtained a DSC of 0.99 +/- 0.01 vs. 0.97 +/- 0.07 ($p < 0.001$), HD error of 0.88 +/- 1.84 vs. 9.57 +/- 3.62 mm ($p < 0.001$), and volume error of 13.7 +/- 28.1 vs. 47.9 +/- 51.8 cc ($p < 0.001$).

CONCLUSION

The automated tool generalized well to the external CRLM dataset and can potentially reduce the cumbersome manual annotation of Couinaud segments on CT, which requires > 2 hours to perform.

CLINICAL RELEVANCE/APPLICATION

The tool may be useful for accurate volumetry on patients undergoing portal vein embolization to increase the FLR and estimation of liver segmental volume ratio (LSVR) for diagnosis of liver fibrosis and cirrhosis.

M5A-SPGI-16 EFFECTIVENESS AND SAFETY OF A NOVEL MANGANESE-BASED LIVER SPECIFIC MR CONTRAST MEDIA AGENT, ACE-MBCA: QUANTITATIVE ASSESSMENTS FROM THE SPARKLE STUDY

Madeleine Sertic, MBBCh (*Presenter*)
Beatrice L. Madrazo, MD (*Abstract Co-Author*)
Nadilka Hettiarachchige (*Abstract Co-Author*)

Andreas Norlin, PhD (*Abstract Co-Author*)
Alvin C. Silva, MD (*Abstract Co-Author*)

PURPOSE

To assess the efficacy of a novel oral manganese-based liver-specific magnetic resonance (MR) contrast media agent, ACE-MBCA (Ascelia Pharma Manganese Based Contrast Agent), based on quantitative outcomes from the phase III SPARKLE study.

METHODS AND MATERIALS

This prospective, global, multicenter study included 85 patients with known or suspected liver lesions and severe renal impairment. Patients underwent unenhanced MR imaging (UMRI) before administration of the liver-specific contrast agent, followed by an enhanced MRI (ACE-MBCA MRI). Signal intensity was measured within regions of interest of the normal liver parenchyma, focal liver lesions (up to 5) and outside the patient (background), in pre- and post-contrast T1-weighted MR images by 3 independent readers. Quantitative endpoints included percent signal intensity enhancement (SI%) of liver parenchyma, liver-to-lesion contrast (LLC), signal-to-noise ratio (SNR), and contrast-to-noise ratio (CNR). Safety endpoints included adverse events (AEs).

RESULTS

Mean liver SI% increased from 59.6% to 72.2% in ACE-MBCA-enhanced images across the 3 readers. Mean LLC rose from 0.109-0.143 in unenhanced images to 0.291-0.331 in ACE-MBCA images. SNR and CNR exhibited similar changes. These quantitative parameters align with previously reported significant improvements in lesion visualization in the same study. No patients were withdrawn from the study. The most reported post dose AEs were mild to moderate nausea (16.1%), diarrhea (13.8%), vomiting (9.2%), and increased blood urea (3.4%). No drug-related serious AE or deaths were reported.

CONCLUSION

The study demonstrated a change in signal intensity of the liver parenchyma and focal liver lesions in T1-weighted MR images consistent with a hypointense contrast agent. ACE-MBCA 800 mg provides significant improvement in focal lesion visualization over unenhanced MR and was safe for patients with suspected or known liver lesion and severe renal impairment.

CLINICAL RELEVANCE/APPLICATION

The use of ACE-MBCA in liver MRI may benefit patients lacking alternatives to Gadolinium-based agents when the use of the latter is medically inadvisable or when use of IV contrast agents cannot be administered.

M5A-SPGI-17 ADVANCING CHRONIC PANCREATITIS DIAGNOSIS WITH CT RADIOMICS: NEW BIOMARKERS FOR DIAGNOSIS AND STAGING

Surenth Nalliah, MD (*Presenter*)
Esben Bolvig Mark (*Abstract Co-Author*)
Soren Nicolai Frederiksen Hostrup (*Abstract Co-Author*)
Marjolein H. Liedenbaum, MD, PhD (*Abstract Co-Author*)
Erlend Hodneland, PhD (*Abstract Co-Author*)
Ingfrid H. Haldorsen, MD, PhD (*Abstract Co-Author*)
Trond Engjom (*Abstract Co-Author*)
Soren Schou Olesen (*Abstract Co-Author*)
Asbjorn Mohr Drewes, MD,PhD (*Abstract Co-Author*)
Jens Brondum Frokjer, MD, PhD (*Abstract Co-Author*)

PURPOSE

Chronic pancreatitis (CP) is a progressive inflammatory disease causing pancreatic damage and complications such as exocrine pancreatic insufficiency (EPI), diabetes and pain. Standard imaging often detects CP only at advanced stages and provides limited insight into associated complications. Radiomics, combined with artificial intelligence (AI), can extract pixel-level imaging features and detect subtle tissue changes not visible to the human eye. This study aimed to identify CT-based radiomic features that distinguish CP from healthy controls and classify patients based on complications. A secondary objective was to assess the interpretability of these features and their association with clinical outcomes.

METHODS AND MATERIALS

This multicenter imaging study included 208 prospectively enrolled CP patients from the Scandinavian Baltic Pancreatic Club database and 150 healthy controls from Aalborg University Hospital. All underwent CT imaging in the portal venous phase. Manual segmentation of the pancreas was followed by extraction of 110 radiomic features using PyRadiomics. LASSO regression was used for feature selection. Support vector machine models were trained to classify CP and predict complications (EPI, diabetes, pain), and externally validated on 79 CP patients from Haukeland University Hospital. Feature interpretability was assessed by correlating selected features with imaging findings (atrophy, calcifications, pseudocysts, ductal dilatation). Additionally, AI model prediction probability scores were correlated with fecal elastase levels and disease severity.

RESULTS

The radiomics-based AI models demonstrated high accuracy in distinguishing CP from controls, with an external validation accuracy of 0.85. For predicting EPI, diabetes, and pain, accuracies were 0.68, 0.65, and 0.58. Sixteen radiomic features significantly correlated with pancreatic volume and calcifications; none with pseudocysts or ductal dilatation. Fecal elastase levels strongly correlated with predicted EPI probability scores ($p = 0.002$), and higher disease severity was associated with increased prediction probability scores.

CONCLUSION

Radiomics presents a promising approach for diagnosing and staging CP, as well as assessing its complications. Despite variability in predictive accuracy across complications, the results highlight its clinical potential. Future studies with larger, more diverse cohorts and advanced AI models may further enhance diagnostic accuracy and utility.

CLINICAL RELEVANCE/APPLICATION

Radiomics-based AI applied to routine CT offers a new noninvasive method for CP diagnosis and staging, with potential to improve decision-making, enable earlier intervention, and support personalized CP management.

Chuan Zhou, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate the accuracy of automatically extracted radiomic features from CT scans in the differentiation of high- and low-risk adrenal cancer during primary tumor assessment.

METHODS AND MATERIALS

Adrenal cancer is a deadly disease with a 5-year disease-specific survival rate of 50-60% for localized cancer and 10-20% for advanced stage disease. Patients with early-stage disease may be mistaken for having benign lesions, left untreated, and subsequently develop locally aggressive disease and/or metastasis, progressing to more advanced stages. Failure in early diagnosis may result in worse outcomes and survival rates. Therefore, effective imaging biomarkers that can improve early differentiation of high- and low-risk neoplasms are crucial. High-risk adrenal cancers are considered to be pT2 stage and above, while low-risk adrenal cancers are below pT2 stage. Adrenal cancer is a rare disease. Our hospital is a national center specialized in treating and researching adrenal cancer. This allowed an elevated number of cases to be gathered. 89 retrospective adrenal cancer patients were initially identified with IRB approval. Inclusion criteria were: (1) available baseline abdominal CT exam containing the entirety of the adrenal mass; (2) lesion size measuring 5 cm or less; (3) available cancer stage and grade pathology information. 20 eligible cases with 20 cancers (13 high-risk, 7 low-risk) were used in this pilot study. All tumors were segmented and 3D tumor boundary extracted using our Auto-Initialized Cascaded Level Set (AI-CALS) system. 91 radiomic biomarkers including 59 tumor heterogeneity and 32 morphological features (volume (V), 23 gray level (GL) and 8 shape (S)) were extracted from the segmented lesions. An optimal feature subset was selected from the available feature set. A linear discriminant classifier was used to merge the selected features for classification of high- and low-risk tumors. A two-loop leave-one-out training and testing resampling scheme was implemented for feature classification. The classification performance was evaluated by the area under the receiver operating characteristic curve (AUC).

RESULTS

For the 20 cancers, the test AUC for prediction of high-risk versus low-risk cancer at baseline was 0.85±0.10. The selected useful biomarkers included a 1 GL, 2 S and 1 heterogeneity features.

CONCLUSION

Machine learning of radiomic characteristics of adrenal tumors in CT could achieve high performance in the assessment of cancer stages.

CLINICAL RELEVANCE/APPLICATION

Intelligent analysis of radiomic features has the potential to improve cancer stage assessment for adrenal cancer patients. Early accurate assessment of the high- or low-risk of cancer allows for better treatment planning.

M5A-SPGU-2 RADIOPROTEOMIC CORRELATIONS IN PROSTATE CANCER: LINKING FUNCTIONAL IMAGING TO MOLECULAR PROFILES

Anca L. Grosu, MD (*Presenter*)
Simon Spohn (*Abstract Co-Author*)
Matthias Fahrner (*Abstract Co-Author*)
Constantinos Zamboglou (*Abstract Co-Author*)
Benedict Oerther, MD (*Abstract Co-Author*)
Martin Freitag (*Abstract Co-Author*)
Tobias Fechter (*Abstract Co-Author*)
Ievgen Glavynskyi (*Abstract Co-Author*)
Peter Bronsert (*Abstract Co-Author*)
Oliver Schilling (*Abstract Co-Author*)

PURPOSE

Prostate cancer (PCa) remains the most common malignancy in men in Western countries. While image-guided biopsies are standard for tumour grading, they carry risks of complications and sampling errors, driving interest in non-invasive characterization using multiparametric MRI (mpMRI) and prostate-specific membrane antigen positron emission tomography (PSMA-PET). This study integrates radiomic features from these imaging modalities with histopathological and proteomic data to investigate associations between imaging phenotypes and molecular tumor characteristics.

METHODS AND MATERIALS

Patients with primary PCa underwent preoperative mpMRI and PSMA-PET prior to radical prostatectomy. Imaging datasets were spatially aligned with digitized whole-mount histopathology sections using ex vivo CT. Proteomic analysis of targeted tissue samples from tumor regions was performed via liquid chromatography-tandem

mass spectrometry (LC-MS/MS(. Radiomic features including standardized uptake value (SUV) from PET and apparent diffusion coefficient (ADC) from MRI, were correlated with proteomic profiles using linear regression and gene ontology enrichment.

RESULTS

20 patients with 68Ga-PSMA-PET and 15 with 18F-PSMA_PET were included. Proteomic analysis fo the first 20 patients with 68Ga-PSMA identified over 2,400 proteins across the samples. A positive correlation was observed between PSMAPET SUV and histopathological PSMA expression levels. Linear regression revealed distinct protein subsets associated with SUV and ADC values. Gene ontology analysis demonstrated that regions with higher SUV were enriched for biological processes such as telomere maintenance and RNA processing, while lower SUV regions correlated with structural adhesion pathways. Areas exhibiting the radiomic texture feature "QSZHGE" showed dysregulation of fatty acid metabolism-related proteins. Elevated ISUP grades were associated with increased matrisomal proteins, suggesting extracellular matrix remodeling.

CONCLUSION

This study establishes spatially resolved correlation between imaging markers and proteomic signatures in localized PCa. These insights support the development of non-invasive diagnostic tools for intermediate- and high risk PCa patients. Additional analyses are planned.

CLINICAL RELEVANCE/APPLICATION

Correlation between imaging and biology holds promise to further improve risk stratification and non-invasive tumour charakterisation in PCa, which can be used for further treatment personalization.

M5A-SPGU-3 AN EFFECTIVE BIOIMAGING PROGNOSTIC MARKER FOR CCRCC: A DEEP LEARNING FUSION MODEL UTILIZING MULTIPHASE CT IMAGES AND HISTOPATHOLOGICAL WHOLE SLIDE IMAGES

Changyi Ma, MD (*Presenter*)

PURPOSE

To develop and validate a DL fusion model using multiphase CT images and WSI for postoperative risk stratification in ccRCC patients.

METHODS AND MATERIALS

This retrospective study included 274 ccRCC patients who underwent multiphase CT scans (Jan 2008-Mar 2021), with diagnoses confirmed by histopathology post-surgery. The patient cohort was divided into a training set of 164 patients for model development and a test set of 110 patients for model validation. DL models based on multiphase CT images and histopathological WSIs were developed and validated. Performance comparisons among models were made through accuracy (ACC) and receiver operating characteristic (ROC) curve analyses, with integrated discrimination improvement (IDI) analysis and the DeLong test assessing diagnostic performance. Decision curve analysis (DCA) evaluated clinical utility, and Kaplan-Meier analysis assessed variable-survival correlations.

RESULTS

The CT and Pathology Mutual Guidance Fusion Diagnostic Network (CPNet) exhibited higher predictive performance for postoperative disease-free survival (DFS) in ccRCC patients than the other models. The area under the ROC curves (AUCs) of the CMP-Pathology Fuse, NP-Pathology Fuse, PCP-Pathology Fuse, and Three-phase-Pathology Fuse models were 0.7965, 0.798, 0.8363, and 0.8341, respectively, with corresponding ACCs of 69.09%, 69.09%, 75.45%, and 70.00%, respectively. Moreover, IDI and DCA showed that the PCP-based CPNet model exhibited comparable performance to the three-phase CPNet model (P >0.05) and provided significant net benefits (0.01-0.95).

CONCLUSION

The PCP-based CPNet model is a valuable tool for predicting postoperative DFS in ccRCC patients that can be effectively integrated into clinical practice and has the potential to become An effective bioimaging prognostic marker.

CLINICAL RELEVANCE/APPLICATION

ccRCC is an aggressive, heterogeneous tumor with a poor prognosis. Prognostic assessments need multi-modal data. Radiological images have limits, while pathological images offer micro-level details. Integrating these for ccRCC outcome prediction is important. Our study aimed to develop and validate a DL fusion model using multiphase CT images and WSI for postoperative risk stratification in ccRCC patients.

M5A-SPGU-4 IMPROVING PREOPERATIVE PREDICTION OF MUSCLE INVASION STATUS IN BLADDER CANCER USING ARTIFICIAL INTELLIGENCE MODEL COMBINING INTRATUMORAL AND PERITUMORAL IMAGES OF DUAL-ENERGY CT

Changyu Du (*Presenter*)
Mengting Hu (*Abstract Co-Author*)
Wei Wei (*Abstract Co-Author*)
Yijun Liu (*Abstract Co-Author*)
Jianying Li, PhD (*Abstract Co-Author*)

PURPOSE

To demonstrate the improved preoperative prediction of muscle invasion status in bladder cancer (BCa) using deep learning (DL) models that utilize multi-parameters of dual-energy CT (DECT) images of both intratumoral and peritumoral regions of BCa.

METHODS AND MATERIALS

A retrospective analysis was conducted on 207 patients with pathologically confirmed BCa who underwent DECT urography, including 141 cases of non-muscle-invasive bladder cancer (NMIBC) and 66 cases of muscle-invasive bladder cancer (MIBC). All patients were randomly divided into training and test cohorts in a 7:3 ratio. Radiomic features were extracted from the venous phase 40, 70 and 100keV, and iodine-based material-decomposition (IMD) images of the intratumoral and both intra- and peritumoral regions (IntraPeri). A ResNet50 DL model was also established to extract DL features. Feature selection was carried out sequentially using the Mann-Whitney U test, Spearman correlation analysis, and LASSO. Support Vector Machine classifiers were employed to construct four models: intratumoral radiomics (Intra-Rad), intratumoral DL (Intra-DL), IntraPeri radiomics (IntraPeri-Rad), and IntraPeri DL (IntraPeri-DL). The predictive performance of each model was evaluated by plotting the receiver operating characteristic curve and calculating the area under the curve (AUC), accuracy, sensitivity, and specificity. Calibration curves and decision curves were drawn to assess model accuracy and clinical benefit.

RESULTS

In the test cohort, the diagnostic efficacies of the models combining the intra- and peritumoral regions surpassed that of the intratumoral alone: AUC of 0.981 with IntraPeri-DL vs. 0.632 with Intra-DL; and 0.712 with IntraPeri-Rad vs. 0.608 with Intra-Rad model. Among the four models, the IntraPeri-DL model demonstrated the best predictive performance using the Delong test (AUC = 0.981, accuracy = 0.937, sensitivity = 0.895, specificity = 0.955) (P < 0.001 for all). Calibration curves and decision curves indicated that the IntraPeri-DL model had good calibration ability and clinical applicability.

CONCLUSION

The DL model uses multi-parameters of DECT images of both intra- and peritumoral regions of BCa represents a non-invasive and effective tool for the preoperative assessment of its muscle invasion status.

CLINICAL RELEVANCE/APPLICATION

BCa is a prevalent malignant tumor of the urinary tract, ranking as the fourth most common cancer among men. It is classified into two types based on infiltrative characteristics: NMIBC and MIBC, each requiring distinct clinical management strategies. Accurate assessment of muscle invasion in BCa is vital for developing personalized treatment approaches.

M5A-SPGU-5 CAPTAIN RANDOMIZED CONTROLLED TRIAL OF MRI-GUIDED TRANSURETHRAL ULTRASOUND ABLATION (TULSA) VERSUS ROBOTIC RADICAL PROSTATECTOMY: INITIAL PERIOPERATIVE OUTCOMES

PURPOSE

Randomized controlled trials (RCTs) comparing ablation to standard therapy for prostate cancer (PCa) have failed to recruit due to poor equipoise or acceptance of randomization. The CAPTAIN RCT (NCT05027477) compares TULSA to robotic radical prostatectomy (RP) in 201 men with localized, intermediate-risk PCa. Allocation is 2:1 TULSA:RP. Primary endpoints are the proportion of men preserving pad-free urinary continence and erections sufficient for penetration, and freedom from salvage treatment. Initial perioperative outcomes and return to baseline activity are compared here.

METHODS AND MATERIALS

Patients were randomized balancing key covariates. Full eligibility included intraprostatic calcifications =3 mm through-plane on CT, SW-MRI or FFE-MRI. RP was performed per local standard of care; TULSA ablation plans were subtotal to whole-gland ablation. Hospitalization, blood loss, and 30-day patient diaries (EQ-5D-5L, NRS pain score) were collected.

RESULTS

Recruitment opened in Jan 2022 expanding to 23 sites. By Jan 2025, 201 patients were randomized, with 174 treated or scheduled (69% TULSA, 31% RP). For TULSA vs RP, median (IQR) age was 63 (58-68) vs 64 (59-68) y, proportions with PSA =10ng/mL were 77% vs 74% and 23% vs 26% with PSA>10ng/mL (p=0.90). Proportions of TULSA vs RP patients with GG2/3 PCa were 76%/24% vs 78%/22% (p=0.72). On baseline imaging for TULSA vs RP, gland volume was 41 (31-50) cc vs 35 (29-47) cc (p=0.10). Intraprostatic calcifications were absent/=3mm/>3mm in 63%/18%/17% vs 65%/22%/11% (all p>0.05). There was significantly less intraprocedural blood loss [0 (0-0) vs 100 (100-200) mL] and shorter stay [0.29 (0.27-0.32) vs 1.24 (1.12-1.36) d] after TULSA (both p<0.001). Patients reported significantly less decline in overall health on the EQ-5D 0-100 visual analog scale after TULSA vs RP for all 30 days, lower 0-10 NRS pain to 6 d, and greater ability performing usual activities to 9 d. Significantly fewer patients reported extreme problem/inability after TULSA vs. RP over the first month for mobility (0% vs 12%), self-care (2.8% vs 17%), and usual activities (17% vs 40%). Top-recruiting sites developed pre-screening workflows, fostered equipoised discussion, and offered CAPTAIN to patients seeking RP.

CONCLUSION

Initial CAPTAIN perioperative outcomes demonstrate that TULSA had no blood loss and no overnight stay, along with reduced post-procedure pain, and more rapid recovery to baseline activities and overall health compared with RP.

CLINICAL RELEVANCE/APPLICATION

CAPTAIN is the first RCT of ablative vs radical treatment for PCa to successfully recruit to target. Initial outcomes demonstrate that TULSA had no blood loss and no overnight stay, reduced pain, and more rapid recovery to baseline activities of daily life.

M5A-SPGU-6 DEVELOPMENT AND EXTERNAL VALIDATION OF A DEEP LEARNING MODEL FOR DETECTING CLINICALLY SIGNIFICANT PROSTATE CANCER ON BIPARAMETRIC MRI USING A LARGE-SCALE MULTI-CENTER DATASET

Yasuhisa Kurata, MD, PhD (*Presenter*)
Hirotsugu Nakai, MD (*Abstract Co-Author*)
Ayumu Kido (*Abstract Co-Author*)
Kotaro Yoshida, MD (*Abstract Co-Author*)
Adam T. Froemming, MD (*Abstract Co-Author*)
Jordan LeGout, MD (*Abstract Co-Author*)
Akira Kawashima, MD (*Abstract Co-Author*)
Naoki Takahashi, MD (*Abstract Co-Author*)

PURPOSE

To develop a deep learning (DL) model for detecting clinically significant prostate cancer (csPCa) using a large-scale biparametric MRI dataset and to validate its performance on an external test set.

METHODS AND MATERIALS

This multi-center retrospective study included 13,739 MRI exams (12,041 patients) performed in patients without history of csPCa between 1/2017 and 7/2023 as the training set, and 1,344 exams (1,344 patients) performed between 8/2023 and 12/2023 as the internal test set. The dataset included pathology proven exams and PI-RADS 1-2 exams without pathology as negative cases. Exams with severe metal artifacts were excluded. The publicly available PI-CAI challenge dataset (1,488 exams) was used as an external test set. A DL-based Image model was developed using nnU-Net on 7,413 exams from the training set (2413 exams with csPCa and manually

placed ROIs). A clinical model was developed using neural net on all cases in the training set with age, PSA, PSA density, and transition zone-PSA density. Image+Clinical model combined outputs from Image and Clinical models. Patient-level performance was evaluated using area under the receiver operating characteristic (AUROC). For the internal test set, the model's performance was compared with that of radiologists using DeLong test. Lesion-level performance was evaluated using free-response receiver operating characteristic (FROC) on 766 exams (217 csPCa) from the external test set.

RESULTS

For the internal test set, AUROC for Image model, Image+Clinical model, and radiologists were 0.89, 0.91, and 0.90 ($p=0.54$ for Image model vs. radiologists and $p=0.25$ for Image+Clinical model vs. radiologists), respectively, when cases with PI-RADS 1-2 without pathology were included, and 0.84, 0.86, and 0.77 (both $p < 0.001$) for pathology proven cases. For the external test set, AUROC for the Image model and Image+Clinical model were 0.86 and 0.88, respectively. Lesion-level sensitivities at false positive levels of 0.1, 0.5, 1, 1.5, and 2 lesions per patient were 56.6%, 81.6%, 85.1%, 87.0%, and 88.2%, respectively, on the external test set.

CONCLUSION

DL-based Image+Clinical model demonstrated excellent performance in detecting csPCa in both internal and external test sets, outperforming radiologists in pathology proven cases on the internal test set.

CLINICAL RELEVANCE/APPLICATION

DL model could serve as an objective, reproducible tool to assist radiologists in detecting csPCa on biparametric MRI, potentially improving workflow efficiency and standardizing interpretation. The integration of clinical parameters with imaging enhances diagnostic accuracy beyond visual assessment alone.

M5A-SPGU-7 CAN ERECTILE DYSFUNCTION BE EVALUATED BY THE USE OF ULTRASOUND IMAGING WITHOUT AN INTRACAVERNOSAL INJECTION OF A VASOACTIVE AGENT?

Flemming Forsberg, PhD (*Presenter*)
Priscilla Machado, MD (*Abstract Co-Author*)
Ji-Bin Liu, MD (*Abstract Co-Author*)
Saatvik Kambhampati (*Abstract Co-Author*)
Aaron Hochberg (*Abstract Co-Author*)
Paul H. Chung, MD (*Abstract Co-Author*)

PURPOSE

Erectile dysfunction (ED) is a highly prevalent condition that affects approximately 30 million men in the United States. Penile duplex ultrasound (DUS) has long been considered standard of care, recent advances in ultrasound technology warrant investigation. Superb microvascular imaging (SMI) is a microvascular flow imaging mode represented as a color overlay image or as a grayscale map of flow, named cSMI and mSMI, respectively. Shear wave elastography (SWE) is a technique to measure tissue stiffness. This study investigated the use of cSMI, mSMI and SWE as novel techniques for evaluating ED in subjects undergoing penile DUS.

METHODS AND MATERIALS

To date 36 adult male subjects with clinical ED were enrolled in this ongoing, IRB approved study. Subjects underwent spectral Doppler, cSMI, mSMI and SWE examination of the right and left sides of the penis before and after an ICI of a vasoactive agent (i.e., Tri-mix which is a compounded alprostadil, phentolamine, and papaverine) using an Aplio i800 ultrasound system (Canon Medical Systems USA) equipped with an i18LX5 linear probe. The spectral Doppler data analyzed was peak systolic (PS) velocities and resistance index (RI) values, which is used clinically to evaluate arterial penile flow with the PS values expressed in cm/s and venous penile flow assessed with RI values. The cSMI and mSMI images were analyzed by pixel count using ImageJ (NIH). The SWE values were obtained in kPa. The data was analyzed by comparing pre injection (flaccid penis) and post injection (erect penis) images for all modalities using paired t-tests.

RESULTS

Mean age of subjects was 50 years (range: 23 -78). The mean IIEF score was 11 (range: 3-22; lower values indicate more severe ED). The mean spectral Doppler PSV ± SD were 22.39 ± 9.68 cm/s pre injection and 40.26 ± 16.82 cm/s post injection ($p < 0.0001$), mean RI ± SD were 0.94 ± 0.13 pre injection and 0.88 ± 0.10 post injection ($p = 0.008$). The mean cSMI pixel counts ± SD were 99.64 ± 6.64 pre injection and 101.10 ± 6.14 post injection ($p = 0.69$). The mean mSMI pixel counts ± SD were 124.10 ± 3.72 pre injection and 124.0 ± 3.67 post injection ($p = 0.89$). The mean SWE ± SD were 43.26 ± 22.36 kPa pre injection and 34.24 ± 21.02 kPa post injection ($p = 0.07$).

CONCLUSION

The cSMI, mSMI and SWE imaging modes may be able to identify characteristics consistent with ED in the flaccid penis facilitating clinical practice for providers and improving patient experience.

CLINICAL RELEVANCE/APPLICATION

The sensitive nature of ED and the intimate process of penile DUS makes for a less than ideal patient experience. SMI and SWE may be able identify penile characteristics consistent for ED in the flaccid penis facilitating clinical practice for providers and improve the patient experience.

M5A-SPHN-1 AUTOMATIC COCHLEAR MORPHOMETRY: INTRAINDIVIDUAL COMPARISON OF FULL-DOSE HEAD CT AND LOW-DOSE IMAGING ALTERNATIVES

Jan P. Grunz, MD (*Presenter*)
Henner Huflage, MD (*Abstract Co-Author*)
Andreas Kunz, MD (*Abstract Co-Author*)

PURPOSE

In cochlear implantation, precise estimation of cochlear duct length (CDL) is essential for individualized electrode carrier selection to provide stimulation of all crucial frequency bands. Besides full-dose head CT, the cochlea is also assessable in examinations with lower radiation dose, which are performed additively in different clinical scenarios. This study provides a comparison of CDL measurements based on full-dose head CT versus low-dose cervical spine, carotid artery, and paranasal sinus imaging. The aim was to analyze how radiation dose affects automatic cochlear morphometry.

METHODS AND MATERIALS

In this retrospective investigation, a total of 459 patients (mean age, 70.7 ± 17.8 [SD] years, 240 women) underwent automatic CDL measurements based on full-dose head CT (120 kVp). Additional cochlear morphometry was performed in these individuals based on cervical spine (Sn 150 kVp, 293 patients), carotid artery (100 kVp, 133 patients), or paranasal sinus imaging (Sn 100 kVp, 33 patients). Contrast-to-noise ratios (CNR) were calculated based on standardized measurements in bone and subcutaneous fat tissue. Wilcoxon signed rank and Kruskal-Wallis tests were employed for intraindividual and interindividual radiation dose, CDL, and CNR comparisons.

RESULTS

Full-dose head CT (median 52.9 [49.2-56.8] mGy) was associated with a higher volume CT dose index than cervical spine (16.3 [15.6-16.9] mGy), carotid artery (8.4 [8.2-8.7] mGy), and paranasal sinus CT (fixed dose 5.0 mGy; all P <.001). CNR was highest in full-dose head scans (24.3 [21.4-27.1]). Among the other scan protocols, cervical spine CT (8.6 [8.2-8.9]) was associated with higher CNR than paranasal sinus (6.6 [5.7-7.4]) and carotid artery scans (3.8 [3.7-4.0]; all P <.001). No significant CDL difference was ascertained for head versus cervical spine (35.4 versus 35.5 mm; P =.371) and head versus paranasal sinus CT (34.9 versus 35.0 mm; P =.112), whereas the cochlear duct was measured to be slightly shorter in the carotid artery angiography sample (35.6 versus 35.4 mm; P <.001).

CONCLUSION

Despite lower CNR, automatic CDL measurements based on CT imaging of the cervical spine, carotid artery, and paranasal sinus yield comparable results to full-dose head CT. This suggests potential for considerable dose reduction in cochlear morphometry without decreasing measurement accuracy.

CLINICAL RELEVANCE/APPLICATION

In radiation-sensitive patients, such as children, automatic preoperative CDL measurements can be reliably performed based on different low-dose CT examinations depicting the temporal bone.

M5A-SPHN-2 EXPLAINABLE MACHINE LEARNING ON MULTI-SEQUENCE MRI FOR TREATMENT ALLOCATION IN HYPOPHARYNGEAL CANCER: A MULTICENTRE RETROSPECTIVE COMPARATIVE STUDY

Cheyu Hsu, MD, MS (*Presenter*)
Rou-Yi Chen, MSc (*Abstract Co-Author*)
Sung-Hsin Kuo, MD, PhD (*Abstract Co-Author*)
Hsin-Han Tsai (*Abstract Co-Author*)
Po-Ting Chen, MD (*Abstract Co-Author*)
Kao-Lang Liu, MD (*Abstract Co-Author*)
Weichung Wang, PhD (*Abstract Co-Author*)

PURPOSE

Predicting treatment response is essential for selecting optimal therapy—total laryngectomy (TL) or concurrent chemoradiotherapy (CCRT)—in patients with hypopharyngeal squamous cell carcinoma (HPSCC). We developed and validated a machine learning-based radiomics model using pre-treatment MRI to predict response to CCRT and guide treatment in patients with HPSCC.

METHODS AND MATERIALS

This retrospective study analysed patients with HPSCC from three institutions between January 2004-December 2022. Radiomic features from tumor and peritumoral regions on multi-sequence MRI were combined with clinical factors to create a clinico-radiomic model. A Light Gradient Boosting Machine learning model was trained with nested cross-validation generated radiomic signatures, which were externally validated. Model-derived risk categories were compared to outcomes between TL and CCRT cohorts.

RESULTS

The study included 613 patients (mean age, 56.1 ± 9.83 years; 592 men), divided into discovery (CCRT) (N = 334), validation (CCRT) (N = 121), and comparison (TL) (N = 158) cohorts. The clinico-radiomic model achieved area under the curve values of 0.88 and 0.85 for predicting CCRT response in the discovery and validation cohorts, respectively. Risk stratification revealed significant differences in survival outcomes. High-risk patients benefited from TL over CCRT (5-year disease-free survival: 34% vs. 12%; overall survival [OS]: 42% vs. 24%), while low-risk patients had comparable outcomes across treatments. The model-guided protocol (TL for high-risk, CCRT for low-risk) improved 5-year OS by 11%.

CONCLUSION

The clinico-radiomic model accurately predicted CCRT response and helped stratify patients with HPSCC into risk groups, enabling personalized treatment allocation.

CLINICAL RELEVANCE/APPLICATION

Our study presents a significant advancement in the field of hypopharyngeal squamous cell carcinoma (HPSCC) by introducing a explainable, machine learning-based radiomics model validated across multiple centers. This model demonstrated high predictive accuracy in forecasting the response to concurrent chemoradiotherapy (CCRT) and effectively stratified patients into high- and low-risk groups, thereby guiding personalized treatment decisions.

M5A-SPHN-3 EFFICACY AND SAFETY OF ETHANOL ABLATION FOR BRANCHIAL CLEFT CYST: A RETROSPECTIVE COHORT STUDY

Eun Ju Ha, MD (*Presenter*)

PURPOSE

To evaluate the efficacy, safety and factors influencing the treatment response to ultrasonography (US)-guided ethanol ablation (EA) in patients with branchial cleft cysts (BCCs).

METHODS AND MATERIALS

Between February 2009 and December 2023, 74 patients with second BCCs who either refused surgery or were ineligible for it underwent EA. After excluding 17 patients lost to follow-up, a total of 57 patients were included in this study. All index masses were confirmed as benign through fine-needle aspiration cytology prior to treatment. Under US guidance, EA was performed by aspiration of the internal cystic contents, followed by saline irrigation, and injection of 99% ethanol into the lesion. The therapeutic outcome- including volume reduction ratio, therapeutic success rate, and complications- was evaluated. Factors influencing the treatment response were analyzed based on nodule and treatment characteristics.

RESULTS

The mean initial volume of the cysts was 24.8 ± 19.6 mL (range, 2.0-96.5 mL). Before EA, the mean symptomatic and cosmetic scores were 5.8 ± 3.3 (0 - 10) and 3.6 ± 0.8 (1-4), respectively. Following EA, with a mean of 1.6 ± 1.0 treatment sessions, the mean cyst volume significantly decreased to 0.7 ± 1.1 mL (range, 0.0-3.5 mL), corresponding to a mean volume reduction ratio of 98.1 ± 1.8% (range, 94.3%-100.0%) ($P < .001$) at the last follow-up. Therapeutic success was achieved in all nodules (54/54, 100%), with significant improvements in both symptomatic ($P < .001$) and cosmetic ($P < .001$) scores by the last follow-up. The initial volume was a key factor associated with treatment response to EA for BCCs, with an area under the receiver operating characteristic curve of 0.71 using a cutoff value of 25.8 mL. Intracystic hemorrhage occurred in one patient during the EA.

CONCLUSION

EA is an effective treatment for patients with BCCs who refuse surgery or are ineligible for it. While an initial volume < 25.8 mL is crucial for achieving therapeutic success after a single treatment, multiple treatment sessions can lead to therapeutic success in all patients.

CLINICAL RELEVANCE/APPLICATION

EA is a safe and effective treatment for patients with BCCs, especially those who refuse or are ineligible for surgery. Initial cystic volume predicts the therapeutic success after a single treatment.

M5A-SPHN-5 DEEP LEARNING RECONSTRUCTION FOR ACCELERATED T1WI AND T2WI DIXON SEQUENCES IN HEAD AND NECK TUMORS

Tianjiao Wang (*Presenter*)
Yu Chen, MD (*Abstract Co-Author*)
Yun Wang (*Abstract Co-Author*)
Zhuhua Zhang (*Abstract Co-Author*)
Tong Su, MD (*Abstract Co-Author*)
Zhentan Xu (*Abstract Co-Author*)
Haihong Fu, MD (*Abstract Co-Author*)
Huadan Xue, MD (*Abstract Co-Author*)

PURPOSE

To investigate the impact of deep learning (DL)-reconstructed T1WI and T2WI_Dixon sequences in acquisition time, image quality and diagnostic performance compared with conventional MRI in patients with head and neck tumors.

METHODS AND MATERIALS

Eighty patients who clinically diagnosed with head and neck tumors and underwent neck MRI in our hospital were prospectively collected. Each patient underwent two MRI examinations: conventional sequences included T1WI, T2WI_Dixon (in phase, water, and fat), and DL-reconstructed sequences included DL-T1WI, DL-T2WI_Dixon (in phase, water, and fat). Subjective image quality evaluation used a 5-point scale to score the sharpness, artifacts, overall image quality and diagnostic confidence. Objective image quality was assessed by calculation of the SNR of muscle, fat, tumor and CNR of tumor by one experienced radiologist. The interchangeability of DL-reconstructed sequences and conventional sequences for detection of an abnormality were assessed.

RESULTS

Compared to conventional T1WI sequence, DL-T1WI sequence reduced the scanning time by 46% (conventional: 164 s vs DL: 89 s); compared to conventional T2WI_Dixon sequence, DL-T2WI_Dixon sequence reduced the scanning time by 47% (conventional: 188 s vs DL: 101 s). Sharpness, artifacts, overall image quality and diagnostic confidence were significantly better for DL-reconstructed than for the conventional sequences (DL-T1WI: 4.8±0.9 vs. T1WI: 4.2±1.1, DL-T2WI_Dixon: 4.7±0.7 vs. T2WI_Dixon: 4.0±1.2, all $p<0.001$). There were no statistically significant differences in SNR of muscle, fat, tumor and CNR of tumor between conventional and DL-reconstructed sequences (all $p > 0.05$). The DL-reconstructed sequences and conventional sequences were clinical interchangeable for detection of abnormalities.

CONCLUSION

DL accelerated T1WI and T2WI_Dixon sequences shortened scanning time, improved subjective image quality, maintained good objective image quality and was diagnostic interchangeable with conventional sequences.

CLINICAL RELEVANCE/APPLICATION

With a 47% reduction in examination time, DL accelerated T1WI and T2WI_Dixon sequences could remain excellent image quality and diagnostic performance. Therefore, DL accelerated technique improved the clinical application efficiency and extended the clinical application range in head and neck tumors.

M5A-SPHN-6 PERILESIONAL DOMINANCE: RADIOMICS OF MULTIPARAMETRIC MRI ENHANCES DIFFERENTIATION OF IGG4-RELATED OPHTHALMIC DISEASE AND ORBITAL MALT LYMPHOMA

Jie Li (*Presenter*)
Qinghe Han (*Abstract Co-Author*)

PURPOSE

To develop and validate a diagnostic framework integrating intralesional (ILN) and perilesional (PLN) radiomics derived from multiparametric MRI (mpMRI) for distinguishing IgG4-related ophthalmic disease (IgG4-ROD) from orbital mucosa-associated lymphoid tissue (MALT) lymphoma.

METHODS AND MATERIALS

This multicenter retrospective study analyzed 214 histopathologically confirmed cases (68 IgG4-ROD, 146 MALT lymphoma) from two institutions (2019-2024). A LASSO-SVM classifier was optimized through comparative evaluation of seven machine learning models, incorporating fused radiomic features (1,197 features) from ILN/PLN regions. Diagnostic performance was benchmarked against two subspecialty radiologists (10-20 years' experience) using receiver operating characteristics - area under the curve (AUC) and decision curve analysis (DCA), adhering to CLEAR/METRICS guidelines.

RESULTS

The fusion model (FR_RAD) achieved state-of-the-art performance: training AUC = 0.927 (95% CI 0.902-0.958), external testing AUC = 0.907 (0.857-0.965). Subspecialty radiologists demonstrated lower diagnostic performance, with Radiologist 1 achieving an AUC of 0.671 (95% CI 0.630-0.710) and Radiologist 2 an AUC of 0.740 (95% CI 0.700-0.780), both significantly lower than the model ($p < 0.001$). In terms of accuracy, FR_RAD outperformed Radiologists 1 and 2 by 36.4% (90.0% vs. 66.2%) and 26.8% (90.0% vs. 71.3%), respectively ($p < 0.01$). DCA demonstrated a net benefit of 0.18 at a high-risk threshold of 30%, equivalent to avoiding 18 unnecessary biopsies per 100 cases.

CONCLUSION

The fusion model integrating multi-regional radiomics from mpMRI achieves precise differentiation between IgG4-ROD and orbital MALT lymphoma, outperforming subspecialty radiologists.

CLINICAL RELEVANCE/APPLICATION

This study establishes a clinically validated radiomics framework that non-invasively differentiates IgG4-related ophthalmic disease from orbital MALT lymphoma with high accuracy, outperforming conventional MRI and radiologists' assessments. By integrating intralesional and perilesional radiomics from multiparametric MRI, the model reduces diagnostic uncertainty, supports early treatment initiation, and decreases the need for invasive biopsies in a high-risk anatomical area. Its high sensitivity and specificity enable timely initiation of appropriate therapies, potentially improving patient outcomes and reducing complications. The framework also provides objective, quantitative data to support multidisciplinary decision-making and offers a tool for monitoring treatment response and disease progression, advancing precision medicine in ophthalmology.

M5A-SPHN-7 PREOPERATIVE PREDICTION OF LYMPH NODE METASTASIS IN PAPILLARY THYROID CARCINOMA USING DUAL-ENERGY CT IODINE MAPS COMBINED WITH MORPHOLOGICAL FEATURES

Bo Gao, MD (*Presenter*)
Bo Gao, MD (*Abstract Co-Author*)
Haiqiao Sun (*Abstract Co-Author*)
Huizhi Mi (*Abstract Co-Author*)
Jingbin ZHANG (*Abstract Co-Author*)
Xiaohui Li (*Abstract Co-Author*)
Jiaxing Wu (*Abstract Co-Author*)
Jing Fan Zhang (*Abstract Co-Author*)
Wei Guo Xu (*Abstract Co-Author*)

PURPOSE

To evaluate the predictive value of dual-energy computed tomography (DECT) iodine quantification combined with lymph node morphological characteristics for identifying metastatic lymph nodes in patients with papillary thyroid carcinoma (PTC).

METHODS AND MATERIALS

This retrospective study included 75 histologically confirmed PTC patients who underwent DECT between 2021 and 2023 as an internal validation cohort, and 47 patients from 2023 to 2024 as an external validation cohort. Univariate and multivariate logistic regression analyses were performed to identify independent predictors of lymph node metastasis. A predictive model was constructed based on these variables and validated both internally and externally.

RESULTS

Multivariate analysis identified arterial phase iodine concentration (= 2.6 mg/mL), marked arterial enhancement, heterogeneous enhancement pattern, irregular shape, indistinct margins, and incomplete capsule of the primary thyroid nodule as independent predictors of lymph nodes metastasis. A nomogram integrating DECT- derived iodine metrics and morphological features was developed. In the internal validation cohort, the model achieved an area under the curve (AUC) of 0.992 (95% CI: 0.956-0.984), with a cutoff value of 0.2, sensitivity of 98%, and specificity of 95%. In the external validation cohort, the AUC was 0.950 (95% CI: 0.893-0.884), with a cutoff value of 0.486, sensitivity of 89%, and specificity of 88%.

CONCLUSION

A predictive model combining DECT iodine concentration with CT-based morphological features provides high diagnostic accuracy for preoperative identification of metastasis lymph nodes in patients with PTC.

CLINICAL RELEVANCE/APPLICATION

This non-invasive approach offers a valuable tool to assist clinicians in preoperative surgical planning, enabling more personalized treatment strategies for patients with papillary thyroid carcinoma.

M5A-SPIN-1 A MULTIMODAL MACHINE LEARNING FRAMEWORK FOR COMPREHENSIVE OUTCOMES PREDICTION IN PULMONARY EMBOLISM

Chenhao Lyu (*Presenter*)
Yuli Wang (*Abstract Co-Author*)
Harrison X. Bai, MD (*Abstract Co-Author*)
Zhusi Zhong (*Abstract Co-Author*)
Ihab R. Kamel, MD, PhD (*Abstract Co-Author*)
Zhicheng Jiao (*Abstract Co-Author*)
Cheng Ting Lin, MD (*Abstract Co-Author*)
Jing Wu (*Abstract Co-Author*)

PURPOSE

To develop and validate a multimodal machine learning framework that integrates imaging, textual, and clinical data to predict key outcomes in patients with pulmonary embolism (PE).

METHODS AND MATERIALS

Data were collected from two institutions, each including 11 PESI-related clinical variables, two medical therapies, CTPA scans, initial clinical notes, radiology reports, and echocardiography reports. Institution 1's dataset comprised 1,422 patients with acute PE, identified through automated radiology report analysis using Llama 3.3. This dataset was randomly split 80:20 for training and internal testing. Text embeddings were generated from reports using the Gatortron-base model, while image embeddings were extracted from CTPA scans using a 3D ResNet-50 model. These were combined with structured clinical variables and fed into an XGBoost classifier. Institution 2's dataset, comprising 85 patients, served as an external validation cohort.

RESULTS

The multimodal model demonstrated strong predictive performance across all endpoints in the internal test cohort from Institution 1. For mortality prediction, the model achieved an AUC of 0.873, with 82.8% accuracy and a C-index of 0.832. ICU admission prediction showed comparable performance with an AUC of 0.873, accuracy of 77.5%, and C-index of 0.874. Notably, prediction of chronic thromboembolic pulmonary hypertension (CTEPH) achieved an AUC of 0.928, an accuracy at 98.9%, and a C-index of 0.924. Pulmonary hypertension prediction also performed well, with an AUC of 0.811, accuracy of 81.1%, and C-index of 0.780. In the external validation cohort from Institution 2, the model maintained high performance, achieving an AUC of 0.772 with 98.8% accuracy for CTEPH, and an AUC of 0.983 with 96.5% accuracy for pulmonary hypertension.

CONCLUSION

This multimodal machine learning framework demonstrated robust and generalizable predictive performance across multiple PE-related outcomes by integrating imaging, textual, and structured clinical data.

CLINICAL RELEVANCE/APPLICATION

By enabling precise, real-time risk stratification, this AI system has the potential to enhance clinical decision-making and resource allocation in PE care, with seamless integration into radiology workflows and electronic medical records.

M5A-SPIN-2 EXPLORING MULTIMODAL DATA FUSION APPROACHES IN RADIOLOGY: AN EXAMPLE IN PREDICTION OF POST-SURGICAL MARGIN STATUS IN SOFT TISSUE SARCOMA

Ehsan Alipour, MD, PhD (*Presenter*)
Atefe Pooyan, MD, MPH (*Abstract Co-Author*)
Chankue Park, MD, PhD (*Abstract Co-Author*)
Sara Haseli, MD (*Abstract Co-Author*)
Stephanie K. Schaub, MD (*Abstract Co-Author*)
Matthew J. Nyflot, PhD (*Abstract Co-Author*)
Majid Chalian, MD (*Abstract Co-Author*)

PURPOSE

Multimodal deep learning holds significant potential for enhancing model performance and improving disease outcome prediction by integrating data from diverse sources, including imaging, electronic health records (EHR), genomics, and more. Incorporating heterogeneous data types into a unified deep learning model presents challenges, as each modality often requires distinct modeling strategies that may not be compatible. The process of integrating diverse data types is referred to as "data fusion," and several approaches—namely early, intermediate, and late fusion—have been proposed. These methods differ based on the stage at which data from different modalities are combined and the extent of modality-specific processing that occurs prior to integration. Here, we investigate these data fusion techniques (Figure 1) for combining longitudinal MRI with clinical data to predict post-surgical margin status in patients with soft tissue sarcoma (STS). Post-surgical margin status is an important prognostic factor for recurrence in many cancers, including STS, and accurate preoperative risk stratification could play a key role in improving patient outcomes.

METHODS AND MATERIALS

We conducted a retrospective analysis of 202 patients diagnosed with primary STS who received neoadjuvant radiotherapy followed by surgical resection. To predict clinical outcomes, we developed a deep learning framework that integrated clinical, pathological, and imaging data using various data fusion strategies. Deep learning model performance was evaluated based on AUROC, sensitivity, and specificity on the hold-out test set.

RESULTS

The intermediate fusion approach demonstrated the best performance, achieving an AUROC of 0.82 (0.61 - 1.0) on the longitudinal test set, reaching a sensitivity of 67% and specificity of 78%, surpassing the performance of unimodal models. This was followed by the early fusion model that achieved an AUROC of 0.79 (0.62 - 0.97) on the test set. The late fusion approach achieved the lowest performance among all fusion strategies.

CONCLUSION

We demonstrated that the choice of data fusion approach in multimodal deep learning has a substantial impact on the overall predictive performance of the model. Our findings underscore the importance of exploring multiple fusion approaches when working with multimodal data, including imaging. Our model can be used to stratify patients based on their risk of having a positive post-surgical margin and potentially improve care.

CLINICAL RELEVANCE/APPLICATION

Post-surgical margin status is one of the strongest predictors of local recurrence in STS. Utilizing multimodal patient data to identify patients at a high-risk for positive margins has the potential to improve care and prevent negative outcomes.

M5A-SPIN-3 GROUNDING TECHNIQUES TO ENSURE TRACEABILITY AND IDENTIFY HALLUCINATIONS IN LLM GENERATED IMPRESSIONS

Sinan Batman (*Presenter*)
Ashwin Geet D'Sa (*Abstract Co-Author*)
Aldo Javier Vazquez Mezquita, MD (*Abstract Co-Author*)
Gene Urrutia (*Abstract Co-Author*)

PURPOSE

In the impression section of the radiology report, the reading radiologist summarizes important findings for prioritized communication to the referring physician. Using large language models (LLM), researchers and industrial partners have sought to auto-generate impressions from the findings, with recent work displaying expert-level performance in completeness, correctness, and conciseness. Nevertheless, it is well known that LLM sometimes hallucinate. The referring physician may look up the source of the summarized impressions to find additional details. Traceability saves time by providing links to the source. Hence, whether the content is written by a radiologist or an LLM, there is a strong need for traceability. The studies on traceability of source text remains less explored. Recent studies suggest using LLM based prompting technique to extract the source text for summaries. However, we argue that LLM based grounding techniques are less efficient than traditional lexical techniques and show that an ensemble aids in improving the accuracy of grounding techniques. Here, we compare grounding methods which automatically 1) identify source material from the finding and 2) detect hallucinations, that is, impressions which are not generated from the findings.

METHODS AND MATERIALS

We use three open-source radiology report datasets: MIMIC, CARES and OpenI. truth mapping from original impression to source is established and then reviewed by clinical experts. LLM is used to produce an artificial impression. Mapping is performed as with the original, but also hallucinations are identified as needed. We compare 3 techniques a) text match b) fuzzy matching and c) LLM based matching for grounding and evaluate the significance of each method and compare against their ensemble. We use LLM based techniques for hallucination detection. We compare two LLMs, the one with smaller number of model parameters and one with the larger number of model parameters to present the performance of varying sized LLMs for traceability and hallucination detection in clinical text content.

RESULTS

Text match can identify mapping for 80%, fuzzy matching for 90% and LLM with 5% additional for the impressions. Hallucinations are detected at an AUC of 90%.

CONCLUSION

Traditional techniques in combination with LLM based techniques are able to better achieve grounding and hallucination detection compared to any single technique.

CLINICAL RELEVANCE/APPLICATION

As GenAI and LLM's are incorporated more and more into clinical practice, guardrails are required to ensure quality of care is not impacted. Automated approaches with high accuracy have the potential to retain the time-savings of automatically generated impressions while ensuring that hallucinations are minimized.

M5A-SPIN-4 SHOW ME THE MONEY: EVALUATING UTILIZATION OF AI/ML-ENABLED MEDICAL DEVICES USING NATIONAL MEDICARE CLAIMS DATA

Babajide Owosela, BS (*Presenter*)
Janice M. Newsome, MD (*Abstract Co-Author*)
Yubin Park (*Abstract Co-Author*)
Hari Trivedi, MD (*Abstract Co-Author*)
Judy W. Gichoya, MBChB, MS (*Abstract Co-Author*)

PURPOSE

Artificial intelligence (AI) and machine learning (ML) continue to transform clinical practice. As of March 2025, the FDA has approved 1,016 AI/ML-enabled medical devices, 77% in radiology. These tools promise to improve diagnostic accuracy, reduce clinical workload, and expand access to care. However, real-world adoption of these tools is low due to lack of perceived value. Using Medicare Claims Data, we evaluate utilization of AI devices by analyzing claims and amount paid out for these tools.

METHODS AND MATERIALS

Using the 2024 AMA CPT code set, we identified CPT codes linked to FDA approved AI/ML devices. Medicare claims data from 2018-2023 were extracted from CMS datasets. For each CPT code, we extracted the associated clinical specialty, total claims, and Medicare reimbursement. Trends in utilization and Medicare spending were analyzed over time and by specialty.

RESULTS

Eighteen distinct AI-related CPT codes were identified, with radiology comprising 50% of the codes, followed by cardiology (17%), and other specialties. 95,290 claims were submitted for AI-enabled services between 2018 and 2023, accounting for $7.4 million in Medicare spending. AI utilization rose sharply over this period. Annual spending on AI-related services increased from $31,261.58 in 2018 to $4.18 million in 2023, a >130-fold increase. Radiology led this growth, expanding from $31,000 to over $4.1 million annually, accounting for the majority of AI reimbursement. Despite overall growth, subspecialty adoption varied widely. A few CPT codes, such as those used in cardiac imaging and ophthalmologic screening, contributed most claims. In contrast, multiple AI-enabled procedures for genetics and oncology had little or no reported usage. Spending also varied by geography, with the top 5 regions including Manhattan, NY; Fort Lauderdale, FL; NYC Suburbs, NY; NC; and Santa Clara, CA.

CONCLUSION

AI/ML-enabled medical devices are increasingly represented in Medicare claims, with exponential growth driven largely by radiology. There is a disparity between regulatory approval and clinical adoption demonstrated by spending concentrated in a few procedures, while many FDA-cleared tools show little real-world use. These findings highlight a growing but uneven integration of AI into routine care, emphasizing the need for continued evaluation of implementation, reimbursement, and equity in access.

CLINICAL RELEVANCE/APPLICATION

Understanding billing trends regarding AI-enabled services provides critical insight into the real-world use and adoption gaps of medical AI. These findings inform stakeholders about which AI tools are gaining traction, where clinical gaps remain, and how resource allocation and reimbursement policies may influence adoption across specialties.

M5A-SPIN-5 THE SHARED GENETIC ARCHITECTURE BETWEEN SCHIZOPHRENIA AND CARDIAC MAGNETIC RESONANCE IMAGING PHENOTYPES

Yingying Xie (*Presenter*)
Dairong Cao, MD (*Abstract Co-Author*)

PURPOSE

Schizophrenia (SCZ) is a complex psychiatric disorder often accompanied by systemic physiological abnormalities, including cardiac dysfunction. Cardiac magnetic resonance imaging (CMR) provides detailed markers of cardiac structure and function, enabling investigations into cross-system biological links. However, the shared genetic architecture between SCZ and cardiac imaging traits remains largely unknown. This study aims to explore the common genetic underpinnings connecting SCZ and CMR phenotypes.

METHODS AND MATERIALS

We leveraged European ancestry GWAS summary statistics for SCZ (53,386 cases and 77,258 controls) and 28 CMR phenotypes (n=31,875) with six categories (ascending aorta [AAo], descending aorta [DAo], left ventricle [LV], right ventricle [RV], left atrium [LA], and right atrium [RA]). Pleiotropic SNPs were identified using Pleiotropic analysis under composite null hypothesis (PLACO), with significance defined at P PLACO < 1×10?6. Independent SNPs were determined via LD clumping 250kb, $r^2 < 0.1$). FUMA was used to perform the SNP-level annotations for these pleiotropic SNPs, using Combined Annotation Dependent Depletion (CADD) scores, regulomeDB (RDB) scores, and minChrState values. Gene ontology enrichment analysis was conducted via ToppGene.

RESULTS

We found a total of 437 unique significant independent pleiotropic SNPs between SCZ and 28 CMR phenotypes, including 170 pleiotropic SNPs for the left ventricle (LV), 71 SNPs for right ventricle (RV), 48 SNPs left atrium (LA), 70 SNPs for right atrium (RA), 76 SNPs for ascending the aorta (AAo) and 53 SNPs for descending aorta (DAo) (Figure 1). Functional annotations revealed that over 60% of SNPs were intronic, with several exhibiting high CADD and regulatory scores. Enrichment analysis highlighted 44 biological processes, with a strong emphasis on synapse-related functions, suggesting synaptic dysfunction as a shared pathological mechanism linking SCZ and cardiac alterations (Figure 2).

CONCLUSION

Our findings reveal significant genetic overlap between SCZ and cardiac structure/function, particularly implicating synaptic biology. These insights advance understanding of the complex systemic manifestations of SCZ and suggest potential avenues for integrated therapeutic strategies.

CLINICAL RELEVANCE/APPLICATION

This study underscores the importance of incorporating cardiac imaging biomarkers in the comprehensive assessment of individuals with SCZ, revealing that alterations in cardiac structure may be partially driven by shared genetic liabilities. The identification of common genetic pathways suggests the potential utility of cross-disciplinary diagnostic frameworks and highlights novel targets for integrated therapeutic strategies.

M5A-SPIN-6 EARLY RISK ESTIMATION OF PANCREATIC DUCTAL ADENOCARCINOMA USING PRE-DIAGNOSTIC CT IMAGING AND RADIOLOGY REPORTS

David Le, PhD (*Presenter*)
Ramon Correa-Medero, BS (*Abstract Co-Author*)
Amara Tariq, PhD, MS (*Abstract Co-Author*)
Yifan Peng, PhD, MEng (*Abstract Co-Author*)
George L. Shih, MD, MS (*Abstract Co-Author*)
Zhen J. Wang, MD (*Abstract Co-Author*)
Bhavika K. Patel, MD (*Abstract Co-Author*)
Motoyo Yano, MD, PhD (*Abstract Co-Author*)
Imon Banerjee, PhD (*Abstract Co-Author*)

PURPOSE

Pancreatic ductal adenocarcinoma (PDAC) carries high mortality due to late diagnosis. We evaluated deep learning-based risk estimation models that integrate pre-diagnostic CT-derived radiomic and body composition, demographics, and free-text radiology report embeddings to stratify early-stage PDAC risk.

METHODS AND MATERIALS

Pre-diagnostic CT were segmented (pancreas, visceral fat (VF), subcutaneous fat (SF) and skeletal muscle (SM) via TotalSegmentator; total body area (TBA) via a custom script), and segmentation results were manually reviewed. We extracted 104 pancreatic radiomics features (shape, first-order, second-order statistics) with PyRadiomics. Body composition metrics included VF / total fat, VF / (VF + SM), SF / (SF + SM), and VF, SF, and SM were normalized to TBA. Demographics include age, sex, race, and ethnicity. Reports were parsed into Indications, Findings, Impressions, and Pancreas-specific sections; embeddings for each section were generated using Sentence-BERT (all-MiniLM-L6-v2). Fusing all features, our models were trained with the negative partial log-likelihood loss. Performance was assessed by concordance index (C-index), and Kaplan-Meier (KM) curves on internal and external cohorts. KM curves were compared using the log-rank test. Predicted risk scores stratified high (>0) versus low (=0) risk groups.

RESULTS

We retrospectively collected pre-diagnostic abdominal CTs (within 5 yrs) from 2,495 PDAC patients at the XX institute (2011-2023) by referring to our institutional cancer registry. Across cohorts, the mean time to diagnosis was ~58 months with censoring rates of 38% - 43%. Pancreatic PyRadiomics-only model achieved C-indices of 0.65 (95% CI: 0.61-0.68) and 0.59 (95% CI: 0.56-0.62) on internal and external cohorts, respectively. Report-embedding model (Indications + Pancreas) yielded 0.67 (95% CI: 0.63-0.70) and 0.64 (95% CI: 0.60-0.68). Fusion of radiomics and embeddings yielded 0.68 [95% CI: 0.65-0.71] and 0.65 [95% CI: 0.61-0.68]). The full fusion model (radiomics + embeddings + demographics + body composition) achieved the highest C-indices: 0.71 (95% CI: 0.68-0.74) internal and 0.70 (95% CI: 0.66-0.73) external. KM analysis clearly separated low- and high-risk groups ($p < 0.001$).

CONCLUSION

A deep learning fusion approach combining CT pancreatic radiomic, body composition, free-text report embeddings, and demographic features yields robust prognostic performance for pre-diagnostic risk stratification in PDAC.

CLINICAL RELEVANCE/APPLICATION

Incorporating CT and radiology report data into prognostic models may enable earlier identification of high-risk PDAC patients and could support prompt, evidence-based clinical decision-making.

M5A-SPIN-7 USING GENERATIVE SIMULATION TO PREDICT TUMOR RESPONSE FOR TREATMENT

Yijun Yang (*Presenter*)
Alan Yuille, PhD (*Abstract Co-Author*)
Zongwei Zhou, PhD (*Abstract Co-Author*)
Kang Wang, MD,PhD (*Abstract Co-Author*)
Yang Yang, PhD (*Abstract Co-Author*)
Jieneng Chen (*Abstract Co-Author*)

PURPOSE

To estimate treatment outcomes in HCC patients without follow-up imaging, we simulate post-treatment tumors based on pre-treatment status and treatment plan.

METHODS AND MATERIALS

Accurately predicting TACE response in HCC patients is crucial for optimizing patient selection and improving outcomes, as not all patients benefit equally. To address this, we have developed a generative AI model that simultaneously predicts post-treatment tumor appearance and overall survival using pre-treatment CT scans. Tumors were localized and segmented using a previously validated AI algorithm, nn-UNet. We trained a tumor diffusion model conditioned on the pre-treatment CT volume, treatment plan, and patient demographics to synthesize the post-treatment tumor appearance. A deep prognosis model was then developed to predict treatment outcomes, including viable/non-viable tumor classification and overall survival analysis from the pre-treatment tumor CT and generated post-treatment tumor CT volumes. We curated a dataset of 338 paired pre- and post-treatment CT scans from HCC patients, each accompanied by detailed treatment plans and survival outcomes. Internal validation was conducted on 36 held-out HCC patients, and two external validation cohorts included 47 patients collected independently from another center, and 116 patients from the curated public dataset WAW-TACE, respectively.

RESULTS

The synthesized post-treatment CTs resembled their real counterparts. We achieve a Visual Turing Test specificity of 79.17%, 70.83%, and 75.00% from three board-certified radiologists on the internal validation cohort. Our prognosis model trained on real pre-treatment and post-treatment CT scans achieved a C-index of 0.765 for overall survival analysis, and an accuracy, F1-score of 82.4%, 73.1% for viable/non-viable tumor classification, which was superior to two clinically-validated methods with a C-index of 0.724,0.719, on the internal validation cohort. Also, the model generalized well with marginal performance drops on two external validation cohorts, achieving the C-index of 0.676 and 0.620, better than other methods.

CONCLUSION

We demonstrate the feasibility of synthesizing realistic post-treatment tumor appearances while simultaneously predicting treatment response and overall survival, which can be used to assist physicians in early prognosis assessment.

CLINICAL RELEVANCE/APPLICATION

Post-treatment tumor assessment is a critical step in interventional oncology workflows. We simulate these images ahead of time, offering clinicians an early window into likely treatment responses. This potentially provides an AI framework to help clinicians select the most appropriate locoregional treatment therapies for HCC patients.

M5A-SPIN-8 AUTOMATED AI-BASED AORTIC SEGMENTATION AND MEASUREMENT ON NON-CONTRAST CT: A VALIDATED CONTRAST-FREE ALTERNATIVE TO CTA

Sisi CHEN, MSc, BEng (*Presenter*)
Eunice Lo (*Abstract Co-Author*)
Eunsu Min (*Abstract Co-Author*)
Sophia See (*Abstract Co-Author*)
Hoi Kiu Chan (*Abstract Co-Author*)
Qi Dou (*Abstract Co-Author*)
Winnie C. Chu, MD, FRCR (*Abstract Co-Author*)
Randolph Wong (*Abstract Co-Author*)

PURPOSE

To develop and validate a fully automated AI pipeline for aortic segmentation and measurement on non-contrast CT, providing a robust, reproducible, and contrast-free alternative to CT angiography (CTA) for clinical assessment and longitudinal follow-up.

METHODS AND MATERIALS

A deep learning workflow based on nnUNet, was trained on 139 paired CTA and CT plain scans from Prince of Wales Hospital. Manual CTA annotation and measurement, following AHA and ESC guidelines, were performed by three residents (1-years) and corrected by cardiologist (20-years). For CT plain, annotation was registered from CTA images with measurements directly taken from the paired CTA. The system performs automated aortic segmentation and PCA-based diameter measurement aligned with AHA/ACC guidelines. Segmentation was evaluated using Dice similarity coefficient (DSC) and intersection over union (IoU). Measurement performance was compared to manual measurement, including commercial software, 1-year readers, and z-axis methods, using intraclass correlation coefficient (ICC), Pearson's r, Mean absolute error (MAE) , and root mean square error (RMSE). Subgroup analyses were conducted across anatomical regions, landing zones, follow-up status (pre- and postoperative), age, and sex to assess robustness. Longitudinal tracking of pre- and post-operative diameter changes was evaluated.

RESULTS

The pipeline achieved excellent segmentation on CT plain scans (DSC 0.98, IoU 0.97), closely matching gold standard. Automated CT plain-based global maximum diameter measurements showed high agreement with gold standard (ICC = 0.97, Pearson'r = 0.97, MAE = 1.95 mm, RMSE = 2.48 mm), outperformed commercial software, 1-year readers, and the z-axis method, while performing comparably to automated CTA. High reliability (ICC > 0.9) and low error (MAE < 2.5 mm) were seen in all subgroups. For regional measurement in CT plain versus CTA, MAE was 2.31 mm (ascending), 2.19 mm (arch), 2.20 mm (descending). Across all landing zones, MAE ranged from 0.69 to 3.49 mm. Longitudinal tracking showed pre-/post-op change, with an average CTA-CT plain difference of 1.27 mm (anatomical regions) and 1.99 mm (landing zones).

CONCLUSION

AI-enabled CT plain imaging achieves rapid, reproducible, and accurate aortic measurement, offering a practical, contrast-free alternative to CTA in both diagnostic and follow-up settings.

CLINICAL RELEVANCE/APPLICATION

This workflow standardizes aortic assessment, reduce operator variability, and expand access to safe, accurate aortic monitoring, especially for patients contraindicated for contrast. Limitations include higher MAE in complex regions, relatively small dataset size, and the need for further multi-center validation.

M5A-SPIN-9 AI-DRIVEN LIVER LESION DETECTION IN ABDOMINAL CT WITH AUTOMATED REPORTING

Vikas K. Patel, MD (*Presenter*)
Suvrankar Datta, MD, MBBS (*Abstract Co-Author*)
Jitender Singh (*Abstract Co-Author*)
Mohammed Jabeer (*Abstract Co-Author*)
Shweta Tyagi (*Abstract Co-Author*)

Anuj Chandalia (*Abstract Co-Author*)
Dwarikanath Mahapatra (*Abstract Co-Author*)

PURPOSE

Accurate identification and quantification of liver lesions on abdominal CT are critical for the diagnosis, staging, and treatment planning of hepatic diseases, including primary and metastatic liver cancers. Manual segmentation is time-consuming and prone to variability. Liver volume estimation is also clinically important for evaluating hepatic reserve, particularly in surgical planning and treatment monitoring. We aim to implement an AI-based system that automates liver and lesion segmentation, quantifies lesion characteristics and liver volume, and generates structured reports to support radiologists in routine workflows.

METHODS AND MATERIALS

We developed a two-stage deep learning pipeline leveraging the nnUNet framework for automated analysis of contrast-enhanced abdominal CT scans. The first stage performs liver segmentation, isolating the organ from surrounding structures to enable targeted analysis. The second stage focuses on detecting and segmenting intrahepatic lesions within the segmented liver volume. Both stages were trained and validated using an expert-annotated dataset. The dataset consists of 1500 abdominal CT cases and is annotated by an expert radiologist. The system produces detailed outputs including 3D segmentation overlays for liver and lesions, and a report summarizing findings, total liver volume, lesion count, and the diameter and volume of each lesion.

RESULTS

On a test set of 100 CT scans, liver segmentation achieved a Dice score of 0.97. Lesion segmentation reached a mean Dice of 0.85. Lesion detection sensitivity was 93% for lesions >10 mm and 82% for lesions =10 mm. A radiologist verified these results.

CONCLUSION

Our AI system provides accurate and automated liver and lesion segmentation, quantitative lesion characterization, and liver volume analysis. The integrated reporting function can support consistent clinical decision-making and follow-up. In our future developments, we aim to expand this framework to include the types of liver lesions, multi-organ analysis, and detection of other abdominal abnormalities, broadening its utility as a comprehensive AI assistant in abdominal imaging.

CLINICAL RELEVANCE/APPLICATION

This AI solution can enhance radiology workflow efficiency and diagnostic consistency. Liver volume assessment is crucial for evaluating suitability for surgical resection or transplant and assessing treatment impact on liver parenchyma. By automating segmentation and structured reporting, the system can assist in early detection, monitoring, and treatment planning of hepatic disease, with future expansion to multi-organ analysis further broadening its clinical utility.

M5A-SPIN-10 AUGMENTATION IN AI MODELS: ENHANCING RADIOLOGY IMPRESSIONS THROUGH COMPARATIVE VALIDATION, PROMPT-BASED LEARNING, AND ROUGE EVALUATION

Parisa Kaviani, MD (*Presenter*)
Ryan Krishna (*Abstract Co-Author*)
Sheela Agarwal, MD, MBA, MD (*Abstract Co-Author*)
Rupert Brooks, PhD (*Abstract Co-Author*)
Keith J. Dreyer, DO, PhD (*Abstract Co-Author*)
Subba R. Digumarthy, MD (*Abstract Co-Author*)
Mannudeep K. Kalra, MD (*Abstract Co-Author*)

PURPOSE

The results from NLP and/or clinical language understanding (CLU) based generation of auto-impression from radiology findings have limitations. To address these limitations, we explored if a prompt-based LLM (ATARI based on GPT 4o) can augment the performance of an NLP-CLU-based auto-impression generator in a multicenter, multispecialty radiology reports dataset.

METHODS AND MATERIALS

Our IRB-approved study included 2,000 consecutive radiology reports belonging to adult patients, where the impression section was generated using Powerscribe Smart Impression (PSI, Nuance) from four radiology practices (500 consecutive reports from each center). The vendor recorded the use and modification of PSI outputs for each report, user, and practice site. All data were transferred to an encrypted Microsoft Excel file containing the following information: exam type, site code, user code, findings section, smart impression, and final impression. Two physician coinvestigators classified differences between the PSI and final impressions (FI) in 2,000 reports: minor differences (addition/change/deletion of single sentence/number/word/diagnosis in PSI to generate FI) and major differences (change in the entire PSI or multiple sentences, numbers, or diagnoses). Then, we applied prompt-based LLM to generate new impressions (LLM-I) for all PSI requiring changes (n=874) and reassessed LLM-I with the same classification criteria. Descriptive statistics were performed to determine the proportion of modified and non-modified LLM-I outputs for different exam types and practices. We used ROUGE (Recall-Oriented Understudy for Gisting Evaluation) metrics to quantitatively compare the similarity of LLM-I and PSI with the FI.

RESULTS

The PSI and FI impressions were identical for 56.3% (1,126/2,000) reports. Major changes were required for 777 (38.85%) reports, with just 9 (0.45%) reports needing complete revision (Table). LLM-I "fixed" issues associated with 109/874 reports (12.47%) where PSI required minor changes and 33/874 reports (3.77%) where PSI had major changes. However, ROUGE scores for LLM-I were significantly lower than for PSI ($p < 0.001$) across impressions requiring no change versus no changes. The results were generalizable across all four practice centers.

CONCLUSION

Our multicenter, real-world auto-impression clinical implementation data demonstrate that NLP-CLU and LLM can help generate an accurate impression section from the findings section with either no or minor modifications.

CLINICAL RELEVANCE/APPLICATION

LLM-generated impressions can help troubleshoot performance issues related to NLP-CLU-generated impressions. ROUGE scores might not help compare the success of auto-impression-generating methods.

M5A-SPIN-11 SMALL-DATA AI: SEMI-SUPERVISED CONTRASTIVE-LEARNING (SSCL-MTANN) FOR CLASSIFICATION BETWEEN MALIGNANT AND BENIGN LUNG NODULES IN 3D CT IN SMALL SAMPLE-SIZE SCENARIO

Kenji Suzuki, PhD (*Presenter*)
Mustain Billah (*Abstract Co-Author*)
Dichao Liu (*Abstract Co-Author*)

PURPOSE

Accurate classification of volumetric medical images such as classification between malignant and benign lung nodules in 3D CT remains a critical challenge, especially when annotated data is scarce. Manual labeling of 3D medical scans is labor-intensive, costly, and time-consuming for radiologists. This study proposes a semi-supervised contrastive learning framework, SSCL-MTANN, that enhances pulmonary nodule classification by leveraging patch-based modeling and a novel spatial proximity-based pair sampling strategy for contrastive learning, specifically tailored for low-label settings in lung cancer diagnosis.

METHODS AND MATERIALS

We propose SSCL-MTANN, a two-phase semi-supervised framework for classifying lung nodules as benign or malignant in 3D CT scans. In Phase 1, a lightweight encoder is pretrained on unlabeled volumes using a novel spatial proximity-based pair selection (SPPS) strategy for contrastive learning. In Phase 2, the encoder is fine-tuned on a small labeled set using soft labels derived from Gaussian-modeled annotations. The method was evaluated on the public LIDC-IDRI dataset containing 1,018 CT scans. Nodules between 3-30 mm were included, while micro-nodules (<3 mm) and large masses (>30 mm) were excluded. After preprocessing, 400 nodules (200 malignant, 200 benign) were used. Standardized 3D VOIs (51×51×51 voxels) were extracted around each nodule. The model was trained using only 5-15% labeled data, with the rest used as unlabeled.

RESULTS

Our SSCL-MTANN achieved an AUC of 0.76 using only 5% labeled data, significantly outperforming the performance (AUC: 0.50-0.59, 0.50-0.69) of both state-of-the-art (SOTA) semi-supervised (Pseudo labeling, mean teacher, and mix match) and fully supervised baseline models (Alexnet, Resnet18, VGG16, ViT), respectively. With 15% labeled data, our method reached an AUC of 0.81—demonstrating superior feature representation and classification accuracy even under severe data constraints.

CONCLUSION

We proposed a novel semi-supervised framework, SSCL-MTANN, that effectively addresses the small-labeled-data challenge in lung nodule classification in 3D CT. Integrating spatially-aware contrastive learning with patch-based modeling improves feature separation and classification in low-data regimes.

CLINICAL RELEVANCE/APPLICATION

SSCL-MTANN reduces the annotation burden by enabling high-performance AI training with as little as 5% labeled data, significantly reducing radiologists' manual labeling effort. By effectively leveraging unlabeled 3D CT scans, it provides accurate lung nodule classification, supporting radiologists in accurate lung cancer diagnosis and enhancing decision-making in resource-constrained clinical settings.

M5A-SPIN-12 PRECISION IMAGING OF SEX-SPECIFIC ADAPTATION IN GLUTEUS MAXIMUS MORPHOLOGY AND TYPE-2 DIABETES: A LARGE-SCALE MRI STUDY

Louise Thomas, PhD (*Presenter*)
Marjola Thanaj (*Abstract Co-Author*)
Brandon Whitcher, PhD (*Abstract Co-Author*)
Camilo Bell-Bradford (*Abstract Co-Author*)
Hamzah Raza (*Abstract Co-Author*)
Dimitri Amiras, MBBS, FRCR (*Abstract Co-Author*)
Marili Niglas (*Abstract Co-Author*)
Jimmy Bell (*Abstract Co-Author*)

PURPOSE

The gluteus maximus (GM) is one of the body's largest muscles, playing a key role in bipedal motion and metabolic health. MRI studies often focus on measuring its volume or fat infiltration. Statistical shape analysis characterises tissue morphology and localises shape variation via statistical parametric maps (SPMs), independent of volume. While widely used for internal organs, its application to skeletal muscle, especially the GM, remains limited. This study uses UK Biobank MRI data to examine how sex-specific GM morphology is related to body measures and type 2 diabetes (T2D).

METHODS AND MATERIALS

MRI scans were acquired using a Siemens Aera 1.5T scanner, with imaging protocols reported previously. GM was segmented from 61,290 UK Biobank Dixon MRI scans using a deep-learning pipeline trained on 158 manual annotations (Dice = 0.94), with quality visually validated at multiple stages by experienced analysts. Predictors of GM measures were identified using least absolute shrinkage and selection operator regression with stability selection across 86 variables (demographics, biomarkers, and diseases). Population-based templates were built for left/right GM in 300 men and 300 women, then registered to individual segmentations using affine and non-rigid registration to propagate standardised surface meshes (~15,000 vertices) with anatomical correspondence. Surface-to-surface (S2S) distance quantified shape variation as vertex-wise deviations from the template mesh, in millimeters, with positive values for outward expansion and negative for shrinkage. Mass univariate regression with correction for multiple testing identified variables associated with S2S variation.

RESULTS

GM shape exhibited outward S2S deformation in the anterior to posterior view with BMI, alcohol intake, physical activity, and grip strength, and an inward deformation with age, frailty, osteoporosis, and sedentary time ($P<0.05$). In men, T2D was associated with focal areas of inward S2S deformation (median S2S:-0.41mm for right and -0.39mm for left GM, $P<0.05$), suggesting atrophic changes. In contrast, women with T2D exhibited focal outward deformation (median S2S: 0.45mm for right and 0.49 mm for left GM, $P<0.05$), suggesting fatty hypertrophy.

CONCLUSION

This study highlights the value of automated MRI-based 3D phenotyping for musculoskeletal analysis, with SPMs revealing distinct, sex-specific GM morphological signatures associated with T2D, potentially reflecting divergent phenotypes of metabolic dysfunction

CLINICAL RELEVANCE/APPLICATION

Sex-specific GM shape changes in T2D may indicate early functional decline and metabolic compromise, reflecting local differences in response to insulin tolerance that require further investigation.

M5A-SPIN-13 TRIPLE-LOW CT PERFUSION PROTOCOL WITH DEEP LEARNING RECONSTRUCTION IN ACUTE ISCHEMIC STROKE: A DOSE REDUCTION STRATEGY MAINTAINING DIAGNOSTIC QUALITY

Haina Xu (*Presenter*)
Xin Qin (*Abstract Co-Author*)
Weiyuan Huang (*Abstract Co-Author*)
Feng Chen, MD, PhD (*Abstract Co-Author*)
Kun Ma (*Abstract Co-Author*)

PURPOSE

To assess the clinical viability of a triple-low CT perfusion (CTP) protocol, characterized by low radiation dose (80 kV, 80 mA), low contrast volume (40 mL), and low injection rate (4 mL/s), in combination with deep learning image reconstruction (DLIR-H), compared to a standard-dose protocol (80 kV, 120 mA, 50 mL, 5 mL/s) using iterative reconstruction (ASIR-V 50%).

METHODS AND MATERIALS

In this prospective, randomized study, 102 patients with suspected acute ischemic stroke (AIS) were assigned to either the standard or triple-low protocol (n=51 each). Four groups were analyzed: Group A (standard + DLIR-H), Group B (standard + ASIR-V 50%), Group C (triple-low + DLIR-H), and Group D (triple-low + ASIR-V 50%). CT attenuation (HU), noise (SD), signal-to-noise ratio (SNR), contrast-to-noise ratio (CNR), and perfusion parameters (CBF, CBV, MTT, TTP, Tmax) were evaluated in gray and white matter. Radiation dose and contrast parameters were recorded. Two blinded radiologists independently scored perfusion map quality using a 3-point scale (0-2), with interobserver agreement assessed using the Kappa statistic.

RESULTS

The triple-low protocol reduced CTDIvol, DLP, and effective dose by approximately 33%, and contrast volume and injection rate by 20% ($P<0.001$). Gray matter attenuation was consistent across all groups ($P>0.05$), with minor CT value differences (<2 HU) in white matter under identical reconstruction methods. DLIR-H achieved lower noise and higher SNR/CNR than ASIR-V under identical scanning protocols ($P<0.05$). Group C (triple-low + DLIR-H) exhibited SD and SNR comparable to Group B (standard + ASIR-V 50%) ($P>0.05$), but with superior CNR ($P=0.03$). Perfusion parameters (CBF, CBV, MTT, TTP) showed no significant differences between groups ($P>0.05$), while Tmax varied slightly in some regions (<0.5 s, $P<0.05$). Median subjective scores exceeded diagnostic thresholds in all groups, with strong interobserver agreement (Kappa = 0.649-0.708). No significant differences were observed in infarct core and penumbra volumes between DLIR-H and ASIR-V under standard-dose protocols ($P>0.05$).

CONCLUSION

The triple-low CTP protocol with DLIR-H significantly reduces radiation and contrast doses without compromising image quality or perfusion assessment, supporting its clinical application in AIS imaging.

CLINICAL RELEVANCE/APPLICATION

This approach enhances patient safety while maintaining diagnostic reliability, providing a promising alternative for acute stroke imaging, particularly in vulnerable populations.

M5A-SPIR-1 EVALUATING THE SAFETY OF SELECTIVE INTERNAL RADIATION THERAPY FOR PRIMARY AND SECONDARY LIVER MALIGNANCIES: A STUDY OF 4,432 PATIENTS

Thomas J. Vogl, MD, PhD (*Presenter*)
Andreea-Ioana Nica (*Abstract Co-Author*)
Leona Alizadeh, MD (*Abstract Co-Author*)
Christian Booz, MD (*Abstract Co-Author*)
Ibrahim Yel, MD (*Abstract Co-Author*)
Philipp Reschke (*Abstract Co-Author*)

PURPOSE

To evaluate the safety profile of Selective Internal Radiation Therapy (SIRT) in the treatment of primary and secondary liver malignancies, with a specific focus on the incidence and management of periprocedural complications.

METHODS AND MATERIALS

We conducted a retrospective analysis of data from the national quality assurance registry maintained by the German Society of Minimally Invasive Therapies and Interventional Radiology (DeGIR), covering the period from 2018 to 2023. The study aimed to identify adult patients (aged >18 years) who underwent SIRT for liver tumors. We evaluated the incidence, types, and management of complications, classifying them as either 'procedure-related complications' (PRCs), occurring during or within 24 hours of the intervention, or 'post-procedure complications' (PPCs), defined as those arising more than 24 hours after the procedure.

RESULTS

The study included 4432 patients, comprising 1563 females (35.3%) and 2869 males (64.7%), with a mean age of 67.42 ± 11.39 years. Most complications related to SIRT were classified as PRCs, with 36 cases (0.8%) reported. The most common cause was drug side effects (5 patients, 0.1%), followed by arterial bleeding in 3 cases (0.1%). The majority of PRCs (45.7%) fell under Category 2/B, indicating patients who require prolonged monitoring. One death (Category 6/F, 2.9%) occurred within 24 hours post-intervention. In 50% of cases (18), complications were managed by the procedure-performing radiologist, while 27.8% (10 cases) required treatment by other specialties. In 16.7% (6 cases), no treatment was needed, and in 5.6% (2 cases), the treatment status was not specified. PPCs occurred in only 4 patients (0.09%), resulting in a total of 40 patients (0.9%) experiencing periprocedural complications.

CONCLUSION

Our findings suggest that SIRT is a safe procedure for patients with liver tumors, as it demonstrates a low incidence of complications, with many being effectively managed within the same medical specialty.

CLINICAL RELEVANCE/APPLICATION

Our research findings indicate that most complications arise within the initial 24-hour period following the intervention. This underscores the necessity for vigilant patient monitoring during this time frame.

M5A-SPIR-2 CLINICAL OUTCOMES OF TIPS-PVR IN CIRRHOTIC PATIENTS WITH RECENT PORTAL VEIN THROMBOSIS: A SINGLE-CENTER STUDY

Zohaa Faiz, MD (*Presenter*)
Vijay Ramalingam, MD (*Abstract Co-Author*)
Mariam Dogar (*Abstract Co-Author*)
Jeffrey L. Weinstein, MD (*Abstract Co-Author*)
Ammar Sarwar, MD (*Abstract Co-Author*)
Muneeb Ahmed, MD (*Abstract Co-Author*)

PURPOSE

Portal vein thrombosis (PVT) is a significant complication in patients with cirrhosis and may lead to portal hypertension and increased risk of variceal bleeding. The American Association for the Study of Liver Diseases (AASLD) classifies PVT as recent (<6 months) or chronic (>6 months). While most studies have focused on chronic PVT and the role of portal vein recanalization-transjugular intrahepatic portosystemic shunt (PVR-TIPS) in transplant bridging, there is limited data on the safety and efficacy of PVR-TIPS in recent PVT. This study aims to evaluate the safety and effectiveness of PVR-TIPS in cirrhotic patients with recent PVT.

METHODS AND MATERIALS

We conducted a retrospective analysis of cirrhotic patients with recent PVT who underwent PVR-TIPS between 2000 and 2024 at a single academic institution. Patients were categorized by PVT etiology and thrombus extent according to AASLD criteria. Outcomes assessed included technical success, one-year patency of TIPS and PV, need for TIPS intervention, symptom recurrence, and mortality.

RESULTS

A total of 50 cirrhotic patients (55% male; mean age 58 ± 11 years) underwent PVR-TIPS for recent PVT during the study period. The most common etiologies of PVT were portal hypertension (50%), idiopathic causes (34%), and hypercoagulable states (6%). Technical success was achieved in all patients (100%). In terms of thrombus distribution, 76% had involvement of the main, right, or left portal veins (MPV, RPV, or LPV), 60% had superior mesenteric vein (SMV) involvement, and 22% had splenic vein involvement.50 % (25/50) presented with completely occlusive PVT. Of the 33 patients with one-year follow-up data, 94% (31/33) had maintained TIPS patency and 97% (32/33) had maintained portal vein patency. TIPS revision to maintain patency was required in 39% (13/33) of patients. At the one-year mark, 85% of patients had no evidence of vessel occlusion, and 60% were asymptomatic. The overall one-year mortality rate was 22%, with 11 of 50 patients dying within one year of the procedure. Ten patients received a liver transplant after TIPS-PVR with end -to-end anastomosis of the portal vein.

CONCLUSION

PVR-TIPS may be a safe and effective treatment for cirrhotic patients with recent PVT, offering high technical success rates and a viable option for restoring portal venous flow .

CLINICAL RELEVANCE/APPLICATION

This study addresses a critical gap in the literature, as no prior studies have systematically evaluated outcomes of PVR-TIPS in cirrhotic patients with recent portal vein thrombosis (PVT). Our findings show that PVR-TIPS is a safe and effective intervention highlighting its potential as a first-line treatment where evidence-based guidance is lacking.

M5A-SPIR-3 LONG-TERM OUTCOMES OF ENDOBILIARY RADIOFREQUENCY ABLATION PLUS STENTING IN MALIGNANT BILIARY OBSTRUCTION: A PATIENT-LEVEL META-ANALYSIS OF RANDOMIZED TRIALS

Parisa Kaviani, MD (*Presenter*)
Mohamed Sherif Ali Ahmed (*Abstract Co-Author*)
Hassan Magdy, MD (*Abstract Co-Author*)
Yara Ibrahim (*Abstract Co-Author*)
Mohamed Anwar (*Abstract Co-Author*)
Ahmed Elshaboury (*Abstract Co-Author*)
Abdulrahman Mohamed Ibrahim Mohamed Mohamed (*Abstract Co-Author*)
Sara Hosny El-Farargy (*Abstract Co-Author*)
Mohamed Elkasaby, MD (*Abstract Co-Author*)

PURPOSE

To assess the long-term efficacy and safety of RFA combined with stenting compared to stenting alone in patients with MBO using reconstructed individual patient data (IPD) from randomized controlled trials (RCTs).

METHODS AND MATERIALS

We searched Pubmed, Scopus, Web of Science, and Cochrane CENTRAL through March 15th, 2025 for RCTs comparing RFA plus stenting versus stenting alone in MBO. IPD were reconstructed from Kaplan-Meier curves using the tow-step approach. Time-to-event outcomes were analyzed using Cox proportional hazards models, with subgroup analyses by cancer and stent type. Restricted mean survival time (RMST) and landmark analyses were also performed. Pairwise meta-analysis was also performed.

RESULTS

Seven RCTs involving 640 patients were included. RFA significantly improved overall survival (OS) compared to stenting alone (HR = 0.75, 95% CI: 0.63-0.91; p = 0.002; RMST difference = 2.8 months). Subgroup analysis showed no OS benefit in cholangiocarcinoma (HR = 0.82; p = 0.14) or pancreatic cancer (HR = 1.07; p = 0.757). OS improvement was observed only with plastic stents (HR = 0.48; p < 0.001), not metal stents (HR = 0.69; p = 0.312). No overall difference was found in stent patency (HR = 1.05; p = 0.666), but landmark analysis revealed worse patency beyond 6 months with RFA (HR = 2.00; p = 0.008), particularly in metal stents (HR = 2.94; p = 0.018). The rate of adverse events was similar between groups (risk ratio = 1.13; p = 0.53).

CONCLUSION

RFA combined with stenting improves long-term OS in MBO, especially with plastic stents, but offers no overall benefit in stent patency and may increase the risk of late dysfunction in metal stents. The safety profile was comparable to stenting alone. These findings support the selective use of RFA, particularly in patients with favorable prognosis and plastic stent indication.

CLINICAL RELEVANCE/APPLICATION

This individual patient data meta-analysis offers robust evidence on the long-term impact of endobiliary RFA in managing malignant biliary obstruction.The findings support the selective integration of RFA into clinical practice for patients with favorable prognosis and plastic stent use, where a significant survival advantage was observed. In contrast, routine use in metal stent cases is not advised due to potential for late stent dysfunction.These results can guide oncologists, endoscopists, and interventional radiologists in optimizing palliative strategies for MBO, emphasizing the importance of individualized stent selection and careful risk-benefit assessment for RFA use.

M5A-SPIR-4 ADVERSE EVENTS FROM MICROWAVE ABLATION COMPARED TO CRYOABLATION IN PATIENTS WITH PRIMARY AND METASTATIC LUNG CANCER: A SYSTEMATIC REVIEW AND META-ANALYSIS

Milan Patel (*Presenter*)

PURPOSE

Image-guided Thermal Ablation (IGTA) technology is an effective treatment modality for advanced primary and metastatic lung cancer. Microwave Ablation (MWA), Cryoablation (CA), and Radiofrequency Ablation (RFA) are the primary methods used in modern medicine. However, there is limited data comparing their safety profiles. We aim to study the difference in incidence of adverse events (AEs) between MWA and CA in the treatment of primary and metastatic lung cancer.

METHODS AND MATERIALS

We searched PubMed for retrospective cohort studies reporting AEs associated with IGTAs. We conducted a meta-analysis of the common AEs encountered during ablation procedures. Odds Ratios were generated to quantify differences in AEs accounting for random effect models. Rate ratios were utilized to correlate technique differences with the incidence of AEs.

RESULTS

A total of 588 patients across 10 studies were included with 533 patients differentiated between males (50.8%) and females (49.2%) with a mean age of 63 (Range: 58-78). A total of 950 tumors were treated across 656 ablation sessions (42% MWA, 58% CA) with an average tumor diameter of 15.44mm (7.41-30.14mm). Tumors treated ranged from Stages 1-4 NSCLC and extra thoracic metastases. Our findings suggest there was no significant difference in rates of pneumothorax or hemothorax between MWA and CA (Pneumothorax OR: 1.45, CI [0.79-2.66]; Hemothorax OR: 1.41, CI [0.66-3.01]). There was a significant difference in probes used between MWA and CA (RR: 0.58, CI [0.38-0.90], p = 0.02). Primary Technical Success of treatment and Length of hospital stay were comparable between the MWA and CA groups.

CONCLUSION

Both MWA and CA are effective treatment modalities for primary and metastatic lung cancer. The treatment modality used correlates with quantity of probes used, with CA typically requiring more probes for treatment compared to MWA.

CLINICAL RELEVANCE/APPLICATION

These findings suggest there is no difference in rates of pneumothorax and hemothorax between MWA and CA, despite a significant difference in probe usage during intervention.

M5A-SPIR-5 PREOPERATIVE PREDICTION MODEL FOR HISTOPATHOLOGIC CONCORDANCE IN THYROID NODULES: DIAGNOSTIC PERFORMANCE OF FNAB CYTOLOGY COMBINED WITH CLINICAL PARAMETERS

Yujiang Liu (*Presenter*)
Ying Feng (*Abstract Co-Author*)

PURPOSE

To evaluate the concordance between fine-needle aspiration biopsy (FNAB) cytology using the Bethesda System for Reporting Thyroid Cytopathology (TBSRTC) and postoperative histopathology, and to develop a preoperative prediction model for histopathologic concordance.

METHODS AND MATERIALS

This retrospective study included 1071 consecutive patients (age =18 years) with thyroid nodules who underwent both FNAB and surgical resection at a single tertiary center between January 2019 and August 2020. Clinicopathologic variables were analyzed using ?2 tests. A multivariable logistic regression model incorporating key predictors was developed with 10-fold cross-validation in Python.

RESULTS

Overall concordance between FNAB and surgical pathology was 81.0% (867/1071), with sensitivity of 82.2%, specificity of 55.3%, and positive predictive value of 99.4%. Significant predictors of concordance included nodule location (P=0.042), size (P=0.004), TI-RADS subclassification (P=0.006), and TBSRTC category (VI vs V: 97.8% vs 100%). The prediction model demonstrated exceptional performance with an AUC of 0.976 (95% CI: 0.962-0.989), accuracy of 94.9%, sensitivity of 97.1%, and specificity of 87.6%. BRAF mutation status and patient age were identified as critical modulators of diagnostic alignment.

CONCLUSION

This study establishes a robust preoperative prediction model integrating clinical, cytopathologic, and molecular markers to assess histopathologic concordance in thyroid nodules. The high diagnostic accuracy (AUC >0.97) underscores its potential for personalized surgical decision-making, particularly for nodules =0.5 cm. Key innovation lies in quantifying modifiable discordance factors while validating TBSRTC VI/V categories as reliable predictors of malignancy.

CLINICAL RELEVANCE/APPLICATION

The high diagnostic accuracy (AUC >0.97) underscores its potential for personalized surgical decision-making, particularly for nodules =0.5 cm.

M5A-SPIR-6 INTRAPROCEDURAL SPECTRAL CT THERMOMETRY DURING MICROWAVE ABLATION

Nicole Varble, PhD (*Presenter*)
Laetitia Saccenti, MD (*Abstract Co-Author*)
Ivane Bakhutashvili (*Abstract Co-Author*)
Nathan Huber, PhD (*Abstract Co-Author*)
John W. Karanian, PhD (*Abstract Co-Author*)
Bradford J. Wood, MD (*Abstract Co-Author*)
William F. Pritchard JR, MD, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate the performance of dual-layer spectral CT for real-time, non-invasive measurement of tissue temperature during thermal ablation.

METHODS AND MATERIALS

Under a protocol approved by the Institutional Animal Care and Use Committee, healthy swine (n=3) underwent microwave ablation (MWA). Four thermocouples per subject were percutaneously inserted in the expected ablation zone under ultrasound guidance. A 5 min, 65 Watt MWA was performed (Neuwave). Sequential dual-layer spectral CT scans (IQon, Philips) were performed at 1-minute intervals during and after ablation (n=16 scans/subject). Pre- and post-ablation contrast-enhanced CTs were acquired. From spectral base images, virtual monoenergetic images (70 keV) were used to mask air and metal artifacts and to identify and segment ROIs at the thermocouple tips. Conventional CT, effective atomic number (Z-eff), and electron density (EDW) maps were analyzed and the ROIs results were compared to measured temperature using 1 st -4 th order polynomial curve fitting (MATLAB R2023a). Best fit was determined by root mean squared error (RMSE). Explanted ablation zones were sectioned transverse to the MWA probe track, formalin fixed, paraffin embedded, and 7um sections were hematoxylin and eosin stained and examined under light microscopy.

RESULTS

192 temperature measurements with corresponding spectral imaging results were analyzed. Thermocouples were located a mean 8.7±6.3mm from the MWA probe shaft with maximum temperatures of 46-99ºC. CTDI vol for the CT scans were 7.6-8.1 mGy. On post-MWA contrast-enhanced CTs, the mean ablation zone dimensions were 3.5±0.1cm x 2.4±0.7cm. Polynomial curve fitting found a weak linear correlation between temperature and conventional CT and Z-eff ($r=-0.433$, $p<0.001$, $r=0.550$, $p<0.001$, respectively). A strong negative linear correlation was found between temperature and EDW ($r=-0.797$, 95% CI [-0.844 -0.739], $p<0.001$, RMSE = 8.0ºC). Explanted ablation zones showed an ellipsoidal hemorrhagic ring surrounding areas of decreased cell integrity with central necrosis at the probe emitting point, matching non-perfused contrast-enhanced CT zones, and EDW measurements correlated to 60ºC.

CONCLUSION

In vivo monitoring of tissue temperature using dual-layer spectral CT imaging and EDW mapping during thermal ablation is feasible.

CLINICAL RELEVANCE/APPLICATION

Clinical translation of CT thermometry has been challenging, but may be feasible with spectral CT and may be integrated into existing ablation workflow. This offers opportunities to improve treatment monitoring during thermal ablation. While it does require the use of radiation, more judicious use of CT would be expected. Further work to determine the validity in human liver and tumors may be required.

M5A-SPIR-7 "XR MARKS THE SPOT" - TECHNICAL DEVELOPMENT AND INITIAL EVALUATION OF A MIXED REALITY SIMULATOR FOR ENDOVASCULAR TRAINING

Colin J. McCarthy, MD (*Presenter*)
Jeah Kim (*Abstract Co-Author*)
Andrea Cabochan (*Abstract Co-Author*)
Willy Ci (*Abstract Co-Author*)
Jason Morris (*Abstract Co-Author*)
Steven Patterson (*Abstract Co-Author*)
Yi Jenny Wang (*Abstract Co-Author*)
Jeffrey L. Weinstein, MD (*Abstract Co-Author*)

PURPOSE

To develop and test a novel endovascular simulator software application for a commercially available mixed-reality headset, and obtain preliminary feedback from interventional radiology attendings and trainees.

METHODS AND MATERIALS

An immersive mixed reality / spatial computing environment was created for VisionOS 2.4 on the Apple Vision Pro, deployed to the devices using TestFlight (Apple Inc, Cupertino, CA). A completely virtual angiosuite including procedure table, drapes, simulated patient, fluoroscopy screen and other equipment was digitally rendered. The environment is manipulated using custom gestures for fine-wire manipulation, including pinch/pull and pinch/roll, and the native finger and hand-tracking features of

VisionOS, together with hands-free voice commands to toggle the X-ray on and off. The tool includes gamified features such as checkpoint-based progression, real-time feedback through simulated angiographic views, and performance scores. A sample scenario (splenic embolization for trauma) was created and volunteers viewed a recorded simulation and completed a survey. In total, 13 interventional radiology trainees and 10 interventional radiology attendings were invited to participate.

RESULTS

The study was completed by 4 trainees and 5 attending radiologists. Prior to watching the recorded mixed reality simulation, 7 of the 9 respondents noted that they had previously used an endovascular simulator. The prior use of a virtual reality (VR) or augmented reality (AR) headset was 66.7% and 44.4%, respectively. There was a wide range of confidence recorded with regard to use of VR or AR headsets. 5 respondents reported they believed VR/AR could play a role in training, and 3 respondents recorded “maybe”. After watching the recorded simulation, 7 people responded “yes” and 2 responded “maybe” to the same question. Participants rated various aspects of the simulator. Of the 9 participants, 5 believed this technology could replace existing simulators, and 4 reported it may be complimentary to existing platforms.

CONCLUSION

Simulation is a key component of medical training, but can be limited based on access to proprietary simulation platforms. This application requires only a headset, with no additional materials. Preliminary feedback has been positive, and further development is ongoing.

CLINICAL RELEVANCE/APPLICATION

The advanced features available on modern mixed-reality headsets allow for immersive simulation experiences without additional specialized equipment or room space. Potential benefits over existing simulators include analysis of specific metrics related to motion efficiency and attention, using available hand and eye tracking capabilities.

M5A-SPMK-1 RECOMMENDATIONS FOR IMAGING ENDPOINTS IN CLINICAL TRIALS FOR NEUROFIBROMATOSIS TYPE 1-ASSOCIATED MALIGNANT PERIPHERAL NERVE SHEATH TUMORS: A SYSTEMATIC REVIEW

Mona Dabiri, MD (*Presenter*)
Shivani Ahlawat, MD (*Abstract Co-Author*)
Laura M. Fayad, MD (*Abstract Co-Author*)

PURPOSE

To generate evidence-based minimum recommendations for image acquisition, interpretation and quantitative endpoints for use in centralized or decentralized Neurofibromatosis type 1 (NF1)-related malignant peripheral nerve sheath tumors (MPNST) clinical trials.

METHODS AND MATERIALS

PubMed was searched (PRISMA) via Covidence. Original English-language MPNST articles with =10 patients were eligible; reviews, case reports and animal studies were excluded. Two reviewers extracted imaging and quality-assurance data. Of 346 records screened, 45 met inclusion; descriptive statistics summarized findings.

RESULTS

A total of 45 studies (n = 3729 patients) were included. Among these, 1030 patients had histologically confirmed MPNSTs: 557 (54%) were NF1-associated, 243 (24%) were sporadic, and 230 (22%) unclassified. Additional patients included 2400 with benign peripheral nerve sheath tumors (PNSTs) and 570 with plexiform neurofibromas (PNFs). MRI was used in all studies, with T1-, T2-, and STIR sequences reported in 34 (76%), 30 (67%), and 19 (42%) studies, respectively. Diffusion-weighted imaging (DWI) was used in 24 studies (53%), all of which reported ADC values; thresholds for malignancy ranged from 0.9 to 1.4 ×10?³ mm²/s. Only one study used ADC longitudinally to assess treatment response. Dynamic contrast-enhanced MRI (DCE-MRI) was used in 4 studies (9%), mostly with quantitative enhancement metrics. FDG-PET/CT was used in 20 studies (44.4%) with SUVmax cutoffs (3.5-6.1) and tumor-to-liver ratios (TLR) to distinguish MPNSTs from benign lesions. RECIST 1.1 was the most common response criterion (n = 18; 40%), followed by WHO and modified Choi criteria. Five studies (11%) used 3D volumetric analysis, exclusively in MPNSTs, primarily in interventional trials. Centralized image review was reported in only 3 studies (7%), and only 2 (4%) assessed inter-reader agreement. A single study (2%) described centralized data storage or image-sharing infrastructure.

CONCLUSION

There are the gaps of consistency in acquisition protocols, endpoint criteria, and quality assurance in current imaging methods for NF1-MPNST clinical trials. Our systematic review highlights the need for standardization through minimum imaging recommendations—especially in MRI and PET/CT acquisition parameters, ADC/SUVmax thresholds, and centralized image review—to enhance trial comparability and clinical utility.

CLINICAL RELEVANCE/APPLICATION

Standardized imaging will improve reliability and reproducibility of endpoints in NF1-MPNST trials.

M5A-SPMK-2 AI-BASED AUTOMATED DETECTION AND CHARACTERIZATION OF HIP FRACTURES AND BONE LESIONS ON PELVIC RADIOGRAPHS

Krishna Nand Keshava Murthy, PhD, MSc (*Presenter*)
Anirudha Shastri (*Abstract Co-Author*)
Abdallah A. Araji, MD (*Abstract Co-Author*)
Natalie Gangai (*Abstract Co-Author*)
Etay Ziv, MD,PhD (*Abstract Co-Author*)
Sinchun Hwang, MD (*Abstract Co-Author*)
Seth Margolin (*Abstract Co-Author*)

PURPOSE

Detection of bone lesions and fractures on radiograph of the pelvis is an arduous and time-consuming task due to subtle features and overlapping anatomies, but crucial in oncologic patients. Detection consistency varies with radiologist's experience levels. We trained an AI algorithm to spatially localize and classify lesions and fractures and evaluated its performance.

METHODS AND MATERIALS

Our retrospective data set consisted of 2617 images from unique patients (50.1% female; 49.9% male) at a tertiary cancer center, of which 817 were normal and the rest had bone lesions and/or fractures. The abnormalities were identified and annotated with bounding boxes by two board-certified radiologists (totally 3481 lesions and 387 fractures). The Faster RCNN AI model was trained using 70% of the data, validated on 15% for fine-tuning hyperparameters and tested on the remaining 15% held out set. Performance was evaluated using average precision across various intersection over union (IoU) thresholds of predicted abnormality bounding box overlap with ground truth (AP), Receiver Operating Characteristic (ROC) and Precision-Recall (PR) curves. An unpaired t-test was used to assess statistical significance in comparisons.

RESULTS

The overall AP of fracture and lesion detection were 16.73 and 6.29, respectively. The corresponding APs at IoU thresholds of 50 and 75 were 40 and 15.51, and 16.36 and 3.21, respectively. Fracture detection outperformed lesion detection across all metrics—AP, AP50, and AP75—with p-values of <0.001, <0.001, and <0.003, respectively. The area under ROC and PR were 80 and 40 for fracture detection and 70 and 16.4 for lesion detection, respectively.

CONCLUSION

AI algorithm was successful in automatically detecting fractures and lesions on pelvic radiographs, achieving higher performance on fractures compared to lesions.

CLINICAL RELEVANCE/APPLICATION

Automatic detection of pelvic lesions and fractures can help radiologists perform faster with better diagnostic consistency, standardizing interpretation and enhancing patient care.

M5A-SPMK-3 DIFFERENTIATION OF BENIGN AND MALIGNANT LESIONS USING CHEMICAL SHIFT IMAGING WITH THE DIXON METHOD IN VERTEBRAL MARROW LESIONS: ARE TRADITIONAL SIR CUTOFF VALUES USEFUL?

Hirotoshi Maruyama, RT (*Presenter*)

PURPOSE

The signal intensity ratio (SIR) cutoff values are obtained from opposed-phase and in-phase images in chemical shift imaging (CSI). These values are valuable for differentiating benign from malignant vertebral marrow lesions. The Dixon turbo spin echo (Dixon TSE) method has emerged as an alternative to the dual gradient echo (dual GRE) method for CSI. However, the imaging principles of Dixon TSE and dual GRE differ. Therefore, the SIR may differ. Most previous reports have focused on dual GRE, and few studies have reported on SIR cutoff values using Dixon TSE. This study aimed to evaluate the impact of SIR cutoff values from dual GRE in differentiating benign from malignant lesions using Dixon TSE and improve diagnostic accuracy by determining the SIR cutoff values for Dixon TSE.

METHODS AND MATERIALS

A phantom with varying fat fractions (FF) was scanned using dual GRE and Dixon TSE. The SIR was calculated, and the correlation between SIR and FF was analyzed. Lumbar spine MRI using Dixon TSE was performed in 40 patients with suspected vertebral marrow lesions and 29 healthy volunteers. Clinical and radiologic follow-up results were used as the gold standard to classify vertebral marrow lesions as benign or malignant. SIR cutoff values of Dixon TSE were determined using receiver operating characteristic (ROC) analysis. Furthermore, the sensitivity and specificity based on SIR cutoff values of dual GRE, as reported previously, were compared with those of Dixon TSE. Finally, cases with different diagnostic results are presented.

RESULTS

When FF was = 30%, the correlation coefficients between SIR and FF were -0.95 for Dixon TSE and -0.90 for dual GRE. The phantom study results suggest that SIR can effectively evaluate FF of lesions in both dual GRE and DIXON TSE. The SIR cutoff value for Dixon TSE was 0.612 (specificity = 0.930, sensitivity = 1.000). In contrast, the SIR cutoff value for dual GRE, as reported by Zidan et al., was 0.91. In this study's ROC analysis, the specificity and sensitivity most similar to this cutoff value were 1.000 and 0.571, respectively. In Dixon images, when the cutoff value for dual GRE is used, the sensitivity for detecting lesions may decrease. In clinical practice, differentiation between benign and malignant lesions varied between SIR cutoff values for dual GRE and Dixon TSE.

CONCLUSION

The SIR cutoff value for Dixon TSE was 0.612. Using the SIR cutoff value for each CSI method improves the sensitivity of differentiating benign and malignant vertebral marrow lesions.

CLINICAL RELEVANCE/APPLICATION

The cutoff values for the SIR in CSI are valuable for differentiating benign from malignant vertebral marrow lesions. However, to improve the sensitivity of lesion detection, an appropriate cutoff value should be determined according to the CSI method.

M5A-SPMK-4 SACROCOCCYGEAL BENIGN NOTOCHORDAL CELL TUMORS: THEIR PREVALENCE IN MR SACRUM AND STABILITY OVER TIME

Josip Nincevic, MD (*Presenter*)
Onur Yildirim (*Abstract Co-Author*)
Muhammad Atif Naveed, MD (*Abstract Co-Author*)
Junting Zheng (*Abstract Co-Author*)
Marinela Capanu (*Abstract Co-Author*)
Natalie Gangai (*Abstract Co-Author*)
Meera Hameed, MD (*Abstract Co-Author*)
Sinchun Hwang, MD (*Abstract Co-Author*)

PURPOSE

To determine the prevalence and morphological change of benign notochordal cell tumors (BNCT) and their stability at imaging follow-ups.

METHODS AND MATERIALS

This retrospective study included MR sacrum studies performed between 2012 and 2016 in a tertiary cancer center. Each study was reviewed for presence of BNCT, defined as midline T2 hyperintense and T1 iso/hypointense lesions larger than 0.2 cm. The lesion location, number of lesions, contrast enhancement, and atypical features (cortical involvement) were assessed. Follow-up studies (MRI, CT, PET) were assessed for growth and morphological changes. Patient demographic and histologic data were collected. Fisher’s exact test was used to examine associations between synchronous BNCT and pathological chordoma.

RESULTS

In 1469 MR sacrum studies performed on 1006 patients (average age 50 years; 54% male, 46% female), the prevalence of BNCT was 7.8% (78/1006patients). BNCT were typically small (median 0.8 cm, interquartile range: 0.6-1.0) and most frequently found in Co1 (38%) and S5 (32%). Atypical features included cortical scalloping or destruction (9/78, 11.5%), extraosseous extension (5/78, 6.4%), and contrast enhancement (3/75, 4%). The presence of multiple synchronous BNCT (18.1%,14/78) was significantly associated with chordoma (29%, 4/14 vs 6.3%, 4/64 patients with synchronous and single BNCT, respectively, p=0.031). Follow-up imaging, available for 74.3% of patients (58/78) with a median duration of 3.9 years (interquartile range: 2.0-8.7), demonstrated stability in 57/58 (98.3%) patients. Only 1 (1.7%) lesion showed growth from 1.1 cm to 2.1 cm over 3.6 years.

CONCLUSION

BNCTs have low prevalence in MRI sacrum and the majority are small with infrequent growth over a median of four years. They most commonly occur in sacrococcygeal junction and exhibit a potential association with the presence of multiple synchronous lesions and the occurrence of chordoma in a subset of patients.

CLINICAL RELEVANCE/APPLICATION

Sacrococcygeal BNCTs are relatively uncommon on MRI and generally remain small and stable, suggesting that routine aggressive intervention and frequent imaging follow-up are unnecessary. Recognizing their typical imaging features, while being mindful of atypical presentations and the observed association with chordoma, is crucial for accurate radiological interpretation and appropriate clinical management.

M5A-SPMK-5 IMPROVED METAL ARTIFACT REDUCTION FOR 3D-PRINTED CERVICAL VERTEBRAL IMPLANTS USING TIN-FILTERED DUAL-SOURCE CT

Ruixin Yan (*Presenter*)
Ning Lang, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the effectiveness of tin-filtered dual-source CT (Sn150-kVp DSCT), with and without iterative metal artifact reduction (iMAR), in improving postoperative image quality of three-dimensional (3D)-printed artificial vertebral bodies (AVBs) in the cervical spine, compared with conventional 120-kVp single-energy CT (SECT).

METHODS AND MATERIALS

This retrospective study included 30 patients who underwent anterior cervical discectomy and fusion using 3D-printed AVBs. Each patient had paired postoperative SECT and Sn150-kVp DSCT scans. Subjective image quality (artifact severity, soft tissue clarity, bone delineation, and AVB visibility) was scored independently by four blinded readers using a 4-point Likert scale. Fleiss' Kappa assessed inter-reader agreement. Objective metrics included contrast-to-noise ratio normalized to dose (CNRD), signal-to-noise ratio normalized to dose (SNRD), figure of merit (FOM), and paravertebral muscle noise. Radiation doses (CTDIvol, DLP) were extracted from PACS. Wilcoxon signed-rank tests were used for statistical comparisons between SECT, Sn-DSCT, and Sn+iMAR-DSCT protocols.

RESULTS

Both Sn-DSCT and Sn+iMAR protocols significantly outperformed SECT in all subjective metrics ($p < 0.001$). Artifact scores improved from 3.70 (SECT) to 1.95 (Sn) and 1.92 (Sn+iMAR). SNRD was higher in tin-filtered protocols (Sn: 3.10 ± 1.97; Sn+iMAR: 2.78 ± 1.20) than SECT (2.42 ± 1.26; $p < 0.05$), while CNRD showed no significant difference. FOM and noise were substantially lower in Sn-based protocols compared to SECT (FOM: 7.06 vs. 54.4; Noise: 8.55 vs. 20.81; $p < 0.001$). iMAR did not provide statistically significant improvement over Sn alone. Radiation dose was comparable across protocols. Inter-reader agreement was highest in the Sn+iMAR group (? > 0.86).

CONCLUSION

Tin-filtered DSCT substantially improves visualization of 3D-printed AVBs by reducing metal artifacts and noise, without increasing radiation exposure. The additive benefit of iMAR appears limited in porous titanium cages due to already reduced artifact burden from Sn filtration.

CLINICAL RELEVANCE/APPLICATION

This study supports the use of Sn150-kVp DSCT as a superior imaging strategy for evaluating cervical 3D-printed implants, enhancing diagnostic confidence in postoperative settings. These findings may guide standardized imaging protocols for follow-up assessment of osseointegration and implant positioning in spinal reconstruction

M5A-SPMK-6 DIAGNOSTIC VALUE OF 3.0T MAGNETIC RESONANCE DIFFUSION-WEIGHTED IMAGING (DWI) IN BRUCELLAR SPONDYLITIS: IMAGING FEATURE ANALYSIS AND SUBJECTIVE SCORING BY RADIOLOGISTS BASED ON 50 CLINICAL CASES

Chunlong Yan (*Presenter*)
Zerun Wang (*Abstract Co-Author*)

PURPOSE

To explore the diagnostic value of 3.0T magnetic resonance diffusion-weighted imaging (DWI, b=800 s/mm²) in acute-stage Brucellar Spondylitis (BS) and validate its clinical efficacy using radiologists' subjective scores.

METHODS AND MATERIALS

Retrospectively analyzed MRI data from 50 serologically confirmed BS patients (18 acute-stage, 32 chronic-stage) scanned with a GE 3.0T MRI system. Imaging protocols included conventional sequences (sagittal T2WI, sagittal T2WI with fat suppression FS, sagittal T1 FSE, axial T2WI) and axial DWI (b=800 s/mm²). Two senior radiologists independently evaluated the detection capability of each sequence for acute-stage lesions and assigned subjective diagnostic confidence scores using a 5-point Likert scale.

RESULTS

The sensitivity of DWI for acute-stage BS (94.4%) was significantly higher than conventional sequences (T2WI 72.2%, T2WI+FS 68.8%, T1WI 61.1%). Subjective scores indicated the highest diagnostic confidence for DWI (4.8±0.4 vs. T2WI+FS 3.7±0.6 vs. T2WI 3.9±0.6, $p<0.01$). Combining DWI with conventional sequences improved accuracy to 96%. ADC values effectively differentiated active infection (acute: 0.72±0.15 vs. chronic: 1.18±0.21×10?³ mm²/s, $p<0.001$).

CONCLUSION

3.0T DWI is pivotal for diagnosing acute-stage BS. Quantitative ADC values combined with radiologists' subjective scores optimize clinical decision-making, demonstrating significant clinical value through its high sensitivity and enhanced diagnostic confidence.

CLINICAL RELEVANCE/APPLICATION

In this study, with a b-value of 800 s/mm² combined with a slice thickness of 4 mm and a matrix of 512×512, the partial volume effect was reduced, the signal-to-noise ratio and resolution were balanced, and tiny abscesses (less than 5 mm) could be clearly visualized.

M5A-SPMK-7 CONSTRUCTION OF A MACHINE LEARNING MODEL FOR DETECTING OCCULT RIB FRACTURES: EVALUATION OF DUAL-ENERGY CT

Sipin Luo (*Presenter*)

PURPOSE

This study aims to analyze the radiomics features of occult rib fractures using dual-energy CT (DECT) and develop an artificial intelligence model to assist diagnosis.

METHODS AND MATERIALS

Rib DECT data from patients (January to October, 2023) were reconstructed into 120kvplike and Water (HAP) images. Occult fractures and normal ribs were labeled 1:1 based on follow-up results. Radiomics features were extracted and screened using Pearson correlation coefficient, SelectKBest, and LASSO. Seven machine learning models (logistic regression, support vector machine, decision tree, adaptive augmentation, perceptron, random forest, and K-nearest neighbors) were developed. The data were divided into training/validation sets (7:3) and a test set (November-December 2023). Five-fold cross-validation was performed, and AUC was compared using the Delong test.

RESULTS

This study included 153 occult rib fractures and corresponding normal ribs for training/validation, and 59 occult fractures for testing.A total of 1,781 features were extracted, with 14 from 120kvplike and 21 from Water (HAP) images selected for model development. The perceptron model performed well on 120kvplike images (AUC:0.93, sensitivity:0.83, specificity:0.89, accuracy:0.86), while the logistic regression model excelled on Water (HAP) images (AUC: 0.91, sensitivity:0.76, specificity:0.86, accuracy:0.81). The Delong test showed no significant difference in AUC between models ($p>0.05$), but the Water (HAP)-based model was more stable.

CONCLUSION

The perceptron model performs well on conventional CT but has average stability, while the logistic regression model on DECT MD images offers better diagnostic performance and stability. A DECT-based diagnostic model holds significant clinical potential.

CLINICAL RELEVANCE/APPLICATION

This study compared the performance of machine learning models in detecting occult rib fractures between conventional CT and dual-energy CT (DECT) multi-material decomposition (MD) images. The results demonstrated that the DECT MD-based model achieved superior diagnostic efficacy in the test set with enhanced model stability, providing valuable insights for future development and validation of AI-assisted diagnostic systems.

M5A-SPNMMI-1 UTILIZATION OF MODEL-BASED EFFECTIVE HALF-LIFE AND SINGLE-TIMEPOINT IMAGING FOR PERSONALIZED KIDNEY DOSIMETRY

Mercy Akerele, PhD (*Presenter*)
Richard Laforest, PhD (*Abstract Co-Author*)
Justin Mikell, PHD (*Abstract Co-Author*)
Vikas Prasad, MD, PhD (*Abstract Co-Author*)

PURPOSE

Accurate dosimetry in radiopharmaceutical therapy (RPT) requires multi-timepoint imaging, which is difficult to implement given clinical logistics and patient convenience. Alternative single timepoint techniques have been proposed but are limited given they assume a specific clearance and imaging timepoint, whereas clearance exhibit intra- and inter-patient variance. This study evaluates the feasibility of single-timepoint dosimetry for the kidneys using personalized effective half-life (P-T eff) based on patient weight and kidney volume

METHODS AND MATERIALS

Ten 177 Lu-based therapy patients (4 NET, 6 PCa) with multi-timepoint post-therapy SPECT/CT imaging (4-, 24-, or 48 - 96 h) were included. The kidneys were auto segmented with MOOSE AI and time activity data was extracted via MIM. Correlation between the actual T eff was modelled from the multi-timepoint data and several factors (patient weight, kidney volume, creatinine, eGFR, and imaging timepoint). P-T eff was then generated using leave-one-out method for each patient from the remaining 9 patients. Time integrated activity was calculated by voxel-wise trapezoidal numerical integration of the SPECT/CT timepoints plus analytical integration of exponential fit to last two timepoints out to infinity. The absorbed dose was calculated using the Monte Carlo calculation as implemented in Hermes software (Ground-truth). Single-time-point dosimetry was then calculated with the Hanscheid, Madsen and the P-T eff methods using the latest timepoint imaging data (48 - 96 h)

RESULTS

The best models to estimate the patient-specific T eff were found using two combinations of kidney volume (ml), patient weight (kg) and imaging timepoint (s), with correlation coefficient R = 0.71/0.72. Using eGFR and creatine gave R = 0.63 and R = 0.66 respectively. Model 1 is [kidney volume (ml) /(patient weight (kg) * e time (s))], while model 2 is [kidney volume (ml) /(patient weight (kg) * time (s)]. For all ten patients, the average actual T eff is 69.69±37.00 h, while models 1 and 2 gave 68.69±26.38 h and 69.07±25.89 h respectively. Compared with the multi-timepoint dosimetry results, the %error in kidney dose was -15.48±13.34% and -10.21±13.91% for Hanscheid and Madsen methods respectively, while the T eff models 1 and 2 gave %errors of 0.38±16.14% and -0.13±16.13% respectively

CONCLUSION

This study suggests that using personalized effective half-life and single-timepoint imaging could be a suitable alternative for multi-timepoint kidney dosimetry. More data is still needed to consolidate these findings

CLINICAL RELEVANCE/APPLICATION

Implementing individualized patients' dosimetry enables clinical integration for achieving personalized RPT thereby enhancing treatment responses and minimizing toxicity

M5A-SPNMMI-2 DIAGNOSTIC POTENTIAL OF APPARENT DIFFUSION COEFFICIENT-BASED LYMPH NODE CLASSIFICATION IN BREAST CANCER PATIENTS UNDERGOING ^{18}F-FDG PET/MRI

Helena A. Peters, MD (*Presenter*)
Daniel Weiss (*Abstract Co-Author*)
Matthias Boschheidgen (*Abstract Co-Author*)
Vivien Lorena Ivan, MD (*Abstract Co-Author*)
Marie Scheuer (*Abstract Co-Author*)
Julian Kirchner (*Abstract Co-Author*)
Aleksandar Milosevic, MD (*Abstract Co-Author*)
Peter Minko, MD (*Abstract Co-Author*)
Lale Umutlu, MD (*Abstract Co-Author*)
Gerald Antoch, MD (*Abstract Co-Author*)
Kai Jannusch (*Abstract Co-Author*)

PURPOSE

To evaluate the diagnostic potential of apparent diffusion coefficient (ADC) values for classifying lymph nodes as benign or malignant in breast cancer patients undergoing 18 F-FDG PET/MRI staging.

METHODS AND MATERIALS

Mean ADC values and short axis diameters (± standard deviation) of 199 thoracic lymph nodes in 113 newly diagnosed breast cancer patients were analyzed retrospectively. All patients underwent 18 F-FDG PET/MRI staging performed between July 2017 and June 2021. A node-by-node comparison was performed with respect to pathological node status. Nodal FDG-uptake in whole body 18 F-FDG PET/MRI serves as the reference standard for nodal malignancy. Group comparison using Mann-Whitney U test, receiver-operating characteristic curve (ROC) analysis and diagnostic performance was calculated. Using P values below 0.05 were defined as statistically significant. Confidence intervals (CI; 95%) were calculated.

RESULTS

Ninety-three lymph nodes were FDG-negative while 106 lymph nodes were FDG-positive. Benign lymph nodes had significantly lower short-axis diameters ((5.3 ± 1.5 mm versus 12.7 ± 8.6 mm); $p < 0.01$; U: 531; Z: -10.83). ADC values were significantly lower in FDG-positive lymph nodes (0.72 ± 0.16 x 10 -3 mm 2 /s) than in FDG-negative lymph nodes ((1.18 ± 0.18 x 10 -3 mm 2 /s); $p < 0.01$; U: 146.00; Z: -11.80). ROC analysis and Youden's index revealed an ADC cut-off of 0.95 x 10 -3 mm 2 /s (AUC: 0.98; $p < 0.01$; CI: 0.96 -1.01). According to the calculated cut-off, sensitivity, specificity, and accuray of ADC values for differentiating benign from malignant lymph nodes were 98%, 97% and 97%, respectively.

CONCLUSION

ADC values can differentiate benign from malignant lymph nodes in breast cancer patients and correlate significantly with metabolic data from 18 F-FDG PET/MRI. A defined ADC cut-off may support reliable identification of malignant nodes.

CLINICAL RELEVANCE/APPLICATION

Apparent diffusion coefficient (ADC) values obtained from diffusion-weighted MRI offer a reliable, non-invasive tool for lymph node evaluation during the staging of newly diagnosed breast cancer patients. Our defined ADC cut-off value may serve as a valuable tool to support objective, image-guided clinical decision-making.

M5A-SPNPM-1 RADTRANSLATE 2.0: AN AI-BASED APPROACH TO SIMPLIFY AND TRANSLATE EMERGENCY RADIOLOGY REPORTS FOR PATIENTS WITH LIMITED ENGLISH PROFICIENCY

Praneet Khanna, BA (*Presenter*)
Joel K. Samuel, MD,MBBS (*Abstract Co-Author*)
Aneesh Mazumder (*Abstract Co-Author*)
Arya Rao (*Abstract Co-Author*)
Michael Hood, MD (*Abstract Co-Author*)
Marc D. Succi, MD (*Abstract Co-Author*)

PURPOSE

Radiology reports are integral for summarizing diagnostic imaging findings, but contain complex medical concepts that exceed the average American's reading ability. Millions in the U.S. have limited English proficiency (LEP) and face barriers in understanding written medical information, often leading to lower satisfaction and poorer health outcomes. Yet, diagnostic reports are rarely translated, and hospitals frequently lack the resources and time to provide written summaries in the patients' preferred languages. Large language models (LLMs), such as GPT-o1, may be used to improve patient health literacy. Additionally, Google Translate is widely used in healthcare, but its accuracy can vary greatly by language and context. This study evaluates a two-step application of GPT-o1: (1) simplifying emergency radiology reports into patient-friendly language, and (2) translating those simplified reports into Arabic, Mandarin, and Spanish using GPT and the Google Translate API. The findings of this study will outline the use of LLMs to support multilingual, health-literate communication in radiology. They may contribute to the future clinical adoption of LLMs to promote health equity for linguistically diverse patient populations.

METHODS AND MATERIALS

30 de-identified computed tomography (CT) reports of patients undergoing imaging in the emergency room that reflected various common conditions were selected. The entire report was then simplified using GPT-o1 with a standardized prompt. The reports were then translated into Spanish, Mandarin, and Arabic using GPT and Google Translate. For the simplified outputs, three board-certified emergency radiologists assessed each report using a 5-point Likert scale for accuracy and comprehensibility. Professional medical interpreters graded the translated outputs on a similar 5-point Likert scale. Descriptive statistics analyzed ratings and comparisons.

RESULTS

Radiologist validation of the simplified reports showed high average accuracy and comprehensibility of scores. 100% of the reports were rated as useful for patient understanding.The translated outputs varied for translational accuracy based on the model, with GPT dominating in translational accuracy and patient comprehensibility. Interpreters across all three languages universally preferred translations from GPT-o1.

CONCLUSION

GPT consistently demonstrated strong performance in summarizing and translating radiology reports into patient-friendly language. GPT also outperformed Google Translate in multilingual outputs across Arabic, Spanish, and Mandarin translations.

CLINICAL RELEVANCE/APPLICATION

LLMs' use to simplify and translate radiology reports may improve healthcare equity and literacy for LEP patients.

M5A-SPNPM-2 ASSESSING BARRIERS AND CAPACITY FOR EXPANSION OF DIAGNOSTIC RADIOLOGY RESIDENCY PROGRAMS IN THE U.S

Himi Begum (*Presenter*)
Hannah Short (*Abstract Co-Author*)
Sarapettey Sandifer (*Abstract Co-Author*)
Michael A. Bruno, MD, MS (*Abstract Co-Author*)

PURPOSE

The increasing demand and utilization of diagnostic imaging have outpaced the current radiologist workforce, contributing to national shortages. Despite ongoing efforts to expand training capacity, ACGME-imposed complement caps and program-specific constraints may limit sustainable growth. This study aims to evaluate the perceived capacity for complement expansion among ACGME-accredited diagnostic radiology residency programs and to identify barriers to increasing resident complement.

METHODS AND MATERIALS

A Qualtrics survey was distributed to program directors and assistant program directors at 197 ACGME-accredited diagnostic radiology residency programs. The survey collected data on current residency size, perceived capacity for additional residents, history of requests for complement increases within the past five years, ACGME decisions, and reported barriers. Responses were analyzed using descriptive statistics.

RESULTS

A total of 47 programs responded (23.9% response rate). The average program size was 8.5 residents per year (SD = 3.7). Of 46 valid responses, 39 programs (84.8%) reported capacity to expand, with a mean potential increase of 2.8 residents annually (SD = 2.1). Among the 13 programs (27.7%) that requested a complement increase within the past five years, 11 were approved (84.6%) and two were denied, citing faculty/resource limitations and funding barriers. Among programs that had not submitted a request, common reasons included faculty constraints, administrative burden, or unclear benefit. Notably, insufficient patient volume or imaging studies were not major limiting factors.

CONCLUSION

Most responding programs report the capacity to train additional residents, and ACGME data show strong support for expansion requests when institutional resources are sufficient. However, non-clinical barriers, such as funding and administrative support, limit programs from pursuing and achieving complement increases.

CLINICAL RELEVANCE/APPLICATION

As the demand for radiologists continues to rise, augmenting the complement size of existing training programs represents a viable strategy to address ongoing workforce shortages. This study highlights the potential for growth across U.S. diagnostic radiology residencies and the need for systemic support to advance residency program expansion efforts.

M5A-SPNPM-3 DOES AI ADD ECONOMIC VALUE TO RADIOLOGY? - A SYSTEMATIC REVIEW

Isabel Molwitz, MD, MBA (*Presenter*)
Inka Ristow, MD (*Abstract Co-Author*)
Jennifer Erley, MD (*Abstract Co-Author*)
Tugba Akinci D'Antonoli, MD (*Abstract Co-Author*)
Ali S. Tejani, MD (*Abstract Co-Author*)
Michail Klontzas, MD, PhD (*Abstract Co-Author*)
Merel Huisman, MD, PhD (*Abstract Co-Author*)
Gerhard B. Adam, MD (*Abstract Co-Author*)
Lisa C. Adams, MD, PhD (*Abstract Co-Author*)

PURPOSE

To summarize the evidence of AI’s economic value across the radiological workflow.

METHODS AND MATERIALS

A comprehensive search of PubMed, Business Source Ultimate, and EconLit was conducted for original research articles published between January 2010 and November 2024. Medical Subject Headings and keywords included “artificial intelligence/machine learning/deep learning/natural language processing,” “radiology,” and “economic value/cost/budget/revenue/efficiency”. Studies were selected based on explicit quantification of economic outcomes, excluding those with only soft outcome criteria like time savings without cost quantification. Study quality was assessed using CHEQUE criteria.

RESULTS

From the initial 1,879 search results, 21 studies (1.1%) met the inclusion criteria. The majority evaluated machine learning tools (10/21[47.6%], nine on deep learning), followed by computer-assisted diagnostics (CAD; 7/21[33.3%]), natural language processing (NLP; 2/21[9.5%]), and hypothetical AI models (2/21[9.5%]). AI demonstrated economic value, as quantified through cost savings or incremental cost-effectiveness ratios, in resource-intensive tasks, when accuracy matched human performance and costs were fixed. For instance, AI-based lung cancer screening achieved incremental cost savings of up to USD 242 per patient. AI increased costs when specificity was below humans’ or when using pay-per-use models; as observed with CAD systems raising mammography screening costs by up to USD 19 per patient. In fast tasks such as X-ray evaluations, AI showed value in settings with radiologist shortages. AI reduced costs through protocol optimization and increased revenue via improved follow-up compliance.

CONCLUSION

AI’s value in radiology is context-dependent, varying with task complexity, examination volume, and implementation model. Further high-quality economic evaluations of AI tools are essential.

CLINICAL RELEVANCE/APPLICATION

AI holds significant potential to enhance economic value in radiology, yet its financial benefits are highly context-dependent, influenced by factors such as task complexity, sensitivity and specificity of the AI, payment models, and societal or provider willingness-to-pay thresholds for quality-adjusted life year gains.

M5A-SPNR-1 ALTERED INDIVIDUAL-LEVEL BRAIN MORPHOLOGICAL SIMILARITY NETWORKS IN CHILDREN WITH DUCHENNE MUSCULAR DYSTROPHY: LINKING NEUROIMAGING BIOMARKERS TO COGNITIVE IMPAIRMENT

Xiaoyu Niu (*Presenter*)
Huayan Xu (*Abstract Co-Author*)
Yingkun Guo (*Abstract Co-Author*)
Suming Zhang (*Abstract Co-Author*)

PURPOSE

This study aimed to assess alterations in individual-level morphometric similarity networks (MSNs) in children with Duchenne muscular dystrophy (DMD) and their association with cognitive dysfunction, identifying neuroimaging biomarkers linked to cognitive impairment.

METHODS AND MATERIALS

We included 111 DMD children and 80 age-/sex-matched healthy controls (HC). High-resolution 3D T1-weighted structural MRI was acquired for all participants. Cognitive function was assessed in DMD children using the Wechsler Intelligence Scale for Children-Fourth Edition (WISC-IV). Individual morphological networks were constructed by measuring interregional similarity in gray matter volume distributions. Graph theory analysis evaluated global and nodal topological properties. Network-Based Statistic (NBS) identified between-group differences in network connectivity. Pearson correlation analysis was further performed to identify associations between cognitive scores and neural abnormalities.

RESULTS

Both DMD and HC groups exhibited small-world architecture (gamma >1, lambda ˜1). Compared to HC, DMD children showed significant differences in nodal topological properties: increased degree centrality (DC) in bilateral hippocampus and left cerebellar lobule 3, and decreased DC in right cerebellar lobule 7b ($p < 0.05$, FDR-corrected). NBS revealed a hypoconnected subnetwork in DMD (28 nodes, 53 edges), predominantly involving cerebellar-frontotemporal-subcortical circuit, spanning sensorimotor, default mode, and frontoparietal networks. The area under the curve of DC in left cerebellar lobule 3 negatively correlated with full-scale intelligence quotient (FSIQ) and perceptual reasoning index (PRI) scores in DMD.

CONCLUSION

Our study reveals that DMD children retain global network properties but have significant changes in nodal properties of the cerebellum and hippocampus, suggesting these areas may act as critical pathophysiological hubs. Furthermore, disrupted morphological network organization—characterized by hypoconnectivity in cerebellar-frontotemporal-subcortical circuit—likely underpins cognitive impairment. Individualized MSN topological properties may serve as potential neuroimaging biomarkers to advance clinical diagnosis and therapeutic strategies for DMD.

CLINICAL RELEVANCE/APPLICATION

This study identifies distinct morphological network disturbances in DMD, providing imaging biomarkers for early detection of cognitive risk. Findings emphasize the cerebellum's role in DMD-related neurocognitive impairment, guiding future interventions targeting cerebellar-frontotemporal-subcortical circuit plasticity to mitigate cognitive decline.

M5A-SPNR-2 STA-MCA BYPASS SURGERY INDUCED DIFFERENT PERFUSION REDISTRIBUTION PATTERNS IN THE MIDDLE CEREBRAL ARTERY TERRITORY BETWEEN MOYAMOYA ANDCEREBROVASCULAR STENO-OCCLUSIVEPATIENTS: A STUDY BY DSC-PWI

Haotian Chen (*Presenter*)
Zijun Li (*Abstract Co-Author*)
Yuting Wang (*Abstract Co-Author*)

PURPOSE

The Superficial Temporal Artery-Middle Cerebral Artery (STA-MCA) bypass surgery has become an effective treatment for Moyamoya Disease (MMD) but remains contentious for cerebrovascular atherosclerotic stenosis-occlusion (grouped as N-MMD), partly due to the unclear hemodynamic alteration postoperatively. This study aims to compare the perfusion changes after STA-MCA bypass in N-MMD and MMD patients.

METHODS AND MATERIALS

A total of 64 consecutive patients who underwent STA-MCA bypass for either MMD or N-MMD were prospectively included. All patients received preoperative (time point 1, TP1) and postoperative (1-2 weeks, TP2) DSC-PWI MRI. A subset of patients (n=30) reached a long-term follow-up timepoint (6-9 months postoperatively, TP3) and underwent a third DSC-PWI. Normalized CBF (nCBF, calculated as the ratio of mean CBF values of MCA territory to mean CBF values of the cerebellum) related indices were manually calculated, including central nCBF (caudate and lenticular nucleus), MCA territory cortical nCBF, mean nCBF and hemodynamic stress distribution (hdSD, the ratio of central nCBF to cortical nCBF). ANOVA was used to compare the perfusion indices among the groups.

RESULTS

Of the 64 included cases, 32 (50%) were N-MMD cases. The mean age was 52 years and 37 patients (58%) were male. A significant increase of central nCBF ($P=0.02$), cortical nCBF ($P<0.001$) and mean nCBF ($P<0.001$) were observed postoperative in N-MMD patients, indicating an overall increase of perfusion in the MCA territory, while the hdSD showed no significant change. For MMD patients, a significant increase of cortical nCBF ($P=0.004$), mean CBF ($P=0.01$) and decrease of hdSD ($P=0.009$) were observed, indicating redistribution of CBF towards the cortical portion. There was a significant effect of time on perfusion redistribution during long-term follow-up, indicating a sustained hemodynamic remodeling in both MMD and non-MMD patients.

CONCLUSION

There was a significant redistribution of cerebral perfusion towards the cortical portion in MMD patients following surgery. Whereas N-MMD patients hemodynamically benefited from surgery by the increase of both central and cortical perfusion. This indicates STA-MCA bypass induced different patterns of perfusion alteration for the two groups. The long-term clinical outcomes related to these alterations remain to be substantiated through extended longitudinal studies.

CLINICAL RELEVANCE/APPLICATION

Our findings suggest STA-MCA bypass may benefit a broader population of intracranial stenosis/occlusion, but through different patterns of perfusion alteration for MMD and N-MMD patients as revealed by DSC-PWI. This could be further explored for stroke prognosis stratification through extended longitudinal studies.

M5A-SPNR-3 UNFAVORABLE PERFUSION COLLATERAL SCORE IS ASSOCIATED WITH HIGHER ODDS OF POOR OUTCOMES IN LARGE VESSEL OCCLUSION STROKE

Hamza A. Salim, MD (*Presenter*)
Dhairya Lakhani, MD (*Abstract Co-Author*)
Manisha Koneru (*Abstract Co-Author*)
Licia P. Luna, MD, PhD (*Abstract Co-Author*)
Gegory Albers (*Abstract Co-Author*)
Kambiz Nael, MD (*Abstract Co-Author*)
Argye Hillis, MD (*Abstract Co-Author*)
Jeremy J. Heit, MD, PhD (*Abstract Co-Author*)
Tobias Faizy, MD (*Abstract Co-Author*)
Vivek Yedavalli, MD, MS (*Abstract Co-Author*)

PURPOSE

Effective collateral circulation significantly influences clinical outcomes in patients with acute ischemic stroke (AIS) due to large vessel occlusion (LVO). We developed and evaluated a composite Perfusion Collateral Score (PCS), combining the unfavorable dichotomizations of CT perfusion-derived parameters (hypoperfusion intensity ratio [HIR], cerebral blood volume [CBV] index, and prolonged venous transit [PVT]), hypothesizing that higher scores, representing worse collateral status, are associated with poor functional outcomes at 90 days.

METHODS AND MATERIALS

In this retrospective study or a prospectively collected database, we analyzed 225 AIS-LVO patients presenting within 24 hours of symptom onset who underwent diagnostic CT perfusion imaging. PCS was calculated (range 0-3) based on unfavorable values of HIR (=0.4), CBV index (<0.8), and presence of PVT, where each unfavorable parameter is allotted one point when present. The primary outcome was 90-day modified Rankin Scale (mRS) score, categorized into favorable (0-2) and unfavorable (3-6).

RESULTS

Higher PCS correlated significantly with worse 90-day outcomes, lower likelihood of favorable functional independence (mRS 0-2: 62% for PCS 0 vs. 23% for PCS 3; P=0.001), larger infarct volumes, and increased neurologic disability at discharge (P<0.001). In multivariable analysis, increasing PCS was independently associated with reduced odds of favorable outcomes (mRS 0-2: adjusted OR, 0.60; 95% CI, 0.39-0.90; P=0.015). The probability of unfavorable outcome increased progressively from 36% (PCS 0) to 76% (PCS 3).

CONCLUSION

The PCS, integrating three perfusion-based collateral parameters, is associated with 90-day functional outcomes in AIS-LVO patients.

CLINICAL RELEVANCE/APPLICATION

This scoring system offers an efficient, objective method to identify patients at higher risk for poor outcomes, optimizing rapid decision-making and resource allocation. Prospective validation is warranted.

M5A-SPNR-4 COMPARATIVE EVALUATION OF 7T VERSUS 3T SUSCEPTIBILITY-WEIGHTED IMAGING FOR CEREBRAL MICROBLEED DETECTION IN ASYMPTOMATIC MOYAMOYA DISEASE PATIENTS WITH HYPERTENSION

Qi Duan (*Presenter*)
Jinhao Lyu (*Abstract Co-Author*)
Xin Lou, MD, PhD (*Abstract Co-Author*)

PURPOSE

MMD is a major stroke cause in children/young adults. Hemorrhagic MMD has poor prognosis with high disability/mortality rates. Despite unclear pathophysiology, patients often experience recurrent bleeds, even in unaffected hemispheres. Identifying high-risk rebleeding patients remains a key challenge in hemorrhagic MMD management. Cerebral microbleeds (CMBs) may predict hemorrhage risk in moyamoya disease (MMD), with hypertension being a key risk factor. 7T MRI's superior SNR and prolonged T1 relaxation enable exceptional imaging resolution, allowing visualization of fine neuroanatomy. The enhanced resolution of 7T imaging may improve identification of microvascular pathology and hemorrhage risk stratification in this population. This study compares 7T versus 3T SWI quality, specifically evaluating 7T's advantage in detecting CMBs among hypertensive patients with asymptomatic MMD.

METHODS AND MATERIALS

Fourteen asymptomatic moyamoya disease patients with hypertension (mean age, 41.3 years ±10.3, 9 men) were enrolled with informed consent acquired before the study. All the patients underwent both 3T MRI and 7T MRI routine examinations with SWI included within 24 hours. The 7T examination was performed at a whole-body 7T MR scanner (MAGNETOM Terra, Siemens Healthcare, Erlangen, Germany) equipped with an 8Tx/32Rx head coil. The imaging parameters for 7T SWI were: repetition time 21.0 ms, echo time 14.0 ms, thickness 1.5 mm, flip angle 10 o . The imaging parameters for 7T SWI were: repetition time 37.0 ms, echo time 25.0 ms, thickness 3.0 mm, flip angle 15 o . The images were assessed by two neuroradiologists with blinded clinical information. The image quality score (0-5, worse to good), the location and number of CMBs to each patient were recorded.

RESULTS

The image quality score of 7T SWI and 3T SWI was the same (4.8±0.4 points). CMBs were detected present in 8 (61.5%) patients based on 7T SWI and 3 (23.1%) patients based on 3T SWI. Five patients (35.7%) presented CMBs positive on 7T but negative on 3T. 7T SWI presented a total of 14 CMBs in all patients while 3T SWI only presented 9 CMBs. For the 9 CMBs only presented on 7T (Figure 1), 3 of them were located in the anterior circulation, and 6 of them were located in the posterior circulation.

CONCLUSION

7T SWI has a significant advantage in presenting the CMBs in patients with asymptomatic MMD and hypertension, which may help select more hypertension MMD patients with high bleeding risk in clinical.

CLINICAL RELEVANCE/APPLICATION

7T SWI detected CMBs in 61.5% (8/13) of hypertensive MMD patients versus 23.1% (3/13) with 3T SWI, identifying 35.7% (5/14) additional cases. This superior detection capability suggests 7T SWI's clinical value for assessing hemorrhagic risk in asymptomatic patients.

M5A-SPNR-5 NEUROAIHUB: AN AI-DRIVEN FRAMEWORK FOR AUTOMATED DISCOVERY AND RETRIEVAL OF NEURORADIOLOGY DATASETS

Shahriar Faghani, MD (*Presenter*)
Benyamin Gheiji, MD (*Abstract Co-Author*)
Sina Moradi (*Abstract Co-Author*)
Mohammadaref Bagherzadeh (*Abstract Co-Author*)
Mahsa Vatanparast, MD (*Abstract Co-Author*)
Akinmuleya Oluwatobi (*Abstract Co-Author*)
Danial Elyassirad, MD (*Abstract Co-Author*)
Mahsa Heidari Foroozan (*Abstract Co-Author*)
Sina Goodarzi (*Abstract Co-Author*)
Mana Moassefi, MD, MD (*Abstract Co-Author*)

PURPOSE

To develop and evaluate an AI-driven framework, "NeuroAIHub" (https://neuroai.streamlit.com), for automated curation and discovery of neuroradiology imaging datasets to enhance data accessibility and accelerate research in neuroradiology.

METHODS AND MATERIALS

We manually extracted datasets from various sources and compiled them into a comprehensive database. This database is continuously enriched through an automated, agentic AI-based pipeline that utilizes web search tools to keep the data up to date. Additionally, a dataset exploration AI agent and a Python package were developed to enable customized dataset retrieval based on user-defined criteria, further enhancing accessibility and flexibility for researchers and clinicians.

RESULTS

The manual dataset extraction process curated a comprehensive base of 173 datasets across diverse categories, including neurodegenerative, neoplastic, cerebrovascular, psychiatric, spinal, and neurodevelopmental diseases. The automated AI-driven pipeline further enhances this database by continuously updating it with new datasets. On average, the pipeline can add four new datasets and their corresponding metadata for each category in less than a minute. This results in a total update time of approximately 480 seconds for the entire database, ensuring timely enrichment and up-to-date accessibility for researchers and clinicians.

CONCLUSION

NeuroAIHub streamlines neuroradiology dataset discovery, offering a scalable, user-friendly tool for researchers and clinicians. Future community contributions will further enhance its adaptability and impact.

CLINICAL RELEVANCE/APPLICATION

NeuroAIHub accelerates neuroradiology research by enabling efficient dataset access, supporting AI-driven diagnostics and treatment planning.

M5A-SPNR-6 LONG-TERM CLINICAL AND ANGIOGRAPHIC OUTCOME IN INTRACRANIAL ANEURYSMS TREATED WITH PARENT ARTERY OCCLUSION

Ammar Alam (*Presenter*)
Ahsas Nagee, MD (*Abstract Co-Author*)
Wassim Elmasry, MD (*Abstract Co-Author*)
Mahad Siddiqi (*Abstract Co-Author*)
Theodore Liu (*Abstract Co-Author*)
Marlise P. dos Santos, MD,MPH (*Abstract Co-Author*)

PURPOSE

Parent artery occlusion (PAO) remains a valuable treatment option for complex intracranial aneurysms not suitable for conventional endovascular approaches. This study evaluated long-term clinical and angiographic outcomes following PAO, with analysis based on aneurysm morphology, location, rupture status, clinical presentation, and angiographic results.

METHODS AND MATERIALS

We retrospectively analyzed patients treated with PAO between March 2005 and December 2024. Clinical outcomes were assessed using the modified Rankin Scale (mRS), and Pearson's chi-square test was used to identify predictors of occlusion status and clinical outcome.

RESULTS

Data analysis is ongoing. Among 30 patients with complete data analysis, 14 (46.6%) had aneurysms in the anterior circulation, and 16 (53.3%) presented with ruptured aneurysms. Twelve (40%) had fusiform morphology, 15 (50%) were >10 mm in length, 23 (76.6%) had neck sizes <10 mm, and 19 (63.3%) had dome-to-neck ratios <2. Complete occlusion was achieved in 25 patients (83%). At a mean follow-up of 22.1 months, 3 recurrences (10%) were observed. There were no peri-procedural deaths or post-procedural ruptures. Fusiform aneurysms showed a trend toward favorable long-term outcomes ($p = 0.063$).

CONCLUSION

PAO offers a safe and effective long-term treatment for select complex intracranial aneurysms, with low recurrence and no post-procedural rupture. Moderate peri-procedural morbidity highlights the importance of careful patient selection.

CLINICAL RELEVANCE/APPLICATION

For patients with intracranial aneurysms that are not amenable to conventional endovascular techniques, PAO provides a viable alternative with favorable long-term safety and efficacy. Careful patient selection—based on aneurysm characteristics and clinical presentation—can optimize outcomes and reduce the risk of complications, offering patients a durable treatment option with minimal recurrence and high rates of occlusion.

M5A-SPNR-7 CT-BASED HEAD & NECK COMPOSITION METRICS PREDICT RISK OF CONVERSION TO EARLY DEMENTIA

Farzaneh Rahmani, MD, MPH (*Presenter*)
Joseph E. Ippolito, MD, PhD (*Abstract Co-Author*)
Esther Lu (*Abstract Co-Author*)
Yifei Xu (*Abstract Co-Author*)
Tammie S. Benzinger, MD, PhD (*Abstract Co-Author*)

PURPOSE

Visceral adiposity and sarcopenia are related to Alzheimer disease (AD) risk, yet not much is known about the risk associated with fart and muscle composition of head and neck. CT scan quantification of adipose and fat can provide a pretest probability for AD. We investigated the relationship between head CT composition metrics and AD risk.

METHODS AND MATERIALS

Participants with normal cognition and negative amyloid PET at their baseline visit from the Knight ADRC cohort were enrolled. Based on subsequent cognitive measurements, we determined whether each participant: i) stably converted from normal cognition to early dementia or ii) remained cognitively normal throughout the follow up period and calculated the dementia-free survival in both groups. The low-dose attenuation correction CT from the PET/CT scan closest to the last cognitively normal date was used to perform head CT adipose and fat composition analysis using the Data Analysis Facilitation Suite (DAFS, version 3). Closest brain MRI within 1 year of this scan was used to extract concurrent brain volumes.

RESULTS

500 participants met the inclusion criteria (age: 69±8, 41.8% male, 13.2% African American). Over a median follow up of 123 months, 48(2.6%) participants stably converted to early dementia. Individuals with higher fraction of inter-intramuscular adipose tissue in the head had a 3-times increased risk of conversion from normal cognition to early dementia (Fig A). Males with higher normalized temporalis muscle volume were protected against conversion to early dementia (HR(95%CI):0.3(0.1-0.8)) (Fig B). There was a direct relationship between the volume of the temporalis muscles and volume of the precuneus and entorhinal cortices that persisted even after correction for head size (Fig C & D).

CONCLUSION

Head fat and muscle quantifications informs future risk of dementia and correlate with brain atrophy.

CLINICAL RELEVANCE/APPLICATION

Long-term clinical applications of this approach would translate into a CT-driven dementia probability score that helps identify older individuals who are likely to benefit from AD confirmatory tests and potentially disease-modifying therapeutics. Our method could be scaled to the over 25 million head and neck CT scans performed annually in the United States.

M5A-SPNR-8 SIMPLE LINEAR MEASUREMENTS OF THE PUTAMEN RELIABLY DIFFERENTIATE MSA FROM OTHER PARKINSONIAN DISORDERS ON MRI

Taryn Rohringer, MD (*Presenter*)
Victor Lam Shin Cheung (*Abstract Co-Author*)
Paula Alcaide, MD (*Abstract Co-Author*)

PURPOSE

Differentiating Parkinsonian type Multiple System Atrophy (MSA-P) from other parkinsonian disorders remains a clinical challenge, particularly at initial presentation. This study evaluates the utility of simple linear measurements of the putamen to distinguish MSA from idiopathic Parkinson's Disease (iPD) and Progressive Supranuclear Palsy (PSP). The proposed measurements are obtained at the level of reliable MRI landmarks to ensure consistency.

METHODS AND MATERIALS

Two readers retrospectively assessed patients presenting with parkinsonism who underwent 3.0T MRI from 2011-2024 at our institution. Putaminal thickness was measured at the anterior commissure (AC) line and the midline between the AC and posterior commissure (mid AC-PC). Relative measurements were calculated as a percentage of putaminal thickness relative to the inner table diameter. Automatic estimates of putaminal and total intracranial volume using FreeSurfer were also obtained. Statistical analyses included estimation of intraclass correlation coefficients, ROC curve analysis and Pearson correlation coefficients.

RESULTS

The study included 111 patients (35 MSA-P, 11 MSA-mix, 25 PSP, and 40 iPD). No significant differences in age or sex between groups were found. Inter-observer reliability was high, with intraclass correlation coefficients exceeding 0.8 for all described measurements. ROC curve analysis demonstrated that decreased putaminal thickness estimated by simple linear measurements is a strong distinguishing feature for MSA patients presenting with parkinsonism compared to PSP and iPD patients. Putaminal diameter at the AC line (AUC 0.92 95%CI [0.87, 0.97]) and mid AC-PC line (AUC 0.94 [0.90, 0.99]) were comparable in discriminatory performance to relative measurements at these levels (AUC 0.93 [0.88, 0.98] and AUC 0.90 [0.84, 0.97] respectively), as well as to absolute and relative automatic volumetric putaminal segmentation (AUC 0.90 [0.83, 0.96] and AUC 0.87 [0.80, 0.94] respectively). Best differentiating threshold for MSA diagnosis was less than 8.2 mm at the AC line (87% sensitivity, 80% specificity), and less than 3.9 mm at the mid AC-PC line (78% sensitivity, 100% specificity). Pearson analysis showed moderate to strong positive correlations between volumetric and linear measurements.

CONCLUSION

We propose two straightforward linear metrics to assess putaminal atrophy with comparable performance to volumetric measurements in distinguishing MSA from other parkinsonian disorders.

CLINICAL RELEVANCE/APPLICATION

The proposed linear metrics with optimal differentiating thresholds facilitate detection and quantification of putaminal atrophy, providing a simple, reliable method to distinguish MSA from other parkinsonian disorders.

M5A-SPNR-10 OMT AND TENSOR SVD BASED DEEP LEARNING MODEL FOR SEGMENTATION AND PREDICTING GENETIC MARKERS OF GLIOMA: A MULTICENTER STUDY

Zhengyang Zhu, MD (*Presenter*)
Huiquan Yang, PhD (*Abstract Co-Author*)
Mengying Xu, MD (*Abstract Co-Author*)
Xin Zhang, MD (*Abstract Co-Author*)
Bing Zhang, PhD (*Abstract Co-Author*)

PURPOSE

Glioma is the most common primary malignant brain tumor and preoperative genetic profiling is essential for management of glioma patients. Our study focused on tumor regions segmentation and predicting the World Health Organization (WHO) grade, isocitrate dehydrogenase (IDH) mutation, and 1p/19q codeletion status using deep learning models on preoperative Magnetic Resonance Imaging (MRI).

METHODS AND MATERIALS

We developed an optimal mass transport (OMT) approach to transform irregular MRI brain images into tensors. In addition, we proposed an algebraic pre-classification (APC) model utilizing multi-mode OMT tensor singular value decomposition (SVD) to estimate pre-classification probabilities. The fully automated deep learning model named OMT-APC was used for multitask classification. Our study incorporated preoperative brain MRI data from 3,565 glioma patients across 16 datasets spanning Asia, Europe, and America. Among these, 2,551 patients from 5 datasets were used for training and internal validation. In comparison, 1,014 patients from 11 datasets, including 242 patients from The Cancer Genome Atlas (TCGA), were used as independent external test.

RESULTS

OMT segmentation model achieved mean lesion-wise Dice scores of 0.880. The OMT-APC model was evaluated on the TCGA dataset, achieving accuracies of 0.855, 0.917 and 0.809, with AUC scores of 0.845, 0.908 and 0.769 for WHO grade, IDH mutation, and 1p/19q codeletion, respectively, which outperformed the four radiologists in all tasks.

CONCLUSION

These results highlighted the effectiveness of our OMT and tensor SVD-based methods in brain tumor genetic profiling, suggesting promising applications for algebraic and geometric methods in medical image analysis.

CLINICAL RELEVANCE/APPLICATION

This work has considerable clinical significance that would help neuro-oncologists make more appropriate treatment plans for patients.

M5A-SPNR-12 BEGINNER'S MIND: LONGITUDINAL MULTIMODAL MRI UNCOVERS NEUROPLASTIC CHANGES SUPPORTING DIAGNOSTIC SKILL ACQUISITION IN RADIOLOGY INTERNS

Yuxin Bai (*Presenter*)
Minghao Dong (*Abstract Co-Author*)

PURPOSE

To investigate experience-dependent neuroplasticity associated with early-stage diagnostic skill acquisition in radiology interns using longitudinal multimodal MRI. This study aims to identify structural and functional brain changes emerging after short-term clinical exposure and to uncover neural markers predictive of visual diagnostic expertise. Findings may inform cognitively adaptive training strategies in radiologic education.

METHODS AND MATERIALS

In this longitudinal study, 41 radiology interns undergoing one-month clinical training in X-ray interpretation completed behavioral testing, structural MRI (sMRI), and resting-state functional MRI (rs-fMRI) before and after the rotation. Diagnostic performance was assessed using the Radiology Expertise Task. Voxel-based morphometry and whole-brain functional connectivity analyses were conducted. Support vector machine classification with recursive feature elimination differentiated pre- from post-training subjects using sMRI and rs-fMRI data. An independent cohort and leave-one-out cross-validation were used to evaluate model performance.

RESULTS

Visual diagnostic performance improved significantly after training. Classification accuracy reached 91.7% (sMRI) and 93.3% (rs-fMRI), with independent test accuracies of 90.9% and 81.8%, respectively. Overlapping structural and functional changes were found in eight regions, including the fusiform gyrus, anterior cingulate, orbitofrontal cortex, and hippocampus. Functional connectivity between frontal and occipital regions correlated with diagnostic accuracy and reaction time. Gray matter volume changes also correlated with behavioral performance. Network-level reorganization was observed: increased coherence within exogenous networks (e.g., visual, somatomotor) and decreased coherence within endogenous networks (e.g., default mode, frontoparietal), along with increased integration between them.

CONCLUSION

Short-term clinical training induces measurable neuroplastic changes supporting early diagnostic skill development. These changes reflect dynamic interactions between visual perception, attention, memory, and decision-making systems, with implications for evidence-based radiology education.

CLINICAL RELEVANCE/APPLICATION

Identifying neural substrates of diagnostic learning can guide the development of targeted educational strategies and neurofeedback tools that enhance visual reasoning and accelerate radiologic expertise.

M5A-SPNR-13 CORRELATION BETWEEN CAROTID PLAQUE-RADS CLASSIFICATION ON CTA AND ISCHEMIC CEREBROVASCULAR EVENTS: A RISK ASSESSMENT STUDY

Limei Deng (*Presenter*)
Weixiong Zeng (*Abstract Co-Author*)
Lv Dongqin (*Abstract Co-Author*)
Genggeng Qin, MD, PhD (*Abstract Co-Author*)
Weiguo Chen (*Abstract Co-Author*)

PURPOSE

Ischemic cerebrovascular events (ICE), linked to carotid plaque characteristics, are a major cause of death and disability. This study explored the correlation between Carotid Plaque-RADS and ICE, to assess its risk-stratification efficiency for guiding early intervention.

METHODS AND MATERIALS

Retrospectively, 7,228 neck CTA cases (2019 - 2024) were screened, yielding 1,232 cases (774 symptomatic, 458 asymptomatic). Two radiologists assessed plaque traits and Carotid Plaque-RADS. After propensity score matching(PSM) (371 vs. 371), Spearman, Logistic, ROC, Kaplan-Meier, and Cox analyses were performed.

RESULTS

PSM balanced confounding factors. Symptomatic group had more high-level Carotid Plaque-RADS (=3) ($P < 0.001$). The results of Spearman correlation analysis showed that there was a weak positive correlation between the Carotid Plaque-RADS and ICE ($r = 0.347$, $P < 0.001$). Logistic regression analysis indicated that the risk of ICE was the highest in 4c plaques (OR = 7.856, 95% CI: 4.122-14.974, $P < 0.001$), and the high classification grade of Carotid Plaque-RADS was an important independent risk factor for the occurrence of ICE ($P < 0.001$). ROC curve analysis showed that the area under the curve (AUC) of Carotid Plaque-RADS for diagnosing ICE after matching was 0.650, which was significantly better than the simple degree of stenosis (AUC = 0.546, $P < 0.001$), but lower than the combined model of the degree of stenosis and the Carotid Plaque-RADS classification (AUC = 0.676, $P < 0.001$). During 43±19 month follow-up, 11.6% asymptomatic had ischemic stroke, 19.4% symptomatic had recurrent stroke. There were significant differences in the DFS and RFS rates among different carotid Plaque-RADS classifications ($P < 0.001$)and stenosis degree ($P < 0.001$) . As the Plaque-RADS classification increased from 1 to 4, the DFS and RFS rates decreased significantly ($P < 0.001$). For mild/moderate stenosis, Plaque-RADS =3 vs. <3 showed different DFS/RFS ($P < 0.001$). For patients with severe stenosis, the RFS rate of patients who received carotid revascularization was significantly higher ($P < 0.001$). Cox analysis indicated that Plaque-RADS =3 and severe stenosis linked to ischemic/recurrent stroke risk.

CONCLUSION

CTA-based Carotid Plaque-RADS effectively identifies ICE high-risk populations, especially for high-level plaques (=3), improving stroke risk stratification in mild/moderate stenosis. PSM-controlled confounding factors provide evidence for Carotid Plaque-RADS in assessing ICE, aiding early clinical strategies.

CLINICAL RELEVANCE/APPLICATION

Carotid artery; Atherosclerosis; Carotid Plaque-RADS; Computed tomography angiography; Ischemic cerebrovascular events; Propensity score matching

M5A-SPNR-14 AI-DRIVEN ANALYSIS OF BRAIN CT FOR INTRACEREBRAL HEMORRHAGE DETECTION

Vikas K. Patel, MD (*Presenter*)
Praveen Shastry (*Abstract Co-Author*)
Shweta Tyagi (*Abstract Co-Author*)
Mohammed Jabeer (*Abstract Co-Author*)
Jitender Singh (*Abstract Co-Author*)
Anuj Chandalia (*Abstract Co-Author*)
Dwarikanath Mahapatra (*Abstract Co-Author*)

PURPOSE

The intracerebral hemorrhage (ICH) is a critical and potentially fatal type of cerebrovascular disease. In severe instances, it can disrupt vital functions such as breathing and may result in death, making immediate medical intervention essential. Manual interpretation of brain CT can be time-consuming. We aim to develop a system based on AI (Artificial Intelligence) to automatically detect ICH in non-contrast brain CT scans. This system can be integrated into the diagnostic workflow and will assist clinicians with fast, accurate decisions in acute care.

METHODS AND MATERIALS

We developed an AI-based framework utilizing convolutional neural networks, specifically leveraging a two-stage 3D nnUNet architecture. In the first phase, the model segments the brain parenchyma, followed by targeted segmentation of intracerebral hemorrhage in the second phase. Training was conducted on a curated dataset of 700 anonymized non-contrast brain CT scans, each precisely annotated by an expert radiologist to ensure high clinical fidelity. The system performs binary segmentation to distinguish hemorrhagic tissue from healthy brain structures. After inference, the model outputs a DICOM-compatible overlay that highlights hemorrhagic regions, along with a structured report summarizing key clinical details, including hemorrhage presence, lesion dimensions, and volumetric analysis. This AI tool is designed to support radiologists and emergency clinicians by delivering fast, reliable, and quantifiable insights, thereby streamlining decision-making in urgent care environments.

RESULTS

We tested our approach on a private brain CT dataset of 50 samples. Our proposed approach achieved 93% sensitivity, 82.3% specificity, and 84.6% precision for ICH detection. An overall accuracy of 94% is obtained. A radiologist verified the results.

CONCLUSION

The findings of this study demonstrate that our AI system is effective in detecting and localizing intracerebral hemorrhages. With continued validation and integration into clinical workflows, the system holds promise for enhancing diagnostic efficiency and supporting better patient outcomes in acute stroke care. As we continue to develop this system, we aim to broaden its capabilities by including detailed ICH subtype classification and identifying other critical findings, including ischemic stroke, thereby supporting more precise and personalized treatment planning.

CLINICAL RELEVANCE/APPLICATION

Our AI tool automates the detection of intracerebral hemorrhage by integrating it into clinical workflows. It provides real-time decision support, improving diagnostic accuracy and facilitating timely intervention in emergency departments where rapid detection is crucial for patient survival.

M5A-SPNR-17 DIAGNOSTIC ACCURACY OF DUAL-ENERGY CT FOR INTRACEREBRAL HEMORRHAGE VS. CONTRAST STAINING, RADIATION DOSE, AND STROKE APPLICATIONS: A SYSTEMATIC REVIEW AND META-ANALYSIS

Moreno Zanardo, PhD (*Presenter*)
Luigi Asmundo, MD (*Abstract Co-Author*)
Domenico Albano (*Abstract Co-Author*)
Mariachiara Basile, MD (*Abstract Co-Author*)
Massimo Cressoni (*Abstract Co-Author*)
Attilio Prato (*Abstract Co-Author*)
Francesco Sardanelli, MD (*Abstract Co-Author*)
Luca Maria Sconfienza, MD, PhD (*Abstract Co-Author*)
Paolo Vitali, MD,PhD (*Abstract Co-Author*)

PURPOSE

Dual-energy computed tomography (DECT) has emerged as a valuable imaging modality in cerebrovascular diseases, particularly in differentiating intracerebral hemorrhage (ICH) from contrast staining after endovascular procedures. This systematic review and meta-analysis aims to investigate the diagnostic performance of DECT in distinguishing ICH from contrast staining after procedures, alongside its technical protocols, radiation dose implications, and broader cerebrovascular applications.

METHODS AND MATERIALS

A systematic review and meta-analysis was conducted according to PRISMA and PRISMA-DTA guidelines. Literature searches of MEDLINE and EMBASE were performed up to March 2025. Studies were included if they evaluated DECT in cerebrovascular disease with extractable technical and diagnostic performance data. Pooled sensitivity and specificity were calculated for distinguishing ICH from contrast staining using a bivariate random-effects model. Radiation dose metrics, including CTDIvol and DLP, were also pooled from eligible studies using random-effects meta-analysis.

RESULTS

Sixty-eight studies with 5,530 patients were included, of which 10 contributed to the diagnostic accuracy meta-analysis. DECT showed high pooled sensitivity (96.1%, 95% CI: 83.8-99.1%) and specificity (97.8%, 95% CI: 91.4-99.5%) in differentiating ICH from contrast staining. Radiation dose analysis from 13 studies (n=637) yielded a pooled CTDIvol of 28.83 mGy, and from 9 studies (n=485), a pooled DLP of 517.66 mGy·cm—both comparable to single-energy CT. The most common DECT setup used dual-source scanners with 80/140 kVp and post-processing with virtual non-contrast and iodine maps.

CONCLUSION

DECT offers excellent diagnostic accuracy for differentiating ICH from contrast staining without increasing radiation dose compared to conventional CT. These results support its use in acute stroke imaging, particularly following endovascular therapy. DECT's post-processing techniques, such as virtual non-contrast and iodine maps, enhance its ability to assess stroke-related complications. Standardization of protocols remains essential to reduce variability and enable broader clinical adoption.

CLINICAL RELEVANCE/APPLICATION

DECT should be the preferred imaging modality for differentiating ICH from contrast staining in the post-endovascular treatment setting, offering improved diagnostic confidence (pooled sensitivity of 96.1% and specificity of 97.8%) without increased radiation burden (pooled CTDIvol of 28.83 mGy and DLP of 517.66 mGy×cm, comparable to conventional single-energy CT).

M5A-SPNR-18 NON-INVASIVE ASSESSMENT OF GLYMPHATIC SYSTEM FUNCTION IN CSVD WITH MILD COGNITIVE IMPAIRMENT BASED ON MULTIPARAMETRIC MRI

Min Xu (*Presenter*)
Haixia Mao (*Abstract Co-Author*)
Xiangming Fang, MD (*Abstract Co-Author*)

PURPOSE

In this cross-sectional study, we utilized a variety of non-invasive methods based on multi-parameter magnetic resonance imaging (MRI) to evaluate the glymphatic system function in patients with cerebral small vessel disease (CSVD), both with and without mild cognitive impairment. Our objective is to identify changes in glymphatic function among CSVD-MCI patients through imaging analysis, thereby enabling timely intervention.

METHODS AND MATERIALS

We conducted a comprehensive analysis of data from participants with mild cognitive impairment and normal cognition derived from a prospective CSVD study. We calculated the DTI-ALPS index, gBOLD-CSF coupling strength, and choroid plexus volume (CPV) separately and performed comparative analyses. According to the

STRIVE2 criteria, the occurrence of each CSVD markers was quantified into an ordinal "summary SVD score" ranging from 0 to 4. The correlations between the three glymphatic system parameters and CSVD imaging markers were analyzed and we further explored the interaction between glymphatic function and cognitive outcomes.

RESULTS

A total of 308 subjects were recruited (mean age, 72 years ± 9 [SD]; 162 women), of whom 141 CSVDs and 167 healthy controls (HC). The CSVD group was further divided into CSVD-MCI (mild cognitive impairment) and CSVD-NCI (without cognitive impairment). Significant differences were found in the DTI-ALPS indices and CPV between HC and CSVD-NCI groups (P < 0.001) and CSVD-MCI groups (P <0.001) in a univariate general linear model corrected for age, sex, hypertension and diabetes. Severer periventricular (PWMH) (ß = -0.350, p <0.001; ß =0.404, p <0.001)and deep white matter hyperintensities (DWMH) (ß = -0.330, p <0.001; ß =0.324, p <0.001), number of microbleeds (ß= -0.255, p <0.001; ß =0.191, p <0.001),number of lacunas (ß = -0.194, p < 0.001; ß =0.177, p <0.001), and severer enlarged perivascular spaces in basal ganglia (BG EPVS) (ß = -0.335, p < 0.001; ß =0.390, p <0.001) were related to ALPS-index and CPV. Moreover, a significant correlation was found between ALPS-index and CPV (ß = -0.387, p < 0.001).

CONCLUSION

Our results indicated that the difference of ALPS-index and CPV between CSVD with/without mild cognitive impairment are significant. Effective imaging markers may enable non-invasive monitoring of glymphatic changes, thereby facilitating the identification of optimal timing for clinical interventions.

CLINICAL RELEVANCE/APPLICATION

The ALPS index and CPV may serve as non-invasive imaging biomarkers for identifying mild cognitive impairment in CSVDs, thereby facilitating timely clinical intervention for MCI patients and potentially delaying the further development of cognitive impairment.

M5A-SPNR-19 COMPARATIVE EFFICACY OF SBRT AND ABLATION VS SBRT ALONE FOR SPINAL OSSEOUS METASTASES

Jake Schick, BS, MD (*Presenter*)
Sasicha Manupipatpong, MD (*Abstract Co-Author*)
Seulah Choi, MD (*Abstract Co-Author*)
Majid A. Khan, MD (*Abstract Co-Author*)

PURPOSE

The purpose of this study is to evaluate whether ablation can improve pain relief in patients with spinal osseous metastases experiencing refractory pain following SBRT, and whether the combination of SBRT and ablation improves locoregional control.

METHODS AND MATERIALS

Inclusion criteria were patients with painful spinal metastases treated with either SBRT or SBRT combined with ablation between 2015 to 2024. Exclusion criteria included patients without follow up and pediatric patients. Clinical data obtained for retrospective analysis included demographic information (age, sex, primary tumor type), treatment details (radiation dose and fractionation, ablation modality), functional status as measured by Karnofsky performance status, pain scores as measured by VAS, and morphine milligram equivalent (MME). Locoregional control was assessed by follow up imaging via CT, PET, or MR at 3,6, and 12 months. Statistical analysis included Student's t -test for continuous variables and chi-square tests for categorical variables.A p -value of < 0.05 was considered statistically significant.

RESULTS

16 patients were included in the combination treatment group (SBRT+ablation), and 16 age matched controls were included in the SBRT control group. Key differences between the groups include the number of osseous metastases, surgical history, and SBRT dose delivery, which are summarized in table 1. In the combination group, 81 percent of patients previously underwent SBRT and were referred to ablation due to persistent pain or new fracture, with mean time between SBRT and ablation 5.5 months. In both the combined group and SBRT alone, there was a statistically significant decrease in VAS pain score at all time points, with combined therapy decreasing 2.5 points at 12 months compared to baseline (p=.006), vs 1.8 points for SBRT alone (p=.008). There was no significant change in either opioid consumption or functional status following intervention in either group. Combined therapy had improved local control at all time points (6.3% local failure vs 12.5% at 12 months), but this did not reach statistical significance. There were no adverse events.

CONCLUSION

Ablation led to significant reduction in pain scores post-intervention in a cohort mostly composed of patients with refractory pain following SBRT. While there was improved local control in the combined group, this did not reach statistical significance.

CLINICAL RELEVANCE/APPLICATION

Refractory pain following SBRT for osseous spinal metastases is common and ablation can serve as an effective treatment adjunct. Further studies are needed to determine if combined therapy leads to improved local control.

M5A-SPOB-1 MACHINE LEARNING MODEL BASED ON PLACENTA MRI RADIOMICS TO PREDICT THE RISK OF IUGR AND GUIDE CLINICAL FOLLOW-UP

Claudia Cutonilli, MD (*Presenter*)
Lucia Manganaro, MD (*Abstract Co-Author*)
Marco Gennarini (*Abstract Co-Author*)
Federica Curti, MD (*Abstract Co-Author*)
Roberta V. Ninkova, MD (*Abstract Co-Author*)
Sandrine Riccardi (*Abstract Co-Author*)
Valentina Miceli, MD (*Abstract Co-Author*)
Angelica Cupertino, MD (*Abstract Co-Author*)
Chiara Amoroso (*Abstract Co-Author*)
Flaminia Frezza, MD (*Abstract Co-Author*)

PURPOSE

To develop a machine learning model based on Magnetic Resonance Imaging images to stratify the single-subject risk of IUGR.

METHODS AND MATERIALS

We collected images of Magnetic Resonance Imaging (T2W) from 72 subjects. Each image contained exactly one volume of interest (VOI), thus there is a univocal correspondence between subjects and samples. Among these, 37 samples (51.4%) belonged to class "IUGR" (Positive class) and 35 samples(48.6%) belonged to class "healthy" (Negative class), according to clinical follow up. This image set was used for the training, validation, and testing of five machine-learning models (Random Forest, Support Vector Machine, K-NearestNeighbors, Multi-Layer Perceptron, Logistic Regression).

RESULTS

The best model showed ROC-AUC (%) of 75** (67-83), Accuracy (%) of 68** (62-75), Sensitivity (%) of 69** (61-77), Specificity (%) of 67* (54-80), PPV (%) of 70** (63-77), NPV (%) of 67** (60-74) (*p<0.05, **p<0.005).

CONCLUSION

Among the five different machine learning ensembles tested (Random Forest, Support Vector Machine, K-Nearest Neighbors, Multi-Layer Perceptron, Logistic Regression), the Random Forest classifier model demonstrated the best performance for distinguishing between "IUGR" and "healthy" subjects, with a sensitivity of 69%.

CLINICAL RELEVANCE/APPLICATION

The research concludes that the specific machine learning model, particularly the Random Forest implementation, can effectively and significantly predict IUGR risk using placental MRI radiomics, showing good accuracy and reliability.The findings from this research suggest that, with further validation and development, this machine learning model could potentially contribute to the earlier diagnosis of IUGR in the future.

M5A-SPOB-2 PHYSICALLY-PRIMED AI-ENHANCED IVIM ANALYSIS OF PLACENTAL DIFFUSION-WEIGHTED MRI REVEALS FUNCTIONAL DIFFERENCES IN LGA PREGNANCIES ASSOCIATED WITH MATERNAL DIABETES

Moti Freiman, PhD (*Presenter*)
Naama Gavrielov (*Abstract Co-Author*)
Moran Gawie-Rotman (*Abstract Co-Author*)
Zeina Abdel-Rauf (*Abstract Co-Author*)
Roni Shreter, MD (*Abstract Co-Author*)
Esther Maor-Sagie (*Abstract Co-Author*)
Rinat Gabbay-Benziv (*Abstract Co-Author*)

PURPOSE

Maternal diabetes increases the risk of large for gestational age (LGA) fetuses, associated with complications like birth trauma and metabolic disorders. As placental dysfunction underlies LGA, early detection is critical. While IVIM analysis of DWI offers non-invasive placental biomarkers, it is limited by unstable parameter estimates from sparse b-value sampling. This study evaluates whether physically-primed AI models incorporating b-values can improve detection of functional placental differences between healthy and LGA pregnancies.

METHODS AND MATERIALS

Placental diffusion-weighted imaging (DWI) was performed on a 1.5T scanner (Ingenia, Philips Medical Systems, Best, The Netherlands) using a multi-channel coil. Axial 2D spin-echo images with fat suppression were acquired with TR = 4215 ms, TE = 103 ms, slice thickness = 5.0 mm, spacing = 6.0 mm, in-plane resolution = 1.01 × 1.01 mm², and a 121 × 116 matrix. Nine b-values (0-1000 s/mm²) were used, with a total scan time of ~531 seconds. DWI data from pregnant women with uncontrolled diabetes and healthy controls were analyzed to estimate IVIM parameters—D (diffusion), D* (pseudo-diffusion), and f (pseudo-diffusion fraction)—using classical IVIM and two physically-primed AI models, SUPER-IVIM-DC and SUPER-IVIM-DC-Boot, optimized for limited b-value data. Group differences were evaluated using Welch's t-test.

RESULTS

Five pregnant women with maternal diabetes and eight healthy pregnant controls (mean age: 30.0 ± 5.5 vs. 35.5 ± 2.9 years; gestational age: 35 ± 2.8 vs. 30.3 ± 4.9 weeks) were enrolled in the study. Classical IVIM showed no significant group differences. Using SUPER-IVIM-DC, D was significantly lower in the diabetic group

(0.001827 ± 0.000086 mm²/s) compared to controls (0.001997 ± 0.000136 mm²/s, p = 0.03997). SUPER-IVIM-DC-BOOT showed significant differences in both D (0.001931 ± 0.000073 vs. 0.002043 ± 0.000104 mm²/s, p = 0.04365) and f (0.2896 ± 0.0428 vs. 0.3421 ± 0.0279, p = 0.0494), highlighting impaired placental diffusivity and perfusion in maternal diabetes.

CONCLUSION

AI-based methods, especially SUPER-IVIM-DC and BOOT, were more sensitive than classical IVIM in detecting functional placental differences in LGA pregnancies, revealing impaired diffusivity and perfusion. These models show promise as non-invasive tools for early identification of placental dysfunction in high-risk pregnancies.

CLINICAL RELEVANCE/APPLICATION

Physically-primed AI models allow reliable placental biomarker extraction from limited DWI data and reveal functional differences in LGA pregnancies. They offer a non-invasive tool for early detection of placental dysfunction in maternal diabetes, supporting timely intervention and better outcomes.

M5A-SPOB-3 THERAPEUTIC DECISION-MAKING IN PATIENTS WITH BOWEL ENDOMETRIOSIS: THE CLINICAL VALUE OF MRI

Federica Curti, MD (*Presenter*)
Roberta V. Ninkova, MD (*Abstract Co-Author*)
Angelica Cupertino, MD (*Abstract Co-Author*)
Chiara Amoroso (*Abstract Co-Author*)
Alessandro Calabrese, MD (*Abstract Co-Author*)
Claudia Cutonilli, MD (*Abstract Co-Author*)
Carlo Catalano, MD (*Abstract Co-Author*)
Lucia Manganaro, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the role of magnetic resonance imaging (MRI) in guiding the choice between medical and surgical treatment in patients with intestinal endometriosis, through detailed analysis of lesion morphology and anatomical involvement.

METHODS AND MATERIALS

We retrospectively enrolled 215 patients with bowel endometriosis who underwent MRI between 2017 and March 2024, with at least 1 year of follow-up. Of these, 135 patients underwent surgical treatment, either alone or combined with medical therapy, while 80 patients received medical treatment exclusively. The intestinal endometriotic lesions were assessed on MRI, with particular attention to location (low, mid, or upper rectum; rectosigmoid junction; extrapelvic sites), based on the distance from the anal margin. Additional features including the number of nodules, longitudinal extension, lesion thickness, and circumferential involvement were also evaluated.In addition to MRI features, clinical symptoms were systematically assessed using the NRS scale, with comparative analysis of pre- and post-treatment scores. The occurrence of bowel obstruction and post-surgical complications were also recorded.

RESULTS

The upper rectum was the most frequently affected site (33%), followed by the rectosigmoid junction (22%), mid-rectum (20%), lower rectum (13%), and extrapelvic intestinal segments (12%). The overall incidence of bowel obstruction was 5.1%, observed exclusively in patients with lesions located =10 cm from the anal verge and demonstrating circumferential involvement of =4/8. Surgical treatment demonstrated superior efficacy in patients with lesions >14 mm in thickness and =4/8 circumferential involvement, achieving a significantly greater reduction in symptom severity (mean NRS reduction: 4.3 ± 1.2) compared to medical therapy alone (mean NRS reduction: 2.1 ± 1.0; p < 0.001). Conversely, in patients with smaller or less extensive lesions, symptom control was comparable between medical and surgical approaches (mean NRS reduction: 3.0 ± 1.3 vs. 2.9 ± 1.1; p = 0.74). Among patients undergoing surgery, 65.2% experienced postoperative complications, with bladder incontinence being the most frequent adverse event (26.7%).

CONCLUSION

MRI plays a pivotal role in the management of bowel endometriosis, offering detailed lesion characterization and enabling personalized treatment by identifying features linked to symptom severity and the risk of bowel obstruction, thus supporting the selection of the most beneficial treatment approach for each patient.

CLINICAL RELEVANCE/APPLICATION

MRI-derived features may function as imaging biomarkers for risk stratification, assessing the likelihood of bowel obstruction and guiding individualized treatment strategies.

M5A-SPOB-4 RECENT ADVANCES IN AI-BASED MODELS FOR OVARIAN TUMOR DIAGNOSIS AND CLASSIFICATION: A SYSTEMATIC REVIEW AND META-ANALYSIS

Andrew Farah (*Presenter*)
Matthew Bilson, BA (*Abstract Co-Author*)
Aliyah Baakoe (*Abstract Co-Author*)
Labbaik Aas (*Abstract Co-Author*)
Wassim Elmasry, MD (*Abstract Co-Author*)
James Man Git Tsui (*Abstract Co-Author*)
Antonio G. Tongue, MD,FRCPC (*Abstract Co-Author*)

PURPOSE

Ovarian cancer remains a major cause of gynecologic cancer mortality. Early and accurate detection is essential for guiding clinical management and improving outcomes, but current imaging methods are limited by variability and subjectivity. Artificial intelligence (AI) has shown promise in improving diagnostic accuracy, with ongoing advancements in model architecture and imaging applications. Given this rapid progress, there is a continued need to reassess the performance of recent AI-based models for ovarian tumor classification. This systematic review and meta-analysis assess pooled diagnostic performance across imaging modalities and examines the influence of recent model characteristics.

METHODS AND MATERIALS

Following PRISMA guidelines, we searched MEDLINE, Embase, Scopus, Web of Science, and preprint servers for studies published between January 2022 and January 2025. Included studies used AI to perform binary classification of ovarian tumors using ultrasound (US), CT, or MRI. Risk of bias was assessed using QUADAS-2. Pooled diagnostic metrics (accuracy, sensitivity, specificity, diagnostic odds ratio [DOR]) were calculated using common-effect and random-effects models, with subgroup analyses by imaging modality and validation strategy. The protocol was submitted to PROSPERO (awaiting registration ID).

RESULTS

34 studies met inclusion criteria, with 19 eligible for meta-analysis (12 US, 4 CT, 3 MRI). Pooled diagnostic accuracy was 94.5% (95% CI: 94.1-94.9) under the common-effect model and 89.3% (95% CI: 86.6-92.1) under the random-effects model. Sensitivity and specificity were 95.1% and 93.9%, and overall DOR was 65.3 (95% CI: 56.2-75.8) and 82.6 (95% CI: 40.9-166.6) respectively. US models showed high performance, with a random-effects DOR of 106.8 (95% CI: 56.8-201.0), and accuracy, sensitivity, and specificity exceeding 90%. Most models employed deep learning, with ensemble CNNs outperforming radiomics and traditional ML approaches. Risk of bias was low or unclear in most studies. External validation was infrequent while subgroup analyses showed considerable heterogeneity.

CONCLUSION

AI models demonstrate strong diagnostic performance in classifying ovarian tumors, especially in US-based applications. However, heterogeneity and limited data in CT and MRI studies limit generalizability. Greater external validation, standardized protocols, and multicenter datasets are needed for clinical adoption.

CLINICAL RELEVANCE/APPLICATION

Our findings reinforce the need for standardized imaging benchmarks, open-access multicenter datasets, and external validation. Adoption of AI-specific quality frameworks such as QUADAS-AI is essential for safe and effective clinical translation.

M5A-SPPD-1 INTRARENAL REFLUX IS LINKED TO SUBSEQUENT KIDNEY SCARRING: A RETROSPECTIVE STUDY

Jisun Hwang, MD (*Presenter*)
Young Jin Ryu, MD (*Abstract Co-Author*)

PURPOSE

This study investigates whether intrarenal reflux (pyelotubular backflow) isassociated with kidney scarring in children with urinary tract infection (UTI).

METHODS AND MATERIALS

We retrospectively reviewed 441 children diagnosed with UTI who underwentvoiding cystourethrography (VCUG) and a technetium-99m dimercaptosuccinic acid (DMSA) scan more than three months after the UTI. Intrarenal reflux was identified on VCUG. Using multivariate logistic regression, we analyzed the association between intrarenal reflux and kidney scarring on DMSA scans, adjusting for vesicoureteral reflux (VUR) grade and other clinical variables.

RESULTS

Out of 874 kidney units, VUR was detected in 255 units (29.1%), with intrarenalreflux present in 35 units (13.7%). Kidney scarring was observed in 12.7% of all kidney units. Intrarenal reflux was significantly associated with an increased risk of kidney scarring (odds ratio 3.35, 95% confidence interval 1.31-8.58) after adjusting for VUR grade. Notably, 92% of photon defects on DMSA scans in units with intrarenal reflux were located at the reflux site.

CONCLUSION

Intrarenal reflux is an independent predictor of kidney scarring beyond conventional VUR grading. Recognizing and reporting intrarenal reflux during VUR assessment may aid in developing tailored management strategies for children with UTI and VUR.

CLINICAL RELEVANCE/APPLICATION

We suggest that physicians document and report the presence of intrarenal reflux during VCUG. Recognizing intrarenal reflux would be helpful for providing tailoring individualized management strategies, including decision-making processes regarding potential surgical interventions.

M5A-SPPD-2 THE SONORA PROJECT: TOWARDS SAFE, OPTIMIZED AND PERSONALIZED RADIOLOGY AND RADIOTHERAPY PROCEDURES FOR PREGNANT PATIENTS

Francesca De Monte (*Presenter*)
Hrvoje Brkic (*Abstract Co-Author*)
Zeljka Knezevic (*Abstract Co-Author*)
Christos Pafilis (*Abstract Co-Author*)
Dario Faj (*Abstract Co-Author*)

PURPOSE

The European Basic Safety Standards Directive requires that medical procedures involving pregnant patients pay attention to justification and optimisation, taking into account both the expectant mother and the unborn child. In Diagnostic-Interventional Radiology (DIR) and Radiotherapy (RT), the lack of harmonization of clinical practice leads to large differences in fetal dose estimation. The SONORA project aims to harmonize practice by: 1. developing physical and computational phantoms for all gestational stages; 2. quantifying fetal doses and evaluating dosimetry techniques across DIR procedures, RT modalities, and patient anatomies; 3. identifying key factors contributing to discrepancies in current clinical dose estimates; 4. creating and validating a patient-specific proton-therapy dose-estimation tool. This work is supported by PIANOFORTE Open grant call 2023 (HORIZON-EURATOM-2023-NRT-01) and by the Croatian Science Foundation (Project IP-02-2020-3593).

METHODS AND MATERIALS

A survey across the Europe was launched to investigate methods and tools for fetal dose estimation, assess fetal dose ranges for various procedures, identify optimization strategies to reduce fetal exposure across Europe. Fetal doses for specific procedures were evaluated using both in silico models and physical anthropomorphic phantoms ("Tena") representing a pregnant woman in her second trimester. Measurements were conducted at various institutions using radiophotoluminescent dosimeters (RPLDs). Multiple codes Monte Carlo simulation across DIR procedures as well as photon and proton RT were performed.

RESULTS

For DIR , preliminary results show that fetal doses generally remain below 1 mGy unless the fetus lies within the primary beam; abdominal CT may be up to 50 mGy. Observed significant variability in fetal doses for defined procedures further emphasizes the need for protocol optimization and harmonization. Survey analysis is ongoing and results will be presented.

CONCLUSION

The SONORA project will provide a good-practice guide for fetal dose estimation in DIR and RT, alongside with a validated proton-therapy dose-estimation application. Ethical considerations of fetal dose and associated risk data will be considered to increase the quality of risk-benefit communication with the patient.

CLINICAL RELEVANCE/APPLICATION

SONORA's dosimetry framework and decision-support tool will enable clinicians to make evidence-based decisions that reduce fetal radiation exposure while maintaining diagnostic and therapeutic effectiveness. Standardized methods will improve risk-benefit communication with pregnant patients and strengthen radiation safety practices in European radiology and oncology centers.

M5A-SPPD-3 Zhongfeng Xie (*Presenter*)

UNRAVELING THE COMPLEX INTERPLAY BETWEEN GLYMPHATIC FUNCTION, AGE, AND BRAIN STRUCTURE IN SCHOOL-AGED CHILDREN WITH AUTISM SPECTRUM DISORDER

PURPOSE

Autism Spectrum Disorder (ASD) is a complex neurodevelopmental condition. Although extensive research has explored the neurobiological foundations of ASD, the relationship between glymphatic dysfunction, brain structure, and age in children with ASD remains poorly understood and insufficiently studied. Understanding the interactions among these factors is crucial for uncovering the pathological mechanisms of ASD and developing targeted interventions.

METHODS AND MATERIALS

A total of 130 participants, including 67 children with ASD and 63 typically developing (TD) children, were enrolled. Glymphatic function was assessed using diffusion tensor image analysis along the perivascular space (ALPS). Voxel-based morphometry was employed to measure gray matter volume (GMV). Statistical analyses were conducted to explore correlations between age, ALPS indices, and GMV, and to assess whether age moderates these relationships.

RESULTS

Children with ASD exhibited reduced glymphatic function, with significant differences in the ALPS_left (ALPS_L) index ($P = 0.024$) and ALPS_bilateral (ALPS_Bi) index ($P = 0.025$) indices compared to TD children. The ALPS index was positively correlated with age ($P < 0.05$) and negatively correlated with GMV, particularly in regions linked to social and cognitive processing. Moderation analysis revealed that age moderates the relationship between the ALPS index and GMV, with older children showing a more pronounced effect. Receiver operating characteristic (ROC) curve analysis indicated that the ALPS index effectively distinguishes ASD from TD children (ALPS_L index area under the curve (AUC) = 0.710, ALPS_Bi index AUC = 0.712).

CONCLUSION

Our study suggests that glymphatic dysfunction in children with ASD may be age-dependent, influencing brain structure, particularly GMV. The ALPS index holds potential as a diagnostic biomarker for early detection of ASD-related neurobiological changes, with implications for targeted therapeutic interventions.

CLINICAL RELEVANCE/APPLICATION

ALPS, as an indicator of glymphatic function, provides a new perspective for understanding brain development in children with ASD. We found that the increase in ALPS index is associated with the normalization of GMV, suggesting that improving glymphatic function may help mitigate the negative effects on brain development, with age playing an important role in this process. Therefore, early detection and intervention of glymphatic dysfunction could become key to restoring brain structural development, with varying effects across different age groups. This finding not only offers new insights into the developmental mechanisms of autism but may also guide the development of intervention strategies.

M5A-SPPD-4 SEEING THE UNSEEN: THE CHALLENGES OF PRENATAL IMAGING DIAGNOSIS OF SYNTELENCEPHALY - A CASE SERIES AND LITERATURE REVIEW

Mariana Cerdeira Machado, MD (*Presenter*)
Matheus Luis Silva (*Abstract Co-Author*)
Caroline Victorino Felix De Lima, MD (*Abstract Co-Author*)
Adriana De Oliveira, MD (*Abstract Co-Author*)
Fernanda Tovar-Moll, MD,PhD (*Abstract Co-Author*)
Patricia Oliveira-Szejnfeld, MD (*Abstract Co-Author*)

PURPOSE

Syntelencephaly is a rare type of holoprosencephaly (HPE), also called the middle interhemispheric (MIH) variant, characterized by a spectrum of malformations, the hallmark being hemispheric fusion in the posterior frontal and/or anterior parietal lobes. Prenatal diagnosis is crucial, as it directly influences management and prognosis, yet it can be extremely challenging. Through a thorough literature review and the analysis of original cases, we propose a practical imaging-based approach to facilitate early and accurate prenatal diagnosis.

METHODS AND MATERIALS

This is a case series study of 5 fetuses to which the diagnosis of syntelencephaly was attributed through fetal magnetic resonance (fMR). We conducted a systematized analysis and demonstrated key imaging features of cases from our database in which nonspecific or suspicious alterations were identified on neurosonography (nUS) and later diagnosed as the MIH HPE through fMR. We also performed a comprehensive literature review, focusing on prenatal diagnosis and the main imaging findings, follow-up, and prognosis.

RESULTS

The 5 cases we analyzed (100%) on fMR presented a hemispheric fusion on the high frontoparietal convexity, lateral sulcus dimorphism, and absence of the cavum septi pellucidi (CSP). Other findings: 4/5 presented with microcephaly, 4/5 with mild ventriculomegaly (VM), 2/5 with residual frontal horns, 1/5 with a posterior cyst, and 3/5 with thalamic fusion.The literature review demonstrated that prenatal imaging diagnosis of MIH HPE can be challenging, especially for professionals with limited experience in fetal nUS or brain MRI. The main findings are often misinterpreted as isolated VM and, when recognized, the absence of the CSP. Postnatal clinical manifestations include delayed neuropsychomotor and cognitive development, seizures, and others, with severity varying according to the extent of brain involvement and associated anomalies.

CONCLUSION

Neurosonography and fMR performed by experienced professionals are critical for the prenatal diagnosis of syntelencephaly, allowing prompt identification of the interhemispheric fusion in the high frontoparietal convexity. Moreover, we found that 100% of our cases presented with lateral sulcus dimorphism and absence of the CSP; and 80% with microcephaly and VM.

CLINICAL RELEVANCE/APPLICATION

Due to the subtlety of its imaging findings, syntelencephaly remains underdiagnosed prenatally. Improving early recognition through detailed neurofetal imaging enhances diagnostic accuracy, permits better parental counseling, and aids multidisciplinary perinatal planning. This study contributes to refining diagnostic criteria and emphasizes the role of specialized imaging in improving clinical outcomes.

Abstract Archives of the RSNA, 2025

M5A-SPPH-2 (PIXEL) SIZE MATTERS: THE SMALL PIXEL EFFECT IN ULTRA-LOW-DOSE MIDFACE CT

Henner Huflage, MD (*Presenter*)
Andreas Kunz, MD (*Abstract Co-Author*)
Caroline Bestler, MD (*Abstract Co-Author*)
Tobias Wech (*Abstract Co-Author*)
Thorsten A. Bley, MD (*Abstract Co-Author*)
Jan P. Grunz, MD (*Abstract Co-Author*)

PURPOSE

Examinations with ultra-high-resolution (UHR) collimation do not entail a dose burden in photon-counting CT (PCCT), since no post-patient filter is required to narrow the detector aperture. This study investigated whether the acquisition of smaller pixels in UHR mode holds advantages compared with standard-resolution scans of the midface region.

METHODS AND MATERIALS

Fourteen cadaveric heads were examined using both UHR (120 × 0.2 mm) and standard collimation (144 × 0.4 mm) on twelve dose levels (0.08-10 mGy) with a first-generation cadmium-telluride PCCT scanner. UHR images were reconstructed with three dedicated bone kernels (Br64 [spatial frequency at 10% of the modulation transfer function 12.8 line pairs/cm], Hr76 [21.0] and Hr84 [27.9]), whereas only Hr64 and Hr76 could be used for standard-resolution data. Signal-to-noise ratios (SNR) were computed among all datasets. In addition, image quality was assessed subjectively by nine independent radiologists using an in-house programmed forced choice comparison tool totaling 15,930 performed pairwise tests.

RESULTS

Comparing reconstructions with the sharp Hr76 kernel, SNR was higher in UHR images than in standard-resolution data on each dose level (all P <.001). In contrast, no significant difference was established between reconstructions with the intermediate Hr64 kernel (all P =.30). When acquiring data in UHR mode, sharper reconstructions (i.e., Hr84 instead of Hr76 and Hr76 instead of Hr64) were feasible without a significant loss of SNR (all P =.06). Subjective assessment revealed high interrater agreement (Fleiss kappa = 0.711, 95% confidence interval 0.689-0.734) with sharp UHR images being preferred by readers in the majority of comparisons on each dose level.

CONCLUSION

In PCCT of the midface, the smaller pixel size of UHR data allows for a substantial SNR increase over standard-resolution imaging, when employing comparable reconstruction sharpness. This 'small pixel effect' can either be used for dose reduction or higher spatial resolution depending on the convolution kernel selection.

CLINICAL RELEVANCE/APPLICATION

Not entailing a dose burden in PCCT, data acquisition in UHR mode facilitates higher SNR for midface imaging tasks with different dose requirements (i.e., rhinosinusitis, preoperative planning, trauma).

M5A-SPPH-3 HAGGAN: HYBRID-LOSS AND ATTENTION-GUIDED MRI-TO-CT SYNTHESIS FOR INTRACRANIAL CALCIFICATION

Yijun Lv (*Presenter*)
Genggeng Qin, MD, PhD (*Abstract Co-Author*)

PURPOSE

Intracranial calcifications, commonly observed in brain tumors and physiological conditions, hold significant clinical value in diagnosis, radiotherapy planning, and prognosis evaluation. However, due to the inherently low sensitivity of MRI to calcium and bone-like structures, accurately detecting and characterizing calcifications on MRI remains a substantial challenge. This study aims to address this technical limitation by proposing a cross-modal image synthesis algorithm based on a conditional generative adversarial network (cGAN) . We developed and evaluated a novel supervised deep learning framework, termed HAGGAN (Hybrid-Attention-Guided GAN) , which generates high-fidelity synthetic CT (sCT) images from paired MRI inputs to enhance the visualization of calcified structures in MRI-guided workflows.

METHODS AND MATERIALS

The proposed HAGGAN framework incorporates a hybrid objective function and an attention gate (AG) mechanism , with ResNet serving as the backbone network, to produce high-quality sCT images. The dataset included images from 177 patients with brain tumors and 51 patients with physiological calcifications . A total of 760 CT slices from 185 patients were used for training, and 188 CT slices from 47 patients were used for validation and testing. To benchmark HAGGAN’s performance, we compared it with several state-of-the-art supervised and unsupervised methods, including U-Net, Pix2Pix, LSeSim, and CycleGAN. The quality of the generated sCT images was quantitatively assessed using mean absolute error (MAE) , peak signal-to-noise ratio (PSNR) , and structural similarity index measure (SSIM) .

RESULTS

Compared with U-Net, Pix2Pix, LSeSim, and CycleGAN, the proposed HAGGAN outperformed existing supervised and unsupervised approaches in both quantitative and qualitative evaluations. Specifically, it achieved an MAE of 0.032 , an SSIM of 0.815 , and a PSNR of 21.245 dB .

CONCLUSION

Experimental results demonstrate that HAGGAN can generate sCT images with high fidelity in terms of fine calcifications, brain parenchyma, and lesion regions, achieving visual similarity to real CT (rCT) images. In quantitative evaluations, HAGGAN consistently outperformed other advanced methods, including U-Net, Pix2Pix, LSeSim, and CycleGAN.

CLINICAL RELEVANCE/APPLICATION

HAGGAN addresses the technical bottleneck of MRI in identifying calcified and osseous components with high accuracy. It offers valuable support for clinical diagnosis, tumor recurrence monitoring, and prognosis evaluation, enhancing diagnostic precision in neuroimaging. Furthermore, by reducing the need for unnecessary CT scans, it may lessen the imaging burden on patients and optimize clinical workflows.

M5A-SPPH-5 FEASIBILITY OF 50% REDUCTION OF IODINATED CONTRAST MEDIA WITHOUT COMPROMISING IMAGE QUALITY USING PHOTON COUNTING CT: A PHANTOM-BASED APPROACH

Ayuto Ito, BS (*Presenter*)
Hiroki Kawashima, PhD (*Abstract Co-Author*)
Katsuhiro Ichikawa, PhD (*Abstract Co-Author*)
Yasuhiro Kawahara (*Abstract Co-Author*)
Kyo Noguchi, MD (*Abstract Co-Author*)

PURPOSE

To demonstrate the feasibility of a 50% reduction of iodinated contrast media using photon counting CT via a phantom-based approach using diluted-iodine equivalent materials with 6 and 12 mg/mL iodine concentrations that were formed to simulated shapes of large and small contrast-enhanced vessels.

METHODS AND MATERIALS

Two phantom compositions were used in this study. One was that two rod-shaped inserts with the same 30-mm diameter (30-mm target) and the 6 and 12 mg/mL iodine concentrations were placed into a water phantom with a diameter of 300 mm. The other was the same water phantom in which the two inserts were replaced with two wire-shaped inserts with the same 2-mm diameter (2-mm target). Each phantom was scanned using three CT scanners at CTDI of 15 mGy: 64-row multi-slice CT with single energy 120 kV (SE 120 kV), dual-source dual-energy CT (DECT) with 80/Sn150 kV, and photon counting CT (PCCT) with 120 kV. For DECT and PCCT, virtual monoenergetic images at 50 and 40 keV were generated. The mean CT number and task transfer function (TTF) were measured using the 30-mm target. For the 2-mm target, a synthetic oversampled image of the wire over the scan range was generated for analysis; a peak CT number and TTF were measured using the established wire method. The image noise (SD) was measured in the uniform water region. A contrast-to-noise ratio (CNR) and a peak signal-to-noise ratio (PSNR) were calculated from the mean and the peak CT numbers divided by the SD. We compared the measurements obtained with the 12 mg/mL iodine insert for SE 120 kV with those obtained with the 6 mg/mL iodine insert for low keV images.

RESULTS

For the 30-mm target, 50%TTFs were approximately 0.41, 0.34, and 0.40 mm -1 for SE 120 kV, DECT 50 keV, and PCCT 50 keV, respectively. The 6 mg/mL iodine CNRs of DECT and PCCT at 50 keV were higher than the 12 mg/mL iodine CNR of SE 120 kV. For the 2-mm target, 50%TTFs were approximately 0.38, 0.28, and 0.36 mm -1 for SE 120 kV, DECT 50 keV, and PCCT 50 keV. While the 12 mg/mL iodine PSNR of SE 120 kV was 3.9, the 6 mg/mL iodine PSNR of DECT and PCCT at 50 keV were 2.9 and 4.2; those at 40 keV were 3.0 and 5.1.

CONCLUSION

This study demonstrated that PCCT can provide higher iodine CNR and PSNR by the low keV reconstruction, even with half the iodine concentration of SE 120 kV. This study also revealed that the low keV imaging of DECT is insufficient for small vessels, while the PCCT has no such shortage.

CLINICAL RELEVANCE/APPLICATION

The low keV reconstruction of PCCT helps to reduce the patient's iodine burden without compromising image quality, even for small vessels, compared with the widely used SE 120 kV CT.

M5A-SPPH-6 BMI-BASED CONTRAST MEDIA OPTIMIZATION IN CT ANGIOGRAPHY: A SCALABLE APPROACH TO SAFER AND MORE SUSTAINABLE IMAGING

Alessandro Roncacci, MD, PhD (*Presenter*)
Chryssa Paraskevopoulou, MSc (*Abstract Co-Author*)
Cristian Colmo (*Abstract Co-Author*)
Milda Vaisvilaite-Vasilionoke (*Abstract Co-Author*)
Daiva Adomaitiene (*Abstract Co-Author*)
Athanasia Papachristodoulou, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the impact of a BMI-based contrast media and radiation dose optimization protocol for CT angiography, developed as part of a broader strategy to improve patient safety, standardize clinical practice, and promote sustainable imaging.

METHODS AND MATERIALS

A contrast media optimization protocol was developed and piloted at a high-volume European imaging site. Patients undergoing cardiac and peripheral vascular CT angiographies were stratified into three BMI categories (18-25, 25-30, >30). The intervention included standardization of contrast protocols tailored to specific clinical indications, along with comprehensive staff training on safe and effective contrast administration Contrast volume, injection flow rates, and CT acquisition parameters were tailored to each category. Lower tube voltage settings (80-100 kV) were employed when feasible to enhance iodine efficiency via its k-edge while minimizing radiation dose. A radiation dose monitoring system was used to automatically capture patient data, contrast usage, and CTDIvol, enabling a data-driven approach to protocol evaluation and refinement.

RESULTS

Post-implementation analysis demonstrated substantial reductions in both contrast volume and radiation dose. In patients with BMI >30, contrast volume was reduced by 15% and CTDIvol by 10%. For BMI 25-30, contrast volume decreased by 6% and CTDIvol by 19%. In the BMI 18-25 group, Constrast volume was reduced by 9% and CTDIvol by 33%. Across all BMI groups, diagnostic quality was preserved, according to radiologists feedback and with vascular enhancement values consistently within the 350-400 HU target range. Protocol adherence improved, and contrast media use was significantly reduced. The approach is now being adapted for broader implementation across additional imaging sites and procedure types.

CONCLUSION

BMI-based optimization of contrast media and radiation dose in CT angiography is feasible, safe, and clinically effective. This protocol supports a scalable model that enhances diagnostic consistency, reduces patient exposure, and aligns imaging practice with environmental responsibility.

CLINICAL RELEVANCE/APPLICATION

This protocol shows that personalized contrast dosing and acquisition settings based on BMI can improve patient safety, reduce contrast waste, and maintain high-quality imaging outcomes. It offers a practical framework for scaling sustainable imaging practices across radiology networks.

M5A-SPPH-7 CHANGES IN CERVICAL INTERVERTEBRAL DISCS AFTER FLIGHT TRAINING IN NATIONAL GUARD FIGHTER PILOTS

L. Tugan Muftuler, PhD (*Presenter*)
Aditya Vedantam (*Abstract Co-Author*)
Rachel Cutlan (*Abstract Co-Author*)

Keri Hainsworth (*Abstract Co-Author*)
Benjamin Gerds (*Abstract Co-Author*)
Chris Dooley (*Abstract Co-Author*)
Peter Le (*Abstract Co-Author*)
Timothy Meier (*Abstract Co-Author*)
Narayan Yoganandan (*Abstract Co-Author*)
Brian Stemper (*Abstract Co-Author*)

PURPOSE

Neck pain is more prevalent in fighter pilots than other military personnel or civilians. Head rotations during high-g maneuvers strain the cervical spine and expose the discs to injury, triggering degenerative processes that cause pain. Investigating disc changes after flight training can reveal the types of injuries caused by these exposures, ultimately promoting spinal health by fostering the design of more ergonomic environments, training protocols, and gear.

METHODS AND MATERIALS

Eighteen fighter pilots completed a baseline, ten of which participated in follow-up MRI after flight training (ages 28-49y, mean 39.3; military flight hours 500-3500h, mean 2312h). Nineteen age-matched civilian controls were included for comparisons. Participants completed demographic, flight history, and pain questionnaires. Study was approved by IRB and written consents were obtained. Discs were automatically labeled by nnUNet on T2 weighted MRIs and radiomics features were calculated in each disc. Feature values were compared before and after the training, and between pilots and controls.

RESULTS

Paired t-tests revealed lower mean MRI signal in all discs ($p<0.001$), increased kurtosis ($p=0.01$) and skewness ($p<0.001$), primarily in C3C4 and C4C5, after flight exposure. These changes collectively suggest measurable disc hydration loss. T-tests showed lower kurtosis, skewness, and higher mean for the pilots at baseline compared to matched controls (all $p<0.001$). ANOVA with height as covariate revealed no significant differences in disc volume between pilots and controls. These indicate that water content in discs was higher for the pilots, and there was no measurable disc height loss.

CONCLUSION

Radiomics analysis provided a quantitative, unbiased and precise assessment of changes in discs after flight training. Disc dehydration seen in the pilots after training was expected since it is common after heavy physical exercises and recovers with rest. The disc heights were comparable to matched controls, but pilots had better hydrated discs, possibly due to better physical fitness. Disclosure: Views expressed are those of the authors and do not reflect the official views of the USAF, nor the Department of Defense. Mention of trade names, commercial products, or organizations do not imply endorsement by the U.S. Government. Acknowledgements: This research was part of the Military Aircrew Neck and Back Pain Study, and was supported by Air Force Research Laboratory contract FA8650-22-C-6461 and the Department of Veterans Affairs Medical Research.

CLINICAL RELEVANCE/APPLICATION

Understanding neck injuries in individuals exposed to periods of heavy spine loading is crucial for developing effective prevention and treatment strategies.

M5A-SPPH-9 COMPARATIVE EFFECTIVENESS OF TERIPARATIDE-DENOSUMAB SEQUENTIAL VERSUS DENOSUMAB MONOTHERAPY IN ACUTE POST-FRACTURE OSTEOPOROSIS MANAGEMENT: A 12-MONTH RANDOMIZED TRIAL

Fang Wang (*Presenter*)

PURPOSE

To evaluate differential bone mineral density (BMD) responses between teriparatide-to-denosumab sequential therapy versus denosumab monotherapy during the critical 6-month post-fracture window in osteoporosis patients.

METHODS AND MATERIALS

The trial enrolled 39 patients with acute fractures (=6 months post-injury) at our hospital between June 2023 to June 2024. Participants were randomized to 1) sequential group (n=18): Teriparatide 20 μg/day subcutaneously ×6 months ? Denosumab 60mg biannually; 2) Monotherapy group (n=21): Denosumab 60 mg biannually. All patients received calcium, vitamin D supplementation and standardized osteoporosis education. Dual-energy X-ray absorptiometry (GE Lunar iDXA) measured BMD at lumbar spine (LS), femoral neck (FN), and total hip (TH) for every six months. Clinical outcomes included biochemical markers, VAS, and incident fracture events.

RESULTS

There were no significant differences in baseline characteristics between groups except for elevated bone turnover markers in the sequential groups (P1NP: 55.8 vs 46.5 ng/ml; ß-CTX:682.5 vs 428 pg/ml, both $p<0.05$). Both regimens significantly improved BMD at 12 months (all sites $p<0.05$ vs baseline), with sequential therapy exhibiting superior gains at LS (+ 12.25%±7.07% vs + 6.36%±5.80%, $p<0.05$) and TH (median +5.71% [IQR 2.12%-8.24%] vs +2.13% [0.14%-3.69%], $p<0.05$). Significant reduction in VAS (both $p<0.05$ vs baseline) and comparable new fracture incidence (sequential group: 5.6%; monotherapy: 4.8%) were observed in both groups. Declined P1NP and ß-CTX were also observed in both groups (both $p<0.05$ vs baseline), though intergroup differences did not reach statistical significance.

CONCLUSION

While both regimens effectively reduce pain and bone turnover markers (P1NP, ß-CTX), sequential therapy (Teriparatide-to-Denosumab) demonstrates superior gains in BMD at LS and TH for those acute post-fracture patients compared to denosumab monotherapy.

CLINICAL RELEVANCE/APPLICATION

The sequential treatment strategy of osteoporosis provides an important idea for optimizing long-term management. For patients with extremely high fracture risk, it is recommended to give priority to the use of bone formation drugs, then sequential inhibition of bone resorption drugs, which significantly increase BMD and reduce fracture risk.

M5A-SPPH-10 TECHNOLOGICAL INTEGRATION BETWEEN CANON PRIME SP WITH BAYER SMART INJECTOR: CLINICAL AND ECONOMIC BENEFITS IN PULMONARY ANGIOTOMOGRAPHY

Jose Castro, PhD (*Presenter*)
Hortencia Ferreira, MSc, PhD (*Abstract Co-Author*)
Danielle Cristina Novais Da Silva (*Abstract Co-Author*)
Sergio S. Dertkigil, MD (*Abstract Co-Author*)
Fabiano Reis (*Abstract Co-Author*)

PURPOSE

The evolution of computed tomography (CT) includes AI and automated injection systems to optimize imaging and resource use. Canon Prime SP applies AI for image enhancement and dose reduction, while Bayer's Medrad Stellant SmartFlow ensures precise contrast control, reducing waste. This study evaluates the clinical and economic impact of integrating these technologies.

METHODS AND MATERIALS

Pulmonary angiotomography exams from two CT systems were retrospectively analyzed: Aquilion 64 CT (2008) and Canon Prime CT (2024) with AiCE (Advanced Intelligent Clear IQ Engine). The Canon Prime used the Medrad Stellant SmartFlow(Bayer) injector for real-time contrast monitoring. A total of 200 exams from 2024

(Canon Prime SP) and 100 exams from 2023 (Aquilion 64) were compared. Only patients aged 18 years or older were included. Parameters assessed included radiation dose (DLP, mGy·cm), contrast volume (mL), vascular enhancement (HU), and image acquisition time (s) to determine the impact of technological integration.

RESULTS

The use of Canon Prime SP, combined with Bayer's intelligent injector, brought significant advances in radiation dose optimization, contrast savings, and image quality. AI implementation in Canon Prime SP allowed up to 72% reduction in radiation dose compared to the Aquilion 64, without compromising diagnostic quality. The intelligent injector enabled an 18.75% saving in contrast per exam, averaging a 16 mL reduction per procedure. Considering a routine of three PET exams per day and a unit cost of R$1.50/mL, estimated annual savings reach R$26,280.00. Image quality was maintained or improved through AI, with enhanced sharpness and noise reduction, allowing lower radiation doses. Another key benefit was improved contrast traceability and safety. Bayer's system enabled real-time monitoring of variables such as batch, expiration date, pressure, and flow—minimizing adverse events and standardizing processes. It also allowed automatic generation of individualized injection reports sent to the PACS, ensuring better control of contrast administration.

CONCLUSION

The incorporation of newer technologies reduces patient radiation exposure, improves image quality, and optimizes costs, reinforcing the need for continuous protocol updates.

CLINICAL RELEVANCE/APPLICATION

These findings highlight the importance of implementing customized protocols per device to maximize diagnostic efficiency and promote safety and sustainability in pulmonary angiotomography.

M5A-SPPH-11 DEEP LEARNING IMAGE RECONSTRUCTION ENHANCES DIASTOLIC CORONARY CTA IMAGE QUALITY UNDER TRIPLE-LOW PROTOCOLS ACROSS BMI CATEGORIES

Xiaohua Zhang (*Presenter*)
Xiaoyan Lei (*Abstract Co-Author*)
Feng Chen, MD, PhD (*Abstract Co-Author*)
Weiyuan Huang (*Abstract Co-Author*)
Kun Ma (*Abstract Co-Author*)

PURPOSE

To investigate the efficacy of high-strength deep learning image reconstruction (DLIR-H) in improving diastolic-phase coronary CTA image quality across body mass index (BMI) strata under a triple-low protocol (low radiation dose, low contrast volume, low injection rate), in comparison with 50% adaptive statistical iterative reconstruction (ASIR-V).

METHODS AND MATERIALS

In this prospective single-center study, 47 patients with suspected coronary atherosclerosis underwent coronary CTA between August 2024 and April 2025. Patients were grouped by BMI: Group A (<24 kg/m², n=20), Group B (24-28 kg/m², n=21), and Group C (>28 kg/m², n=6). Scans were performed at 70, 80, or 100 kVp with tailored contrast doses (35-55 mL) and injection rates (3.0-5.0 mL/s), followed by 40 mL saline flush. Diastolic-phase datasets were reconstructed using both DLIR-H and ASIR-V 50%. Quantitative evaluation included CT attenuation, image noise (standard deviation), signal-to-noise ratio (SNR), and contrast-to-noise ratio (CNR) across major coronary segments (LM, pLAD, pLCX, pRCA, mRCA, dRCA) and the aortic root (AO). Image quality was rated independently by two experienced cardiothoracic radiologists on a five-point Likert scale, with inter-observer consistency assessed using Kappa statistics.

RESULTS

DLIR-H significantly enhanced image quality in all BMI groups. In Group A, DLIR-H reduced pRCA noise (51.92 ± 16.38 to 40.61 ± 14.76, $P < 0.001$) and increased AO CNR (21.5 ± 8.1 to 36.09 ± 12.87, $P < 0.001$). In Group B, LM noise decreased (38.32 ± 9.17 to 29.78 ± 8.97, $P < 0.001$) and dRCA SNR improved (12.43 ± 5.13 to 15.18 ± 5.30, $P < 0.001$). In Group C, AO noise dropped substantially (29.95 ± 10.35 to 15.85 ± 4.62, $P = 0.002$), with a marked increase in pRCA CNR (25.92 ± 11.19 to 46.65 ± 19.14, $P = 0.002$). Subjective image quality ratings were significantly higher for DLIR-H across all BMI categories (Group A: $P = 0.003$; Group B: $P < 0.001$; Group C: $P = 0.022$), with excellent interobserver agreement (Kappa > 0.8). Despite BMI-associated increases in effective dose (Group A: 0.77 ± 0.14 mSv; Group B: 1.34 ± 0.25 mSv; Group C: 2.02 ± 0.58 mSv, all $P < 0.05$), DLIR-H consistently maintained superior image quality under reduced exposure conditions.

CONCLUSION

DLIR-H markedly enhances diastolic coronary CTA quality across BMI levels, reducing noise and improving contrast under ultra-low-dose protocols.

CLINICAL RELEVANCE/APPLICATION

DLIR-H delivers high-quality diastolic coronary imaging under reduced radiation and contrast, supporting accurate diagnosis, especially in overweight patients.

M5A-SPRO-1 LOCATION ACCURACY AND REPRODUCIBILITY OF ISOCENTERS USING TRANSARTERIAL MARKERS FOR SBRT OF LIVER LESIONS

Nasreddin Abolmaali, MD (*Presenter*)
PHILIPP SCHILLING (*Abstract Co-Author*)
Stephanie Abolmaali (*Abstract Co-Author*)
Seyed Schahin Tillmann Abolmaali (*Abstract Co-Author*)

PURPOSE

In patients with liver tumors SBRT may require markers for accurate treatment planning. Transarterial placed coil markers (TAM) are safer than percutaneously inserted markers since only one puncture is required and risks of puncture (e.g. pneumothorax, liver bleeding, tumor seeding) and marker migration are avoided. The aim of our study was to determine whether TAM show spatial stability of the markers position in tissue during the duration of the entire treatment. Additionally, we investigated the precision of the definition of the tumor isocenter (TI) as specified by TAM during therapy.

METHODS AND MATERIALS

Between January 2017 and March 2020, twelve patients received 2-4 TAM for liver SBRT. TAM were placed in close vicinity around the liver tumors using coaxial transarterial coils (length 10mm) placed in tumor feeding arteries. 4D-averaged CTs fused with MRI were used for ITV contouring, a total of 140 fractions were allocated with safety margins of 10mm. For all fractions, a CBCT was acquired to verify tumor and TAM location. Local stability of TAM during the entire therapy were measured in every CBCT by distance measurements between the coils in each fraction and the movement of their center-of-mass (COM) over time. Additionally, the fusion of the TIs as defined by the physician was compared to the TI that resulted from the automatic generated isocenter using TAM.

RESULTS

Eight patients received two markers and were treated with 108 fractions; four patients were treated with eight fractions each, three of them received three markers and one patient received four markers. TAM appeared as a 32 mm² structure on average in the CBCT of the linac and produced only minor artifacts. The average distance between the markers was 50.5 mm and the mean difference of COMs, i.e. the inter-fractional movement over the treatment time, was 1.5mm±1.1mm(SD). The upper quartile of the mean difference of COMs was less than 2.0mm, in one patient the maximum deviation in one fraction was 5.5mm. None of the TAM left the liver. The distance between the TIs positioned by a physician and the TIs generated by the automatic matching algorithm applied to the TAMs resulted in a mean deviation of 3.5mm±2.6mm(SD) during the entire therapy and thus revealed almost identical positions.

CONCLUSION

TAM for SBRT of liver lesions showed high local spatial stability over the entire therapy allowing for accurate tumor localization using CBCT for each fraction. Definition of tumor isocenters for every fraction using TAM and automatic matching was fast and revealed high accuracy.

CLINICAL RELEVANCE/APPLICATION

Since TAM are as accurate as percutaneous markers for liver SBRT, but provide an advantageous safety profile, we recommend TAM as new standard for accurate and fast treatment planning in SBRT of the liver.

M5A-SPVA-1 IMPROVED DETECTION OF ASCENDING AORTITIS USING MOTION-CORRECTED DIFFUSION-WEIGHTED MRI

Tomoko Hyodo, MD (*Presenter*)
Hayato Kaida (*Abstract Co-Author*)
Atsushi K. Kono, MD, PhD (*Abstract Co-Author*)
Yuji Nozaki (*Abstract Co-Author*)
Kazunari Ishii, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the diagnostic performance of diffusion-weighted MRI with Acceleration Motion Compensation (AMC-DWI) in detecting inflammation of the ascending aorta in patients with suspected or diagnosed large-vessel vasculitis.

METHODS AND MATERIALS

This retrospective study included patients who underwent whole-body MRI at 1.5T, consisting of DWI (b = 800) with and without AMC, and balanced turbo field echo (b-TFE) sequences, and also underwent FDG-PET/CT within ±2 weeks of MRI. Patients with prior thoracotomy or insufficient image quality were excluded. For ascending aorta, signal intensity was scored on DWI (0-3), and diagnostic confidence for ascending aortitis was scored (0-4) using DWI with and without AMC. Diagnostic confidence was also reassessed by adding b-TFE to AMC-DWI; b-TFE was used to assess the anatomical position and wall thickening of the ascending aorta, providing supplemental information to support diagnostic confidence. FDG-PET/CT served as the reference standard based on binary visual assessment of FDG uptake in the ascending aorta: uptake equal to or greater than that of the liver was defined as positive (ascending aortitis), while uptake below that of the liver was defined as negative. Target-to-background ratio (TBR; SUVmax of the ascending aorta / SUVmean of the superior vena cava) was also calculated for correlation analysis.

RESULTS

Thirty-one patients (mean age, 61 years; 24 women) were included. DWI signal score increased after applying AMC, and this change tended to be greater in PET-positive aortitis cases, although the difference was not statistically significant (Wilcoxon rank-sum test, p = 0.162). Diagnostic confidence score with AMC-DWI showed higher diagnostic performance for detecting ascending aortitis than non-AMC-DWI (AUC: 0.84 vs. 0.62, ROC analysis). The addition of b-TFE slightly increased the AUC to 0.85, with no significant differences among the three (DeLong's test, all p > 0.1). In PET-positive aortitis, the increase in diagnostic confidence score after applying AMC was significantly greater than in PET-negative cases (Wilcoxon rank-sum test, p = 0.011). Additionally, AMC-DWI confidence score showed a significant positive trend with increasing PET-derived TBR (Jonckheere-Terpstra test, p = 0.050).

CONCLUSION

AMC-DWI outperformed non-AMC-DWI in detecting ascending aortitis, demonstrating higher signal intensity and diagnostic confidence, and showing consistency with PET-based TBR.

CLINICAL RELEVANCE/APPLICATION

Incorporating motion-corrected DWI for the ascending aorta may enhance the feasibility of whole-body MRI as a practical tool for evaluating large-vessel vasculitis, offering a radiation-free alternative to FDG-PET/CT.

M5A-SPVA-2 FULLY AUTOMATED DETECTION SYSTEM FOR ABDOMINAL AORTIC ANEURYSM USING DEEP LEARNING AND API INTEGRATION

Taehun Kim, PhD (*Presenter*)
Kim Jiyoon (*Abstract Co-Author*)
Yongwon Cho, PhD (*Abstract Co-Author*)
Hyokee Kim (*Abstract Co-Author*)
Yeo Eun Han, MD, PhD (*Abstract Co-Author*)

PURPOSE

Although abdominal CT is widely performed for various clinical indications and consistently includes the abdominal aorta within its field of view, radiologists often overlook subtle changes in aortic diameter during routine interpretations, as these scans are typically not acquired with aortic pathology in mind. However, an abdominal aortic diameter of 3 cm or greater necessitates regular follow-up due to the risk of aneurysmal progression and potential rupture. While automated algorithms for measuring aortic diameter have been explored, none have specifically targeted portal venous phase (PVP) abdominal CT, which represents the standard imaging phase for most abdominal CTs. This study is to develop a fully automated algorithm using deep learning (DL) and an application programming interface (API) for measurement of the abdominal aortic diameter on PVP abdominal CT, thereby facilitating incidental detection of early abdominal aortic aneurysm (AAA) in routine clinical practice.

METHODS AND MATERIALS

PVP abdominal CT scans from 332 patients including normal and AAA were enrolled from two institutions between 2004 and 2023. A total of 232 AAA cases (212 and 20 from each institution) were manually segmented by medical doctors. The nnU-Net was used 90% and 10% for training and test, respectively. An independent test dataset consisting of 100 AAA patients from the original cohort and 100 additional controls were predicted and converted into 3D models. A manual 3D measurement protocol was established and then used to develop a fully automated algorithm using API. Segmentation performance was evaluated using the Dice similarity coefficient (DSC) and 95th percentile Hausdorff distance (HD95). Automated measurement was compared with manual ones, and diagnostic performance was evaluated using a 3 cm clinical threshold.

RESULTS

The segmentation achieved a DSC of 0.9250 ± 0.0390 and an HD95 of 6.11 ± 9.24 mm. The differences between manual and automated measurements were 3.77 ± 2.14 mm for normal and 3.81 ± 3.37 mm for AAA. Measurement time was reduced by 16.92-fold for normal and 5.02-fold for AAA using automation. Manual

measurement showed one false positive and false negative, whereas automated measurement showed three false positives.

CONCLUSION

We developed a DL and API-based system for automated segmentation and measurement of AAA, on PVP abdominal CT. It demonstrated high accuracy and significantly improved efficiency, overcoming limitations of manual approaches.

CLINICAL RELEVANCE/APPLICATION

Given the high mortality and complications of AAA, early diagnosis through accurate measurement is crucial. This study presents a clinically applicable DL and API-based system that offers a reliable and efficient solution for automated AAA screening.

M5A-SPVA-3 THE USE OF LOW-CONCENTRATION IODINE CONTRAST AGENTS AND DUAL-ENERGY CT (DECT) IS SUPERIOR TO THE USE OF HIGH-CONCENTRATION IODINE CONTRAST AGENTS AND SINGLE-ENERGY CT (SECT) IN TERMS OF BOTH CONTRAST ENHANCEMENT AND PREVENTION OF RENAL DYSFUNCTION IN AORTIC CT ANGIOGRAPHY

Akira Yamada, MD, PhD (*Presenter*)
Hiroyuki Kubota (*Abstract Co-Author*)
Yasunari Fujinaga, MD (*Abstract Co-Author*)

PURPOSE

Low-keV virtual monochromatic X-ray CT imaging (VMCT) using dual-energy CT (DECT) is expected to strengthen contrast-enhanced effect of iodinated contrast agents (CA), thereby potentially reducing risk of acute kidney injury (AKI) associated with iodine dose reduction. However, to date, there have been no reports comparing CT-Angiography (CTA) with use of low-concentration CA and DECT (LC-DE-CTA) and CTA with use of high-concentration CA with single-energy CT (HC-SE-CTA) in terms of both contrast enhancement and prevention of AKI. The purpose of this study is to verify that LC-DE-CTA is superior to HC-SE-CTA in terms of both contrast enhancement and prevention of AKI.

METHODS AND MATERIALS

This retrospective study at a single institution was approved by institutional ethics committee, and informed consent from patients was waived. This study included 679 patients with 1,053 examinations who underwent multiple CTA examinations for preoperative evaluation and postoperative follow-up of aortic diseases between December 2018 and November 2024, with renal function assessment via blood sampling within 74 hours of CT examination. During entire study period, initial examination was performed as HC-SE-CTA using high-concentration CA (370 mgI/mL, 100 mL), and for subsequent examinations, HC-SE-CTA was performed during first half of study period, and LC-DE-CTA using a low-concentration CA (240 mgI/mL, 100 mL) with 50 keV VMCT was performed during second half of study period. Tube voltage in HC-SE-CTA was 120 kVp. Contrast effect was evaluated based on CT values of ascending aorta in CTA. Stage of AKI was assessed using serum creatinine levels before and after CTA from 0 (no AKI) to 3 according to KDIGO 2012 criteria. A stepwise linear regression analysis was performed with stage of AKI as the dependent variable and pre-examination estimated glomerular filtration rate (eGFR), sex, age, use of low-concentration CA, initial or subsequent examination, and examination period as explanatory variables.

RESULTS

Mean CT values and 95% confidence intervals of ascending aorta were 363.4 (351.6-375.1) HU in HC-SE-CTA, 523.6 (504.5-542.7) HU in LC-DE-CTA. Mean stage and its 95% confidence intervals of AKI was 0.12 (0.09-0.14) in HC-SE-CTA, 0.04 (0.02-0.07) in LC-DE-CTA. Stepwise linear regression analysis revealed that only pre-examination eGFR ($P < 0.001$) and the use of low-concentration CA ($P = 0.01$) are statistically significant predictors for stage of AKI after CTA.

CONCLUSION

LC-DE-CTA is superior to HC-SE-CTA in terms of both contrast enhancement and prevention of AKI.

CLINICAL RELEVANCE/APPLICATION

By combining low-concentration CA with DECT, it is possible to perform safe and high-quality CTA in patients at risk of renal dysfunction.

M5B-SPBR-1 PREDICTION OF HIGH AND LOW EXPRESSION OF TUMOR-INFILTRATING LYMPHOCYTES (TILS) IN BREAST CANCER USING MRI BI-RADS FEATURES AND CLINICOPATHOLOGICAL PARAMETERS

Jiejie Zhou, PhD, MD (*Presenter*)
Yang Zhang, PhD (*Abstract Co-Author*)
Yan-Lin Liu (*Abstract Co-Author*)
Jeon-Hor Chen, MD (*Abstract Co-Author*)
Wang Meihao (*Abstract Co-Author*)
Min-Ying Su, PhD (*Abstract Co-Author*)

PURPOSE

Tumor-infiltrating lymphocytes (TILs) in breast cancer are known as promising predictive biomarkers associated with responses to neoadjuvant chemotherapy and immunotherapy, and they are also prognostic biomarkers associated with progression-free survival. The assessment based on a small biopsy specimen may suffer from sampling bias. This study aimed to investigate how the MRI features and clinical/histological parameters can be combined to distinguish high and low TILs groups.

METHODS AND MATERIALS

A total of 678 patients with pathologically diagnosed BC were included in the study, divided into training and testing sets with approximately a 7:3 ratio. MRI features were reviewed by two radiologists by consensus using BI-RADS lexicon descriptors. The expression of TILs was evaluated on H&E-stained slides. The percentage of TILs in the stroma adjacent to the tumor cells was assessed, and they were separated into low (<10%) and high (= 10%) groups. The machine learning models were trained to differentiate the two groups. Initially, a support vector machine (SVM) classifier was trained using imaging features to distinguish between the two groups and provided an imaging score, which reflects the likelihood of high or low TILs expression based on imaging alone. Then, the imaging score was added to the clinical and histological parameters (age, age = 50, ER, PR, menopause, N-stage, Ki-67) to train a nomogram model and a final combined SVM machine learning model. The predictions were evaluated using Receiver Operating Characteristic (ROC) analysis.

RESULTS

When only using imaging features, the SVM achieved an AUC of 0.79 on the training set and 0.74 on the testing set. By combining the imaging score with clinical and molecular biomarkers, the predictive performance improved. The nomogram model achieved an AUC of 0.81 in training and 0.79 in testing, showing a modest enhancement in prediction accuracy. The SVM model using both feature sets yielded the best performance, reaching an AUC of 0.84 in training and 0.81 in testing sets. Figure 1 illustrates two cases with HR+/HER2- subtype BC with high and low TILs. Figure 2 shows two HER2+ cases, and Figure 3 shows two triple-negative cases. Figure 4 shows the nomogram developed by using all parameters.

CONCLUSION

Machine learning algorithms using integrated pre-treatment MRI features and molecular/clinical features can be used to build models for predicting TIL expression, which may contribute to refined stratification and personalized management.

CLINICAL RELEVANCE/APPLICATION

MRI features and molecular biomarkers could differentiate high vs. low TILs. Sophisticated machine learning models combining MRI and clinical-histological parameters could further improve accuracy to guide treatment selections.

M5B-SPBR-2 TRENDS IN POSITIVE BREAST BIOPSY RATES IN WOMEN UNDER 40

Annina N. Wilkes, MD (*Presenter*)
Nafisa Reya (*Abstract Co-Author*)
Jason Shames, MD (*Abstract Co-Author*)

PURPOSE

The incidence of breast cancer is increasing in women. Recent data suggests that women under 40 are more likely to be diagnosed with later-stage and more aggressive breast cancer subtypes, leading to increased mortality rates. Non-Hispanic Black women under 40 have the highest incidence and mortality rates. Breast radiologists are often the first point of contact for these women to receive a workup, biopsy, and referral for surgical consultation. This retrospective study investigates the recent breast cancer trends in women under 40 at an academic breast imaging center.

METHODS AND MATERIALS

This IRB-approved retrospective study assessed the image-guided core-needle breast biopsy results for all women under age 40 from 2016 to 2024. The age, ethnicity, race and biopsy results were documented. Cancer subtype and receptor status were documented for patients diagnosed with breast cancer.

RESULTS

A total of 920 women under age 40 underwent an image-guided core biopsy from 2016-24 at our facility. Sixty-eight (7.4%) women were diagnosed with breast cancer, of which 61 (90%) had invasive disease. The average age of diagnosis was 31 years old, with the youngest patient being 17 years old. Among the patients with invasive breast cancer, 18 (30%) had triple negative breast cancer (TNBC). Over this time period, there was a relatively stable incidence of 1.3 cancers per month, with significant increases in 2019 (2.7 per month) and 2024 (2.3 per month). Among the patients diagnosed with breast cancer, 31 identified as Black (46%), 4 as Asian (6%), 3 as Hispanic (4%), and 29 as White (43%). Among the patients diagnosed with TNBC, 9 identified as Black (50%), 1 as Hispanic (6%), and 7 as White (39%).

CONCLUSION

While the overall incidence of breast cancer in women under 40 remains low, this study supports previously observed higher rates of aggressive cancer subtype (30% TNBC) in this age group compared to the typical rate of 15-20% in the routine screening patient population. While there was no statistically significant change in the observed incidence of breast cancer in women under 40 at our institution over our study period. Larger-scale reviews of cancer registry data would be important to confirm the trend in breast cancer incidence in women under 40.

CLINICAL RELEVANCE/APPLICATION

There is limited data on the increasing incidence of breast cancer in women under 40. Studies suggest this patient population has a higher incidence of aggressive breast cancer subtypes,. Further research is needed to evaluate the breast cancer trends in patients outside the routine screening age to determine if updates to screening recommendations or targeted assessment protocols are warranted.

M5B-SPBR-3 TOTAL-BODY STAGING AND SURGICAL PLANNING IN BREAST CANCER WITH PHOTON-COUNTING CT

Deborah Fazzini, MD, MD (*Presenter*)
Fatemeh Darvizeh, MD (*Abstract Co-Author*)
Daniela Maria Giacinta Bossi (*Abstract Co-Author*)
Marco Gerli (*Abstract Co-Author*)
Marco Ali, PhD (*Abstract Co-Author*)
Isabella Castiglioni (*Abstract Co-Author*)

PURPOSE

To assess photon counting detector computed tomography (PCD-CT) as a single session imaging modality for locoregional and systemic total-body staging in breast cancer patients, aiming to reduce reliance on MRI, lower contrast and radiation dose, and improve patient experience and surgical planning.

METHODS AND MATERIALS

A PCD-CT protocol for total body staging and surgical planning was developed, including virtual non-contrast, arterial (upper abdomen), portal (thorax and abdomen), and delayed phases (abdomen and brain), with spectral reconstruction. Contrast (Iomeron 400 mg/mL) was administered at 0.7 mL/kg via venous access in the arm contralateral to the tumor. The protocol was validated in 17 consecutive adult female patients (mean age: 51; range: 30-78) with biopsy proven breast cancer scheduled for neoadjuvant chemotherapy or mastectomy, retrospectively evaluated with available breast MRI. For confirmed malignancies, the abovementioned protocol was applied. In cases with mixed benign/malignant findings, an additional thoracic arterial phase was included, as benign nodules may enhance earlier, while malignancies are better seen in the venous phase. Two radiologists independently reviewed each case on PCD-CT and MRI, assessing the primary tumor, locoregional lymph nodes, and extramammary findings.

RESULTS

PCD-CT demonstrated effective detection of the primary tumour and locoregional lymphadenopathy, with diagnostic efficacy for preoperative management comparable to breast MRI; in all cases, PCD-CT showed consistent findings with MRI in tumor detection, size, multifocality, lymph node, and pectoralis muscle involvement. Microcalcifications were seen only on PCD-CT, showing superior spatial resolution. Among 17 cases, PCD-CT revealed axillary adenopathy (n=12), internal mammary adenopathy (n=3), pectoralis fascia invasion (n=1), brain metastasis (n=1), and suspicious liver lesions (n=1), supporting its systemic staging value. Compared to MRI+CT, the PCD-CT protocol was faster (10 min vs 30 min) with a single contrast injection. Radiation dose was ~35 mSv, 60% lower than 64-slice CT. Finally, unlike MRI, PCD-CT is performed with the patient in a supine position, judged by surgeons as more anatomically and surgically favourable.

CONCLUSION

The PCD-CT protocol enables efficient and accurate staging and improves preoperative planning with precise locoregional and total-body imaging in a single session, while reducing contrast media, radiation dose, time, and cost compared to the MRI+conventional CT protocol.

CLINICAL RELEVANCE/APPLICATION

PCD-CT allows efficient locoregional and total-body staging in breast cancer patients, easing patient workload and enhancing surgical planning with precise anatomical detail.

M5B-SPBR-5 A PRELIMINARY EVALUATION OF NNU- NET FOR AUTOMATED BREAST DENSITY SEGMENTATION IN DIGITAL BREAST TOMOSYNTHESIS

Nehal Doiphode (*Presenter*)
Sree Kuntamukkala (*Abstract Co-Author*)
Walter Mankowski (*Abstract Co-Author*)
Despina Kontos, PhD (*Abstract Co-Author*)

PURPOSE

Breast density is a well-established risk factor for breast cancer, and digital breast tomosynthesis (DBT) enables routine volumetric breast density (VBD) estimation from 3D imaging. However, existing methods often rely on 2D projections or require raw DBT data, which is rarely archived. As nnU-Net has emerged as a leading out-of-the-box deep learning framework for biomedical image segmentation, validated across 23 diverse public datasets, it presents a natural baseline for this task. In this study, we examine the performance of nnUNet on DBT based breast density segmentation to assess its generalizability to this domain.

METHODS AND MATERIALS

We used a subset of anonymized DBT studies from a larger institutional dataset acquired at a medical academic center. The subset included 100 participants representing a range of breast density patterns. Reference segmentations of dense tissue were obtained from a previously validated software that uses both raw and processed images. All data were preprocessed and structured following nnU-Net's standardized format. Upon ingestion, nnU-Net generated a dataset fingerprint that informed its automatic pipeline selection. We tested two default configurations generated by nnU-Net for this 3D imaging task: (1) 2d, a slice-wise 2D U-Net applied to each DBT slice independently, and (2) 3d_fullres, a fully volumetric 3D U-Net operating at high resolution. Both models were trained using nnU-Net's default settings without manual tuning.

RESULTS

We trained both 2d and 3d_fullres nnU-Net configurations on DBT data using 5 fold cross validation. In the 2D configuration, validation loss decreased gradually, with pseudo Dice scores plateauing around 0.80 after approximately 30 epochs. In contrast, the 3D configuration showed faster convergence, achieving slightly higher maximum pseudo Dice values (~0.825) earlier in training

CONCLUSION

nnU-Net achieved moderate performance on the task of dense tissue segmentation from DBT, with pseudo Dice scores stabilizing around 0.80-0.825 across both 2D and 3D configurations. Increasing the training set size beyond an initial cohort did not yield substantial improvements, indicating that the task remains challenging even with well-established segmentation frameworks. These results highlight the need for DBT-specific model development and suggest that out-of-the-box pipelines may be insufficient for capturing the complex patterns associated with breast density in tomosynthesis.

CLINICAL RELEVANCE/APPLICATION

Our findings emphasize the limitations of current general-purpose segmentation frameworks in this domain and underscore the need for tailored solutions to fully leverage DBT for routine, reproducible density assessment in clinical practice.

M5B-SPBR-6 EARLY WASHOUT PHENOMENA IN ULTRAFAST DCE-MRI: THE POTENTIAL OF NOVEL ANALYTICAL METHODS

Kosuke Nanataki, MD (*Presenter*)
Mami Iima, MD, PhD (*Abstract Co-Author*)
Hiroko Satake, MD (*Abstract Co-Author*)
Yusuke Jo, MD (*Abstract Co-Author*)
Satoko Ishigaki, MD (*Abstract Co-Author*)
Rintaro Ito, MD, PhD (*Abstract Co-Author*)
Ryota Hyodo, MD, PhD (*Abstract Co-Author*)
Yutaka Kato (*Abstract Co-Author*)
Hiroshi Imai, MS,RT (*Abstract Co-Author*)
Yoshito Ichiba, RT (*Abstract Co-Author*)
Aki Mano (*Abstract Co-Author*)
Marcel D. Nickel (*Abstract Co-Author*)
Shinji Naganawa, MD, PhD (*Abstract Co-Author*)

PURPOSE

Ultrafast dynamic contrast-enhanced MRI (UF-DCE MRI) provides high temporal resolution for assessing early contrast enhancement in breast lesions. While early-phase kinetics like maximum slope (MS) are diagnostically useful, late washout patterns in UF-DCE MRI are less explored, despite their value in conventional DCE-MRI. This study evaluates breast cancer diagnostic performance using UF-DCE MRI by analyzing both early-phase kinetics and late-phase signal changes.

METHODS AND MATERIALS

This IRB-approved retrospective study included 175 patients who underwent UF-DCE MRI at Nagoya University Hospital in 2024. Contrast-enhanced imaging began at injection and continued for 72 seconds, acquiring 20 phases at 3.5-second intervals. Kinetic curves were generated with base-phase at injection start, early-phase at the kinetic curve inflection point (typically 35 seconds post-injection), and late-phase at 72 seconds post-injection. Washout was defined as >10% signal decrease from early to late phase. Enhancement patterns on UF-DCE MRI were compared with conventional DCE-MRI and correlated with pathology.

RESULTS

Some lesions showed signal decrease between early and late UF-DCE phases, indicating washout occurred before early conventional DCE-MRI (Figure 1). Fast enhancement patterns were similar between UF-DCE and conventional DCE-MRI, but conventional washout cases showed varied UF-DCE patterns (washout, plateau, or persistent) (Figure 2). In the late-phase UF-DCE MRI, the Luminal A (LA) subtype was more common in the washout group (63.6%, 14/22) than in the non-washout group (46.5%, 53/114), though not statistically significant (P = 0.166). Among cases with whole-lesion washout, 83.3% (5/6) were LA subtype (P = 0.106). MS showed no correlation with cancer subtypes, but was significantly higher in invasive cancer (median: 21.4%/sec) than in DCIS (median: 12.2%/sec) (P = 0.017). On the other hand, no significant difference in invasive carcinoma proportion was found between washout and non-washout groups.

CONCLUSION

UF-DCE MRI revealed washout patterns in some cases during its late phase, suggesting that washout occurs earlier than detectable in conventional DCE-MRI (Figure 1). Washout on UF-DCE MRI was associated with the LA subtype, and MS significantly differed between invasive cancer and DCIS. These parameters may improve lesion characterization.

CLINICAL RELEVANCE/APPLICATION

UF-DCE MRI could identify washout patterns without requiring prolonged scans, enabling abbreviated protocols that reduce imaging time without compromising diagnostic value. The combination of MS and washout patterns may help determine when delayed-phase imaging can be omitted safely.

M5B-SPBR-7 DOES THE PRESENCE OF IODINATED CONTRAST AFFECT TOMOSYNTHESIS PERFORMANCE?

Wendie A. Berg, MD, PhD (*Presenter*)
Bronwyn Nair, MD (*Abstract Co-Author*)
Denise M. Chough, MD (*Abstract Co-Author*)
Amy E. Kelly, MD (*Abstract Co-Author*)
Amy H. Lu, MD (*Abstract Co-Author*)
Priya B. Patel, MD (*Abstract Co-Author*)
Margarita L. Zuley, MD (*Abstract Co-Author*)
John Drescher, BS (*Abstract Co-Author*)
Amy Klym (*Abstract Co-Author*)
Andriy I. Bandos, PhD (*Abstract Co-Author*)

PURPOSE

Among a mix of asymptomatic and symptomatic women going to biopsy who had both a native digital breast tomosynthesis (DBTn) examination and also another DBT performed after iodinated contrast injection (DBTc), to assess the impact of iodinated contrast (e.g. "shine through") on false-positive recalls (FPR) from DBT.

METHODS AND MATERIALS

In an IRB-approved, HIPAA-compliant protocol, 5 radiologist observers (with 1-17 years' experience interpreting DBT) reviewed 175 routine-view DBT examinations twice. We excluded known cancers and examinations more than 100 days apart, leaving 158 paired exams, 53 (33.5%) of which had new cancer. Observers reviewed either the DBTn or DBTc examination for each case, then the complement 4 weeks later. DBTn included synthetic 2D images and DBTc included the low-energy exposure from the concurrent contrast-enhanced mammography (CEM) examination. Recalled findings were detailed, and a forced BI-RADS assessment was locked in through software developed for this study (BI-RADS 1 or 2; 3; 4A; 4B; 4C; 5, with BI-RADS 3 or higher considered recall). Sensitivity, FPR rate, and areas under the receiver operating characteristic curve (AUC) were determined and odds ratios (OR) were calculated.

RESULTS

Mean participant age was 53.6 years (range 30-81) and median lesion size 12 mm. Among 53 cases with malignancy, across 265 interpretations, sensitivity was fractionally larger at 241/265 (90.9%) for DBTc versus 233/265 (87.9%) for DBTn, OR 1.4 (95% CI 0.89 to 2.15); difference was 0.03 (95% CI from -0.01 to 0.06). FPR rates were fractionally smaller at 59.8% (314/525) for DBTc versus 63.2% (332/525) for DBTn, OR 0.86 (95% CI 0.69 to 1.07); difference was -0.03 (95% CI from -0.09 to 0.01). Post-contrast assessments resulted in fractionally larger AUC, albeit not statistically significantly greater, at 0.81 for DBTc versus 0.77 for DBTn (95% CI for difference from -0.01 to 0.08). At least some of the differences observed were due to positioning; review of discrepant cases is ongoing.

CONCLUSION

We observed non-inferiority of DBT sensitivity, false-positive recall rate, and AUC in the presence of iodinated contrast.

CLINICAL RELEVANCE/APPLICATION

Adding concurrent DBT to CEM does not adversely affect the diagnostic performance of DBT.

M5B-SPBR-8 ULTRASOUND-GUIDED CRYOABLATION FOR BREAST CANCER IN NON-SURGICAL PATIENTS

Laura Abelairas Lopez, MD (*Presenter*)
Lucia Grana Lopez, MD (*Abstract Co-Author*)
Laura Lopez, MD (*Abstract Co-Author*)
Ignacio Fernandez Sobrado (*Abstract Co-Author*)

PURPOSE

To present our single-center experience on the use of percutaneous cryoablation (PCA) for the local control of breast cancer (BC) in patients who chose not to have surgery or were considered inoperable.

METHODS AND MATERIALS

All biopsy-proven BC diagnosed in our institution and managed with PCA were retrospectively reviewed. In this study we include those BC diagnosed in non-surgical patients with, at least, 6 months imaging follow-up. PCA was performed under ultrasound (US) guidance, using a liquid nitrogen-based system. Imaging follow-up with mammography and US or contrast-enhanced mammography (CEM) was scheduled every 6 months. Patient's tolerance to the procedure, adverse effects and results regarding local control of the disease were assessed.

RESULTS

From May 2019 to April 2025, 79 BC, diagnosed in 73 women that were considered inoperable, were treated under local anesthesia with PCA in our institution. All cases were previously reviewed in a multidisciplinary tumor board. Sixty-nine of them (median age 87 years, range 48-98 years) have, at least, one imaging examination performed 6 months after the procedure. Median tumor size was 23 mm, range 6-46 mm. The mean follow-up was 19.8 months (range 6-45 months). Sixty were luminal BC, 3 were Her2 (+) and 8 were triple negative tumors. All luminal cancers received endocrine therapy. Complete tumoral necrosis was achieved in 56 tumors (81.2%). There was axillary progression in two triple negative BC. Recurrence in a different location was diagnosed in two patients. PCA was successful 100% of luminal cancers up to 2.5 cm. No major complications were seen and the procedure was well tolerated.

CONCLUSION

PCA is a safe and well-tolerated outpatient procedure. The study outcomes suggest that PCA is effective and could be an alternative to surgery for the management of luminal BC up to 2.5 cm in those women that are considered not candidates for surgery.

CLINICAL RELEVANCE/APPLICATION

Percutaneous cryoablation is a minimally invasive procedure, without significant complications. It could be a safe alternative to surgery for the management or early-stage breast cancer.

M5B-SPCA-1 RELAX: THE EFFECTS OF COMPRESSED SENSING AND DEEP LEARNING-BASED RECONSTRUCTION ON NATIVE T1-RELAXATION TIMES OF THE MYOCARDIUM

Alessio Perazzolo, MD (*Presenter*)
Camilla Vittoria Vita, MD (*Abstract Co-Author*)
Vincenzo Scialo (*Abstract Co-Author*)
Mohamed Gamal, MD (*Abstract Co-Author*)
Tzu Cheng Chao (*Abstract Co-Author*)
Jacinta Browne, PhD (*Abstract Co-Author*)
Omer Demirel (*Abstract Co-Author*)
Spencer Waddle (*Abstract Co-Author*)
Tim Leiner, MD, PhD (*Abstract Co-Author*)

PURPOSE

Quantitative native T1 mapping is a key component in CMR for myocardial tissue characterization; however, slow acquisition and the lack of whole-heart coverage remain limitations. Undersampling techniques in k-space, such as compressed sensing (CS), and deep learning-based reconstruction methods focused on denoising (SmartSpeed, SS) have improved morphological and cine imaging, but their impact on quantitative relaxation times remain underexplored. This study evaluated image quality and native T1 quantification across 10 methods with varying CS acceleration levels, spatial resolutions, and presence/absence of denoising reconstruction.

METHODS AND MATERIALS

In this prospective single-center study, 48 healthy volunteers underwent native T1 mapping using a 3T Philips MRI scanner. After quality review, 41 subjects were included. Image quality (IQ), aliasing, and susceptibility artifacts were rated by two blinded readers using a 4-pt Likert scale. Quantitative analysis was performed on a per-segment basis using custom software, yielding mean and SD for each AHA segment. Nine cases were reanalyzed by three additional readers to assess interobserver variability. The reference T1-mapping protocol was obtained with CS 3, with spatial resolution of 2.0×2.0×10mm. Additional acquisitions were obtained with CS 3, 4, 5 and spatial resolutions of 2.0×2.0×10mm, 1.8×1.8×1mm, and 1.6×1.6×10mm for CS 3 and 2.0×2.0×10mm for CS 4 and 5.

RESULTS

Shapiro-Wilk tests confirmed non-normal distribution for qualitative scores and normal distribution for quantitative T1 values per segment. Significant differences emerged in IQ and aliasing among methods (Kruskal-Wallis, $p<0.05$), but not in susceptibility artifacts. Higher CS levels slightly reduced IQ and increased aliasing. SS slightly improved overall IQ without affecting aliasing. Higher spatial resolution kept qualitatively metrics stable. Segment-wise quantitative analysis showed good inter-operator agreement (ICC2 overall = 0.77). Bland-Altman analysis showed low bias across methods, with a max deviation of 10.51ms (overall) and 22.3ms (per-segment) from the standard.

CONCLUSION

Native myocardial T1 values remained stable across various CS acceleration factors, changes in spatial resolution and application of denoising, with clinically negligible bias for tissue characterization based on native T1 mapping.

CLINICAL RELEVANCE/APPLICATION

These findings support the use of CS and denoising to reduce acquisition time and improve temporal resolution for individual scans, benefiting patients with arrhythmias or elevated heart rates. Overall, these results advocate for patient-tailored T1 mapping protocols, further improving efficiency and diagnostic utility of quantitative CMR.

M5B-SPCA-3 PRE- AND POSTOPERATIVE RIGHT HEART REMODELING IN CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION: INSIGHT FROM CARDIAC MAGNETIC RESONANCE

Blanca Domenech, MD, PhD (*Presenter*)
Olatz Saenz De Argandona, MD (*Abstract Co-Author*)
Carmen Palacios (*Abstract Co-Author*)
Judit Mestres Marti (*Abstract Co-Author*)
Eduard Sole-Gonzalez (*Abstract Co-Author*)
Maria Ascaso (*Abstract Co-Author*)
Marcelo Sanchez, MD (*Abstract Co-Author*)
Joan Albert Barbera (*Abstract Co-Author*)
Isabel Blanco (*Abstract Co-Author*)
Susana Prat-Gonzalez, MD, PhD (*Abstract Co-Author*)
Manuel Castella (*Abstract Co-Author*)
Ana Garcia-Alvarez (*Abstract Co-Author*)

PURPOSE

Right heart remodeling is a relevant prognostic factor for heart failure and mortality in patients with pulmonary hypertension. This study aims to evaluate right heart remodeling in patients with chronic thromboembolic pulmonary hypertension (CTEPH) using cardiac magnetic resonance (CMR), and to compare structural and functional parameters before and after pulmonary endarterectomy (PEA).

METHODS AND MATERIALS

Between 2023-2024, patients with confirmed CTEPH who were eligible for PEA were prospectively enrolled. All patients underwent comprehensive CMR within 3 days prior to surgery and again at 6 months postoperatively. CMR assessment included evaluation of biatrial and biventricular volumes and function. Pulmonary artery (PA)

hemodynamics were analyzed using both phase-contrast and 4D flow sequences. Pulmonary vascular resistance (PVR) was estimated using a validated CMR-derived formula: PVR (Wood Units) = 19.38 - [4.62×Ln(PA average velocity,cm/s)] - [0.08×right ventricle ejection fraction (RVEF,%)]. Myocardial tissue characterization was performed using native T1 mapping and late gadolinium enhancement (LGE).

RESULTS

Twenty patients were included (mean age: 62.7 years; range: 21-80 years; 55% female). Postoperative CMR demonstrated significant reductions in indexed RV end-diastolic volume (pre 86.6±29.4 mL/m² vs. post-op 68.3±22.4 mL/m², p <0.05), RV end-systolic volume and right atrial area, consistent with right heart reverse remodeling. RVEF showed a trend toward improvement, increasing from 42.7 ± 10.8% to 47.7 ± 5.2% (p =0.07). No significant changes were observed in left ventricular parameters. Maximal PA size decreased significantly following surgery (9.4±2 vs 7.9±1.7 cm2, p <0.05) as well as CMR estimated PVR (pre-op: 6.6±1.5 WU vs. post-op: 4.6±1 WU, p <0.001). LGE at the RV insertion points was common, present in 95% of patients at the inferior insertion point and in 90% at the anterior insertion point. Native T1 values at mid septum showed no significant differences between pre- and postoperative assessments.

CONCLUSION

Cardiac MRI demonstrates significant reverse remodeling of the right heart and a reduction in CMR estimated PVR following PEA in patients with CTEPH. Although RVEF showed only a trend toward improvement, the most consistent changes were seen in right ventricular volumes. These findings underscore the value of CMR in assessing structural and functional recovery, supporting its role in prognostic evaluation and postoperative follow-up in this population.

CLINICAL RELEVANCE/APPLICATION

Cardiac MRI provides a comprehensive, noninvasive assessment of right heart reverse remodeling and pulmonary vascular changes after PEA, offering valuable prognostic insights in patients with CTEPH.

M5B-SPCA-4 INTEGRATING CT-FFR RESULTS INTO CAD-RADS 2.0 CLASSIFICATION FOR IMPROVED ISCHEMIC LESION IDENTIFICATION

Sung-Jin Cha, BS (*Presenter*)
KIM YEON JUN (*Abstract Co-Author*)
Sung Min Ko, PhD (*Abstract Co-Author*)
JUN SIK KIM (*Abstract Co-Author*)
GIYONG AN (*Abstract Co-Author*)

PURPOSE

To evaluate whether integrating CT-FFR results into the anatomical stenosis classification of CAD-RADS 2.0 significantly improves the accuracy of identifying ischemic lesions, particularly in patients with intermediate stenosis (CAD-RADS 3, approximately 50-69%).

METHODS AND MATERIALS

This retrospective study included 101 patients (age 70 ± 10 , height 162 ± 9 cm, weight 66 ± 11 kg, BMI 25 ± 3 kg/m², heart rate 66 ± 10 bpm, calcium score 527 ± 570) who underwent both CT-FFR and invasive FFR. The predictive performances of CT-FFR (=0.80) and CCTA (=50% stenosis) for detecting invasive FFR =0.80 were compared across all RCA, LAD, LCX and subgroup CAD-RADS 3 (50-69% stenosis).

RESULTS

For all pooled vessels, CT-FFR demonstrated superior diagnostic performance compared to CCTA, with specificity of 97% (95% CI: 94-98) vs. 64% (95% CI: 58-70), PPV of 77% (95% CI: 62-87) vs. 29% (95% CI: 22-37), and accuracy of 93% (95% CI: 90-95) vs. 68% (95% CI: 62-73). The AUC for CT-FFR was 0.95 (95% CI: 0.90-0.98) compared to 0.77 (95% CI: 0.71-0.82) for CCTA (p < 0.05) (Table 1 and Figure 2). Similar results were observed in each branch: RCA, LAD, and LCX (Table 1). In moderate stenosis (CAD-RADS 3), CT-FFR showed improved performance with specificity of 91% (95% CI: 80-97) vs. 0% (95% CI: 0-7), PPV of 76% (95% CI: 53-90) vs. 31% (95% CI: 22-43), and accuracy of 82% (95% CI: 71-89) vs. 31% (95% CI: 21-43). The AUC for CT-FFR was 0.96 (95% CI: 0.87-1.00) compared to 0.68 (95% CI: 0.54-0.82) for CCTA (p < 0.05).

CONCLUSION

Integrating CT-FFR into the CAD-RADS 2.0 classification enhances specificity and positive predictive value, improving the accuracy of identifying ischemic lesions, particularly in patients with intermediate stenosis (CAD-RADS 3).

CLINICAL RELEVANCE/APPLICATION

This optimized approach can avoid unnecessary invasive testing for patients with CAD-RADS 3 and CT-FFR >0.80 and identify functionally significant stenosis in patients with CAD-RADS 2 and CT-FFR =0.80, ultimately improving clinical outcomes.

M5B-SPCA-5 HIGH-RESOLUTION DEEP LEARNING CT RECONSTRUCTION FOR WATCHMAN DEVICE ASSESSMENT IN A CARDIAC PHANTOM

Martin Wagner, PhD (*Presenter*)
Kelsey Schluter, BS (*Abstract Co-Author*)
Jakub Siembida, MD,MA (*Abstract Co-Author*)
Sarv Priya, MD, MBBS (*Abstract Co-Author*)
Prashant Nagpal, MD (*Abstract Co-Author*)

PURPOSE

To evaluate deep learning-based reconstruction techniques with varying matrix sizes for the post-procedural assessment of Watchman devices in a dynamic cardiac phantom.

METHODS AND MATERIALS

A dynamic cardiac CT phantom (SKK II, Kyoto Kagaku, Japan) with a Watchman device (Boston Scientific, MN, USA) attached to the heart surface was scanned on a 320-slice CT scanner (Aquilion INSIGHT edition, Canon) using a 0.24 s rotation time, 100 kV, and 90 mA. Heart rates of 60, 80, 100, and 110 bpm were simulated over a full cardiac cycle. . Image reconstruction was performed with retrospective gating over the scanner determined optimal cardiac phase using two advanced deep learning algorithms, AiCE (level 1) and PIQE (level 1), in conjunction with the vendor provided metal artifact reduction technique SEMAR using a matrix size of 512 and 1024 (PIQE only). Signal to noise (SNR) and sharpness of individual wires of the watchman device as well as the size and intensity of hypointense artifacts around the wires was measured. Noise was measured within a 1.74 cm diameter circular region of interest in a homogeneous area of the heart. The individual wires of the Watchman device were manually segmented to facilitate sharpness measurements, which were determined using the maximum gradient of the intensity profile across the wires. Furthermore, the extent of hypointense artifacts surrounding the metallic wires was quantified by measuring the area under the curve of the pixel intensity profile in the vicinity of the device. A Wilcoxon signed rank test was used to test for significant differences.

RESULTS

Across all heart rates, SNR was significantly higher for PIQE 512 compared to AiCE 512 (65.3±8.0 vs. 11.5±2.6 , p<0.0001), and further increased with PIQE 1024 (90.0±11.8 , p<0.0001). Sharpness was significantly higher for AiCE 512 compared to PIQE 512 (155.6±45.3 vs 144.2±54.7 , p<0.0001), but significantly higher for PIQE 1024 compared to AiCE 512 (185.1±70.1 , p<0.0001). Both PIQE 512 and PIQE 1024 show significantly less hypointense artifacts compared to AiCE 512 (PIQE 512 : 274.3±307.5 (p=0.001) , PIQE 1024 : 552.0±304.7 (p=0.007) , AiCE 512 : -749.0±784.7).

CONCLUSION

PIQE reconstruction, particularly with a 1024 matrix size, offers significant advantages for visualizing and assessing a Watchman device in post-procedure CTs due to improved SNR, sharpness, and reduced metal artifacts.

CLINICAL RELEVANCE/APPLICATION

Accurate post-procedural CT assessment of Watchman device placement is critical for detecting potentially life-threatening complications like migration, device-related thrombus, or peri-device leak. High-resolution deep learning reconstruction, such as PIQE 1024 , enhance visualization of fine device structures, thereby aiding in this crucial evaluation.

M5B-SPCA-6 INCREMENTAL PROGNOSTIC VALUE OF PLAQUE BURDEN ESTIMATION IN CAD-RADS 2.0 FOR PREDICTING MAJOR ADVERSE CARDIOVASCULAR EVENTS

Manuel Rafael Lopez De La Torre Carretero, MD (*Presenter*)
Jose Marlon Rodriguez Ortega, MD (*Abstract Co-Author*)
Carlos Delgado, MD (*Abstract Co-Author*)
Miguel Barrio Piqueras I, MD (*Abstract Co-Author*)
Carmen Mbongo, MD (*Abstract Co-Author*)
Gorka Bastarrika Aleman, MD (*Abstract Co-Author*)
Ana Ezponda, MD (*Abstract Co-Author*)

PURPOSE

To assess whether incorporating plaque burden estimation using the segment involvement score (P-SIS) in CAD-RADS 2.0 improves the prediction of major adverse cardiovascular events (MACE) compared to the stenosis-based classification of CAD-RADS 1.0 in patients undergoing coronary CT angiography.

METHODS AND MATERIALS

A retrospective cohort of 562 patients undergoing CCTA between September 2017 and April 2022 was evaluated using CAD-RADS 1.0 and CAD-RADS 2.0 systems. The P-SIS score (P1-P4) was calculated. MACE was defined as a composite of heart failure, myocardial infarction, unstable angina, stroke, or cardiac death.Cox regression models (univariate and multivariate) assessed associations between imaging scores and MACE. Baseline clinical characteristics and medication use were also analyzed.

RESULTS

Over a median follow-up of 51.2± months, 41 patients (7.3%) experienced MACE. Patients with MACE were older and had higher rates of comorbidities including COPD, hypertension, diabetes, chronic kidney disease, and arrhythmias. Notably, 72.5% of MACE cases occurred in patients with CAD-RADS 1-2. Moderate-to-severe plaque burden (P3-P4) was present in 85.4% of MACE cases. In univariate analysis, P-SIS was significantly associated with MACE (HR 4.08; 95% CI 1.71-9.75; p=0.002). A high-risk classification using CAD-RADS 2.0 (CAD-RADS =3 or any CAD-RADS with P=3) showed stronger predictive performance for MACE in both univariate (HR 4.6; 95% CI 1.80-11.78; p<0.001) and multivariate analyses (HR 3.69; 95% CI 1.25-10.86; p=0.018), whereas CAD-RADS 1.0 did not retain independent prognostic significance.

CONCLUSION

CAD-RADS 2.0, by incorporating plaque burden estimation through P-SIS, significantly improves the prognostic assessment of patients undergoing CCTA. This enhanced classification allows for better identification of individuals at risk of major adverse cardiovascular events, even among those with non-obstructive coronary artery disease.

CLINICAL RELEVANCE/APPLICATION

Routine inclusion of plaque burden modifiers in CCTA reports, as proposed in CAD-RADS 2.0, facilitates more accurate cardiovascular risk stratification and may inform earlier preventive or therapeutic interventions in patients traditionally considered low risk.

M5B-SPCA-7 OXYGEN-SENSITIVE MRI (OS-MRI)-BASED EVALUATION OF CARDIO-CEREBRAL OXYGENATION RESERVE IN HEART FAILURE PATIENTS

Yang Lei (*Presenter*)
Yong Ju Yang (*Abstract Co-Author*)
Feifei Zhou, MD (*Abstract Co-Author*)

PURPOSE

To investigate whether oxygenation sensitive magnetic resonance imaging (OS-MRI) can be an emerging tool to quantify cardio-cerebral oxygenation reserve in patients with heart failure and the relationship between decreased cardio-cerebral oxygenation reserve and cognitive dysfunction.

METHODS AND MATERIALS

The study is a prospective, single-center cohort study that evaluates the cardio-cerebral oxygenation reserve and cognitive function status of patients hospitalized for heart failure from March 2025 to December 2025, and divides heart failure into four stages: A, B, C, and D according to the American Heart Association stage. The included population underwent oxygen-sensitive magnetic resonance imaging (OS-MRI) combined with the Montreal Cognitive Assessment (MoCA) scale during hospitalization, and a group of healthy volunteers were recruited to use their cardio-cerebral oxygenation reserve as a diagnostic criterion. Primary outcome measures are change in MORE and CORE (?SI)and MoCA score (less than 26 points consider mild cognitive dysfunction).

RESULTS

60 patients with HF (age 64.4±8.3 years; 37.5% women) were included in the analysis. Both cerebral oxygenation reserve and MORE in HF patients were lower than those in healthy volunteers (MORE: 0.57±2.9 and 4.8±3.3, CORE: 0.25±0.39 and 1.22±0.50, respectively), and the Montreal Cognitive Assessment score (HF, 23.6±2.8; Health, 27.5±1.2; P=0.002) with cardio-cerebral oxygen reserves. The Montreal cognitive assessment score was correlated with MORE (r=0.56, P=0.040).

CONCLUSION

Our findings suggest that oxygen-sensitive magnetic resonance imaging can identify patients with heart failure with reduced cardiocerebral oxygenation reserves, and that this impaired response is associated with cognitive decline.

CLINICAL RELEVANCE/APPLICATION

This study provides quantitative and definitive diagnostic criteria for assessing oxygenation reserve in heart failure patients, enriches the clinical understanding of cardio-cerebral comorbidities, and promotes the development of multi-organ integrated treatment strategies.

M5B-SPCA-10 DEEP LEARNING-BASED AUTOMATED SEGMENTATION OF INTRACARDIAC 4D FLOW MRI USING CT-DERIVED SEGMENTATION TRANSFER

Ji-Hoon Jung (*Presenter*)
Jong Eun Lee, MD, PhD (*Abstract Co-Author*)
Hongmin Oh (*Abstract Co-Author*)
Hyungkyu Huh (*Abstract Co-Author*)

Gyu-Han Lee (*Abstract Co-Author*)
Hojin Ha (*Abstract Co-Author*)
June-Goo Lee, PhD (*Abstract Co-Author*)
Dong Hyun Yang, MD (*Abstract Co-Author*)

PURPOSE

To develop and evaluate a fully automated deep learning-based segmentation method for intracardiac 4D flow MRI using segmentation masks transferred from chest computed tomography angiography (CTA).

METHODS AND MATERIALS

This retrospective study included consecutive patients who underwent both 4D flow MRI and chest CTA for preoperative evaluation of valvular heart disease between January 2023 and December 2024. Segmentation masks of cardiac chambers, the aorta, and pulmonary artery were automatically generated using an in-house deep learning algorithm to transfer CT-derived segmentations obtained by the publicly available TotalSegmentator tool. Non-rigid registration aligned these segmentations to the corresponding 4D flow MRI datasets. Segmentation accuracy was assessed using the Dice similarity coefficient against the reference standard: cine MRI-based semiautomatic manual segmentation by a cardiothoracic radiologist. Concordance correlation coefficients (CCCs) were calculated to assess agreement for quantitative metrics including left ventricular (LV) end-diastolic volume (EDV), end-systolic volume (ESV), LV ejection fraction (LVEF), and aortic volumes.

RESULTS

Of the included 44 patients (mean age, 66.7 ± 15.0 years; 24 men), transferred CT-derived segmentation masks demonstrated high spatial agreement with both cine MRI-based and semiautomatic manual segmentations, achieving a mean Dice coefficient of 0.81 ± 0.05. Quantitative metrics derived from automated CT-based segmentation showed good correlation with reference standards, yielding CCCs ranging from 0.77 to 0.82 for LV EDV, LV ESV, LVEF, and aortic volumes.

CONCLUSION

Deep learning-based CT-derived segmentation transfer enables accurate and reproducible segmentation and quantification in intracardiac 4D flow MRI, eliminating the need for additional cine MRI acquisitions.

CLINICAL RELEVANCE/APPLICATION

This automated segmentation approach may streamline cardiac imaging workflows, reduce examination times, enhance reproducibility, and facilitate broader clinical adoption of comprehensive hemodynamic assessments using 4D flow MRI.

M5B-SPCA-11 DEEP LEARNING RECONSTRUCTION ENHANCES SYSTOLIC CORONARY CTA IMAGE QUALITY UNDER TRIPLE-LOW PROTOCOLS ACROSS BMI CATEGORIES

Xiaohua Zhang (*Presenter*)
Xiaoyan Lei (*Abstract Co-Author*)
Feng Chen, MD, PhD (*Abstract Co-Author*)
Weiyuan Huang (*Abstract Co-Author*)
Kun Ma (*Abstract Co-Author*)

PURPOSE

To assess the impact of high-strength deep learning image reconstruction (DLIR-H) on image quality of systolic-phase coronary CTA in patients with varying BMI, under protocols incorporating low radiation, low contrast volume, and low injection rate, compared to conventional iterative reconstruction (ASIR-V 50%).

METHODS AND MATERIALS

In this prospective single-center study, 47 patients with suspected coronary atherosclerosis were stratified by BMI: Group A (<24 kg/m², n=20), Group B (24-28 kg/m², n=21), and Group C (>28 kg/m², n=6). Coronary CTA was performed using tailored triple-low scanning protocols (70-100 kVp; contrast 35-55 mL; injection rates 3.0-5.0 mL/s). Images were reconstructed using DLIR-H and ASIR-V 50%. Objective assessments included CT attenuation, image noise (SD), signal-to-noise ratio (SNR), and contrast-to-noise ratio (CNR) in the LM, LAD, LCX, RCA (proximal, mid, distal), and aortic root (AO). Two radiologists independently rated subjective image quality using a five-point Likert scale.

RESULTS

DLIR-H significantly reduced image noise compared to ASIR-V in all BMI groups ($P < 0.001$). For example, in Group A, proximal RCA noise decreased from 44.38 ± 14.05 to 37.13 ± 13.91 (-16.3%); in Group C, AO noise dropped by 46.9% (35.18 ± 10.54 to 18.68 ± 8.68). DLIR-H markedly improved SNR and CNR in all BMI groups. In Group B, distal RCA CNR increased from 19.46 ± 6.71 to 32.70 ± 14.09 (+68.1%). Subjective image quality was significantly higher with DLIR-H in all groups ($P < 0.05$), with median Likert scores of 4 (IQR: 4-5) versus 3 for ASIR-V in Group A. Inter-reader agreement was excellent (Kappa > 0.9). Although effective radiation dose (ED) increased with BMI (Group A: 0.77 ± 0.14 mSv; Group C: 2.02 ± 0.58 mSv; $P = 0.004$), DLIR-H consistently delivered the largest noise reductions and CNR gains across all BMI strata.

CONCLUSION

DLIR-H significantly enhances systolic coronary CTA image quality across BMI groups under triple-low protocols. It achieves substantial noise reduction (16.3%-46.9%) and marked increases in SNR and CNR (up to 76.7%), with consistently high subjective ratings. These results support DLIR-H as a robust tool for low-dose, high-clarity coronary imaging, particularly in patients with elevated BMI.

CLINICAL RELEVANCE/APPLICATION

DLIR-H enables high-quality systolic-phase coronary CTA imaging even under stringent dose-reduction protocols. Its capacity to preserve diagnostic clarity in overweight and obese patients is critical for accurate detection of coronary artery disease, making it a valuable advance in personalized, low-exposure cardiac imaging strategies.

M5B-SPCA-12 MINIMIZATION OF CALCIFIC PLAQUE BLOOMING IN CT ANGIOGRAPHY BY ENERGY OPTIMIZATION WITH RAPID-SWITCHING DUAL-ENERGY EID-CT: PHANTOM STUDY WITH AUTOMATED LINE PROFILE ANALYSIS

Livia Silva, MD (*Presenter*)
Shawn Newlander, MS (*Abstract Co-Author*)
Balint Szilveszter, MD, PhD (*Abstract Co-Author*)
Marton Kolossvary, MD, PhD (*Abstract Co-Author*)
Milan Vecsey-Nagy, MD, PhD (*Abstract Co-Author*)
Hugo M. Marques, MD, PhD (*Abstract Co-Author*)
Jadranka Stojanovska, MD, MS (*Abstract Co-Author*)
Elliot R. McVeigh, PhD (*Abstract Co-Author*)
George E. Wesbey III, MD (*Abstract Co-Author*)

PURPOSE

Previous spectral PCD-CT phantom studies confirmed the value of high keV virtual monoenergetic images (VMI) in reducing calcium blooming in CTA. Similar studies with EID-CT have not been reported. This study aims to quantify energy dependent blooming in EID-CT across 11 different VMI energy levels using a cylindrical phantom with an intermediate density calcium hydroxyapatite (CaHA) plaque insert. The objective was to determine the VMI energy level(s) that minimize blooming using reference ground truth ultra-high-resolution EID-CT.

METHODS AND MATERIALS

A cylindrical phantom with a 1.5 mm-thick, 10 mm-long CaHA plaque (370 mg CaHA/cm³), simulating 50% stenosis in blood-equivalent contrast (blood ˜ 45 HU at 120 kVp), was positioned in a water bath at isocenter within an anthropomorphic thorax phantom surrounded by a 35 cm fat attenuation ring. A standard CTA protocol was used: 0.6 mm helical slices, 0.5 s rotation, 200 mA, with rapid-switched dual-energy (80/140 kVp) acquisition on a 256-slice CT scanner (1.2 mm focal spot). Images were reconstructed with 25 cm FOV, standard kernel, and deep learning noise reduction. Eleven VMIs (40-140 keV) were generated. All acquisition parameters remained identical across VMIs. Plaque diameter was measured computing edge width at half maximum (EWHM) and full width at half maximum (FWHM) from five averaged line profiles. Ground truth was obtained using a high-resolution 120 kVp axial temporal bone protocol in air (7 cm FOV, 0.7 mm focal spot).

RESULTS

Noise power spectra showed no significant variation across VMIs. Line profiles demonstrated that both EWHM and FWHM decreased linearly with increasing energy (R^2 = 0.922, and 0.922, respectively), confirming increasing blooming at lower keV (ANOVA $p < 0.0001$). The ground truth plaque diameter was 1.37 mm, while plaque diameter measured as FWHM ranged from 1.43 mm at 140 keV to 1.59 mm at 40 keV ($p<0.0001$). Post hoc Tukey analysis revealed significant differences in FWHM between lower and higher VMI energies. Compared to 40 keV, values at 70 keV and above were significantly lower ($p < 0.01$), confirming a consistent reduction in blooming at higher energies. No significant difference was observed between adjacent high-keV levels.

CONCLUSION

High energy VMI synthesis from dual energy EID-CT produces the most accurate measure of CAC diameter, presumably by minimizing beam hardening artifact from the stronger photoelectric absorption of calcium relative to water at low keV.

CLINICAL RELEVANCE/APPLICATION

Calcium blooming is a major limitation in CT angiography, often leading to overestimation of stenosis.

M5B-SPCA-13 MYOCARDIAL ULTRASONIC RADIOMIC FEATURE ANALYSIS FOR THE ETIOLOGICAL DIFFERENTIATION OF LEFT VENTRICULAR HYPERTROPHY

Yue Liu (*Presenter*)
Xinyue Liu (*Abstract Co-Author*)
Yansong Liu (*Abstract Co-Author*)

PURPOSE

Cardiac ultrasound is usually insufficient for the etiological diagnosis of left ventricular hypertrophy (LVH). We aimed to develop an artificial intelligence algorithm using myocardial ultrasonic radiomic features to differentiate common etiologies of LVH, such as hypertrophic cardiomyopathy (HCM), hypertensive heart disease (HHD), uremic cardiomyopathy (UCM) and cardiac amyloidosis (CA).

METHODS AND MATERIALS

In this study, 249 HCMs, 148 HHDs, 148 UCMs and 182 CAs were recruited. The data were randomly divided into a training set and a test set at an 8:2 ratio. On the basis of the four-chamber view of two-dimensional cardiac ultrasound, we selected the interventricular septum as the region of interest (ROI) to extract radiomic features. Several causal diagnosis models for left ventricular hypertrophy, including RandomForest, ExtraTrees, XGBoost and LightGBM, were constructed using the features after dimensionality reduction.

RESULTS

The LightGBM model (area under the curve of 0.844 for HCM, 0.734 for HHD, 0.813 for UCM and 0.749 for CA) based on radiomics outperformed the other three models. (RandomForest: area under the curve of 0.797 for HCM, 0.666 for HHD, 0.759 for UCM and 0.658 for CA; ExtraTrees: area under the curve of 0.823 for HCM, 0.632 for HHD, 0.778 for UCM and 0.715 for CA; XGBoost: area under the curve of 0.839 for HCM, 0.701 for HHD, 0.807 for UCM and 0.709 for CA).

CONCLUSION

We developed several artificial intelligence-based classification models and then selected the one with the highest diagnostic efficacy (LightGBM). This model utilizes radiomics based on cardiac ultrasound to enhance the diagnostic and differential capabilities of LVH.

CLINICAL RELEVANCE/APPLICATION

Although cardiac ultrasound is an important method for detecting LVH, distinguishing its etiology is difficult. This study revealed that the radiomics-based LVH etiology diagnosis model constructed on the basis of cardiac ultrasound has good diagnostic performance. The fundamental reason is that radiomics can extract a large amount of image information that the human eye cannot observe, which to some extent can compensate for the deficiency of diagnosis by ultrasound physicians relying only on experience and the naked eye, highlighting the importance of this method in the etiological diagnosis of diseases via relevant images.

M5B-SPCA-14 IMPACT OF SUPER-RESOLUTION DEEP LEARNING RECONSTRUCTION ON CORONARY CT ANGIOGRAPHY-DERIVED PLAQUE QUANTIFICATION

Limiao Zou (*Presenter*)
Yunxin Zhong (*Abstract Co-Author*)
Min Xu, PhD (*Abstract Co-Author*)

PURPOSE

Coronary CT angiography (CCTA) allows for noninvasive coronary plaque quantification, with moderate to good correlations to intravascular ultrasound, and provides powerful cardiovascular risk prediction. However, CCTA still has some limitations regarding spatial resolution and soft tissue contrast, which diminish its capacity to accurately quantify coronary plaques. Utilizing data from ultra-high-resolution CT as training target, a novel super-resolution deep learning reconstruction (SR-DLR) technique has been developed and the possible impact on coronary plaque quanfication remains unknown. Therefore, the aim of this study was to compare SR-DLR with conventional hybrid iterative reconstruction (HIR) on quantitative plaque assessment.

METHODS AND MATERIALS

From September 2023 to November 2024, 109 patients who underwent clinically indicated CCTA for assessment of suspected or known coronary artery disease were consecutively enrolled. CCTA images were reconstructed with both HIR (Adaptive Iterative Dose Reduction (AIDR) 3D, FC43 kernel) and SR-DLR (Precise IQ Engine (PIQE), Cardiac kernel). Total plaque volumes were quantified and further classified into three components based on the specific Hounsfield unit (HU) threshold: low-attenuation plaque (LAP) (<30 HU), fibrous plaque (30—350 HU) and calcified plaque (>350 HU).

RESULTS

A total of 223 plaques were identified. Overall, total plaque volumes were significantly higher with SR-DLR than with HIR (196.36 mm 3 [107.44, 333.50] vs. 166.64 mm 3 [87.90, 295.76], P < 0.001). While calcified plaque volums were significantly lower with SR-DLR compared with HIR (79.64 mm 3 [33.46, 149.78] vs. 80.50 mm 3 [32.58, 151.92], P=0.04), LAP volume (1.44 mm 3 [0.00, 11.38] vs. 0.26 mm 3 [0.00, 4.50]) and fibrous plaque volume (79.26 mm 3 [37.42, 160.76] vs. 61.76 mm 3 [29.02, 130.20]) (all P < 0.001) were significantly higher with SR-DLR.

CONCLUSION

Compared with HIR, higher total plaque volumes were obtained with SR-DLR, with lower calcified plaque volume and higher LAP and fibrous plaque volume.

CLINICAL RELEVANCE/APPLICATION

CCTA-derived plaque quanfication via SR-DLR may potentially improve risk stratification of coronary artery disease

M5B-SPCH-1 TRACHEOBRONCHIAL TREE 3D PRINTING ACCURACY: EFFECTS OF PATIENT PHYSICAL CHARACTERISTICS, IMAGE RECONSTRUCTION AND SEGMENTATION PARAMETERS ON POLYJET 3D PRINTED MODELS COMPARED TO CT SOURCE IMAGES

Lucas Betts, MD (*Presenter*)
Kalley Johnson (*Abstract Co-Author*)
Richard Csordas, BS (*Abstract Co-Author*)
Athillesh Sivapatham, MD (*Abstract Co-Author*)
Christian W. Cox, MD (*Abstract Co-Author*)

PURPOSE

To determine how segmentation threshold (upper Hounsfield unit, HU), patient factors (BMI, age, sex), and CT reconstruction kernel influence the dimensional accuracy of PolyJet-printed tracheobronchial models, and to identify threshold values that minimize print-CT diameter discrepancies.

METHODS AND MATERIALS

Following IRB approval, twelve adults (6F/6M; mean age 68.3 years; mean BMI 28.08) with standard chest CT (= 1 mm slices) were retrospectively selected with even representation of BMI categories. The mid trachea (MT), bronchus intermedius (BI), and left lower lobe superior segmental bronchus (SSB) were segmented in Materialise Mimics using upper HU thresholds ranging from -900 to -200 HU in 100-HU increments. The resulting meshes were exported as STL files and printed on a Stratasys J5 Medijet PolyJet 3D printer. Printer validation with geometric calibration models confirmed intrinsic error below 0.1 mm. Printed luminal diameters were measured with digital calipers and compared to electronic measurements on axial CT images. Linear mixed-effects models assessed the effects of HU threshold (per 100 HU), BMI (per unit), age (per year), sex, airway diameter, and reconstruction kernel on print-CT discrepancy, including interaction terms to probe threshold sensitivity.

RESULTS

Incremental adjustment of upper limit HU for segmentation produced near linear relationships to model airway diameter with greatest accuracy relative to CT measurement between -300 (SSB) to -400 (BI and MT). Patient BMI demonstrated statistically significant main effect on MT and BI print diameters ($p=0.0025$ and $p=0.048$). Statistically significant main effects on tracheal prints were present for patient age ($p=0.0362$) and BI prints for biologic sex ($p=0.012$). Interaction effects between HU and other variables were significant for BMI/Age/biologic sex for the trachea, BMI/Age/Reconstruction kernel for BI and biologic sex for SSB.

CONCLUSION

Upper HU thresholds of -300 to -400 HU yield submillimeter-accurate airway prints and were not subject to segmentation artifacts present at lower cutoff values. A predictable, near-linear relationship between HU and model diameter allows for predictable segmentation tuning, and accounting for BMI, age, and sex can further refine fidelity. The sample size of our study was a limitation; this could be addressed through the use of an automated segmentation and measurement algorithm to scale up model generation and analysis.

CLINICAL RELEVANCE/APPLICATION

Applying optimized HU thresholds and patient-specific adjustments enables production of highly accurate 3D airway models for surgical planning, simulation training, and custom device development.

M5B-SPCH-2 A STUDY ON PREDICTING STROKE-RELATED PNEUMONIA IN INTRACEREBRAL HEMORRHAGE PATIENTS BASED ON HEAD CT RADIOMICS

Zhiming Zhou (*Presenter*)

PURPOSE

To investigate the value of head non-contrast enhanced CT (NCCT) radiomics in predicting stroke-associated pneumonia (SAP).

METHODS AND MATERIALS

A total of 522 ICH patients from China were retrospectively analyzed, including 421 from our hospital (295 for the training cohort and 126 for the validation cohort) and 101 from another hospital as the testing cohort. Patients were divided into pneumonia and non-pneumonia groups based on whether pneumonia occurred within seven days of stroke onset. Independent risk factors were identified using univariate and multivariate analysis to construct a clinical model. Optimal radiomics features of brain hematoma and edema were selected using radiomics analysis methods, and radiomics scores (Radscore) were calculated. Multiple models were constructed by incorporating ICH_Radscore and EDEMA_Radscore into the clinical model. Model performance was evaluated using receiver operating characteristic (ROC) curves, and the best model was visualized as a nomogram.

RESULTS

Baseline NIHSS, dysphagia, NLR, and SII were identified as independent risk factors for SAP. Using feature selection methods, we identified 6 optimal hematoma features and 5 optimal edema features. Significant differences between the SAP and non-SAP groups were found in multiple features, including ICH_Radscore and EDEMA_Radscore. Multifactor analysis showed that EDEMA_Radscore remained significant when combined with clinical risk factors. Various models, including APS-A-Score, ICH_Radscore, EDEMA_Radscore, Clinical_Model, Clinical_ICH_Model, Clinical_EDEMA_Model, and Combined_model, demonstrated good predictive performance in validation and test cohorts, with AUCs ranging from 0.780 to 0.915. The Combined_model performed slightly better, with good consistency and clinical applicability in predicting SAP occurrence. Additionally, the Combined_model achieved AUCs of 0.846 and 0.834 in predicting the prognosis of ICH patients in the verification and test cohorts.

CONCLUSION

Head NCCT radiomics is effective for predicting SAP in ICH patients, and the nomogram of the Combined_model can serve as a predictive tool for SAP in ICH patients.

CLINICAL RELEVANCE/APPLICATION

This study offers a non-invasive and cost-effective radiomics-based tool using head NCCT to predict SAP risk in ICH patients, enabling early identification of high-risk individuals and guiding personalized management strategies to enhance clinical outcomes.

M5B-SPCH-3 ADDITIVE VALUE OF BODY COMPOSITION BASED ON BASELINE CHEST CT FOR LONG-TERM PROGNOSIS IN NSCLC

Junli Tao (*Presenter*)

PURPOSE

To explore whether CT-quantified body composition parameters, including skeletal muscle, subcutaneous fat and pericardial fat are associated with prognosis of NSCLC,and aiming to establish a simple and synergistic prediction model that combine body composition and clinical indicators to improve prognosis for patients with NSCLC.

METHODS AND MATERIALS

This retrospective study included patients from 2017 to 2022 with NSCLC confirmed by pathology.The skeletal muscle area (SMA) and density (SMD) (including pectoralis major and pectoralis minor muscle) and subcutaneous fat parameters (area and density) were obtained semi-automatically at the fourth thoracic vertebrae (Th4). Pericardial fat volume (PFV) and density (PFD) were automatically calculated. The skeletal muscle and subcutaneous fat index (SMI and SFI) were calculated as SMA and SFA divided by height squared respectively, while pericardial fat index (PFI) was PFV divided by body surface area (BSA).Cox proportional hazards modelling was used to assess the association between body composition and 5-year overall survival (OS).Four survival prediction models were constructed (model I: including prognostic nutritional index, model II: including body composition, model III: including tumor staging, model IV: including body composition and tumor staging).The effectiveness of the established model in predicting the long-term prognosis of NSCLC was evaluated and compared.

RESULTS

A total of 1160 patients were included. Lower skeletal muscle index (SMI; HR: 0.655, 95% CI: 0.555-0.773, P = 0.00), lower subcutaneous fat index (SFI; HR: 0.383, 95% CI: 0.291-0.505, P = 0.00) and lower pericardial fat index (PFI; HR: 0.652, 95% CI: 0.546-0.780, P = 0.00) were independent prognostic factors for worse 5-year OS in NSCLC. Higher subcutaneous fat densities (SFD; HR: 1.892, 95% CI: 1.605-2.231, P = 0.00) and pericardial fat densities (PFD; HR: 1.892, 95% CI: 1.605-2.231, P = 0.00) were associated with worse 5-year OS. Compared to Model I , Model II had a superior prognostic efficacy for 5-year OS. Model IV had the best predictive abilities for OS (C-index 0.783).

CONCLUSION

CT-quantified body composition were closely related to NSCLC prognosis. Patients with higher SMI, SFI and PFI had longer 5-year OS, whereas higher SFD and PFD were unfavourable prognostic factors. The integration of CT-quantified body composition parameters has added value to the TNM staging system in predicting prognosis in NSCLC.

CLINICAL RELEVANCE/APPLICATION

The body composition of baseline chest CT can be of clinical value as an independent predictor of 5-year OS in NSCLC as well as having additive value for TNM prognostic evaluation indicators for survival stratification and long-term prognostic prediction.

M5B-SPCH-4 EVALUATING LARGE LANGUAGE MODEL FOR IDENTIFYING POSITIVE PULMONARY EMBOLISM CASES IN CHEST CT REPORTS TO ASSESS IMAGING UTILIZATION

Azfar Basunia, MD (*Presenter*)
Satvik Tripathi (*Abstract Co-Author*)
Tessa S. Cook, MD, PhD (*Abstract Co-Author*)
Friedrich D. Knollmann, MD, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate the ability of a large language model (LLM) to automatically identify positive cases of pulmonary embolism (PE) in contrast-enhanced chest CT reports ordered from the emergency department, to support analysis of potential imaging utilization.

METHODS AND MATERIALS

A HIPAA-compliant deployment of GPT-4 was used to process 300 contrast-enhanced chest CT reports. The model was prompted using chain-of-thought (CoT) reasoning to extract structured variables from each report, including: (1) clinical indication, (2) PE presence or absence, (3) PE type (acute, chronic, or acute on chronic), and (4) justification for the PE classification. Additionally, the model inferred the Wells Score and provided a supporting rationale based on the clinical context in the report. All outputs were validated through manual review by a clinical radiologist.

RESULTS

The LLM accurately identified the presence or absence of PE in 299 out of 300 reports (99.7% accuracy). In the one discordant case, the model misclassified the study as showing chronic PE when no embolus was present. Notably, the justification included the correct excerpt from the report, which described the radiologist's consideration of artifact versus chronic thrombus. Among the 93 reports with confirmed PE, the model correctly identified the PE type in 89 cases (95.7% accuracy). The LLM effectively distinguished between acute and chronic emboli using contextual information from the findings and impression sections, even in the absence of explicit labeling in the original report.

CONCLUSION

The model also shows promise in inferring clinical reasoning structures such as Wells Score with justification, making it a viable tool for evaluating diagnostic yield and potential overutilization of imaging.

CLINICAL RELEVANCE/APPLICATION

Automated extraction of structured findings and clinical reasoning from chest CT reports using LLMs may enable scalable analysis of imaging utilization and appropriateness in emergency care settings, supporting more efficient and evidence-based radiology practice.

M5B-SPCH-5 TRANSFORMER-BASED INTEGRATION OF CHEST RADIOGRAPHS AND CLINICAL DATA FOR PREDICTING 30-DAY MORTALITY IN PATIENTS WITH COMMUNITY-ACQUIRED PNEUMONIA

Changi Kim, MS (*Presenter*)
Eui Jin Hwang, MD, PhD (*Abstract Co-Author*)

PURPOSE

Both findings of chest radiograph (CR) and clinical data are essential information for decision-making in patients with community-acquired pneumonia (CAP), while the integration of information from two different domains has been limited. We aimed to develop and validate a transformer-based fusion deep learning model integrating CR and clinical data for prediction of 30-day mortality in CAP patients.

METHODS AND MATERIALS

We retrospectively collected CR images and 17 clinical variables (age, sex, vital signs, and blood tests) from consecutive CAP patients who visited the ED of a tertiary institution between 2010 and 2018 (development dataset) to develop a fusion model. The model combined CR and clinical data, each processed by a transformer-based architecture, with their outputs concatenated and input into a multilayer perceptron. We collected two separate datasets to evaluate the performance of the model: a) Test dataset A, data from consecutive CAP patients who visited ED of the same institution in 2019; and b) Test dataset B, data from CAP patients in a publicly available MIMIC-IV-ED dataset (test dataset B). The area under receiver operating characteristic curve (AUC) of the fusion model for the prediction model of 30-day mortality was evaluated in test datasets, and compared with three benchmark models: a) CURB-65 score, an established risk assessment tool based on clinical data; b) a Cox proportional hazard (PH) model based on clinical data only (clinical model); and c) a convolutional neural network-based deep learning model using CR only (CR model).

RESULTS

The development dataset, and test datasets A and B comprised 6,199 (3,818 male patients; mean age, 67 years; 30-day mortality rate, 7%), 996 (578 male patients; mean age, 70 years; 30-day mortality rate, 7%), and 4,703 (2,405 male patients; mean age, 66 years; 30-day mortality rate, 10%) CAP patients, respectively. The fusion model showed AUCs of 0.80 and 0.84 in test datasets A and B, respectively. The fusion showed higher AUCs than CURB-65 score (0.65 [p<.001] and 0.69 [p<.001] in test datasets A and B, respectively hereafter), clinical model (0.69 [p<.001] and 0.72 [p<.001]), and CR model (0.76 [p=.058] and 0.81 [p<.001]).

CONCLUSION

The transformer-based fusion model integrating CRs with various clinical data could predict 30-day mortality of CAP patients with higher accuracy compared to traditional CURB-65 score, and prediction model solely based on either clinical data or CR images.

CLINICAL RELEVANCE/APPLICATION

Integration of CR image findings and clinical data using the transformer-based fusion model may enable more precise prognostication of patients with CAP. It may help clinical decision-making regarding hospitalization, intensity of monitoring, and critical care interventions.

M5B-SPCH-6 ROLE OF ARTIFICIAL INTELLIGENCE IN EVALUATION OF NCCT THORAX IN PATIENTS WITH FEBRILE NEUTROPENIA

Saurabh Bhangare, MBBS, MD (*Presenter*)
Akshay D. Baheti, MD, MD (*Abstract Co-Author*)
Vasundhara Smriti, MD (*Abstract Co-Author*)
SUYASH KULKARNI (*Abstract Co-Author*)
Nitin S. Shetty, MBBS, MD (*Abstract Co-Author*)

PURPOSE

Non-contrast CT (NCCT) thorax is used to evaluate patients with hematological malignancies with febrile neutropenia. It is however suboptimal in its accuracy to identify the infectious pathogen. We developed a deep learning model to automatically segment lung abnormalities and identify the infectious agent on NCCT images.

METHODS AND MATERIALS

This IRB-approved retrospective study included 374 patients with febrile neutropenia (from Jan 2015 to May 2024), selected from 500 NCCT scans after excluding mixed infections, poor quality images, or cases without confirmed microbiological diagnoses. Infectious opacities were manually segmented by a radiologist with three years' experience using 3D Slicer. Ground-truth labels included bacterial, fungal, TB, viral, and normal lungs. A U-Net with ResNet-34 encoder was used for segmentation, while a parallel ResNet-18 CNN performed classification. Data was split 70/15/15 for training, validation, and testing. Dice Loss and Categorical Cross-Entropy were used for training. Dice score and IoU were calculated for segmentation. Classification performance was evaluated using F1-score, precision, and recall. Statistical tests were performed using SciPy and Scikit-learn.

RESULTS

Out of the 374 patients (58% males, mean age 41.3 years), 112 had bacterial infections, 97 had fungal, 51 had TB, 43 had viral infections, and 71 were classified normal. The U-Net segmentation model achieved Dice scores of 0.61, 0.58 and 0.59 for bacterial and fungal infection and TB respectively on the validation set. Viral infections were excluded from final segmentation analysis due to unstable model convergence. The ResNet-18 classification model demonstrated an overall macro-averaged F1-score of 0.557 on the held-out test set. Per-class F1 score was 0.64, 0.53, 0.45, 0.58, and 0.61 for bacterial, fungal, viral, TB, and normal respectively. Bacterial and TB classes showed better overall accuracy. Misclassification was primarily observed between fungal and bacterial infections and between TB and fungal patterns. Several factors constrained model performance, including underrepresentation of viral and TB cases. External validation on multi-institutional datasets is necessary for assessing generalizability.

CONCLUSION

Our U-Net and ResNet-based model achieved moderate performance in detecting and classifying lung infections in febrile neutropenic patients, with bacterial and TB infections being most reliably identified.

CLINICAL RELEVANCE/APPLICATION

Our model demonstrates a potential role in accurately identifying the infectious etiology for patients with febrile neutropenia, allowing for timely appropriate treatment.

M5B-SPCH-8 GENERATIVE ARTIFICIAL INTELLIGENCE IN CHEST X-RAY INTERPRETATION: EXPERT CONSENSUS OF THE KOREAN SOCIETY OF THORACIC RADIOLOGY USING THE DELPHI METHOD

Won Gi Jeong, MD, PhD (*Presenter*)
Gongyoung Jin, MD, PhD (*Abstract Co-Author*)
Yun-Hyeon Kim, MD (*Abstract Co-Author*)

PURPOSE

Advancements in generative artificial intelligence (AI) have led to the development of automated radiology report generation tools, particularly for chest X-rays (CXRs). While these tools may improve efficiency and address radiologist shortages, their accuracy, reliability, and clinical applicability remain uncertain. Expert consensus is needed to guide their use. This study aimed to establish expert consensus from the Korean Society of Thoracic Radiology on the accuracy and potential clinical applications of an AI-automated CXR report generation tool using the Delphi method.

METHODS AND MATERIALS

A Delphi survey was conducted among 20 thoracic radiologists who reviewed 60 CXR cases across six clinical settings (health screening, inpatient, emergency department, intensive care unit (ICU), respiratory outpatient, and non-respiratory outpatient) using an AI-automated report generation tool (KARA-CXR, version 1.0.0.3). Participants assessed accuracy, hallucination rate, readability, and clinical applicability using a 9-point Likert scale. Consensus was defined as =70% agreement within a response category. Content validity ratio and coefficient of variation were calculated.

RESULTS

Consensus was reached on 41 of 72 survey items (56.9%). The AI tool demonstrated the highest accuracy in health screening (86%) with a 3.5% hallucination rate and 2% interpretation error rate. Lower accuracy was observed in inpatient (64.5%), emergency (66.5%), and ICU (60%) settings, with higher hallucination and error rates. Consensus was neutral on reliability outside the health screening setting and the tool's potential to enhance radiologists' accuracy and efficiency. Standalone AI use was opposed in inpatient, ICU, respiratory outpatient, and non-respiratory outpatient settings. Additionally, 85% of radiologists emphasized the need for education and guidelines before clinical implementation.

CONCLUSION

Consensus among Korean thoracic radiologists was neutral regarding the clinical applicability of AI-automated CXR report generation tool, except in health screening settings where accuracy was highest. Independent AI reporting was not endorsed. Further performance improvements, validation studies, and academic guidelines are needed before broader clinical adoption.

CLINICAL RELEVANCE/APPLICATION

This study underscores the importance of expert oversight, validation, and regulatory guidelines for the safe and effective implementation of AI-automated CXR report generation tool in clinical practice.

M5B-SPCH-9 THE DIAGNOSTIC PERFORMANCE OF CHATGPT 4O IN INTERPRETING CHEST AND ABDOMINAL X-RAY IMAGES

Pietro Giacomo Lacaita, MD (*Presenter*)
Malik Galijasevic, MD (*Abstract Co-Author*)
Michael Swoboda, MD (*Abstract Co-Author*)
Leonhard Gruber (*Abstract Co-Author*)
Gerlig Widmann, MD, MSc (*Abstract Co-Author*)
Gudrun Feuchtner, MD (*Abstract Co-Author*)

PURPOSE

Large language models (LLMs), such as ChatGPT, have emerged as potential clinical support tools, but their reliability in radiological image interpretation remains unclear. The primary aim of our study was to evaluate the diagnostic accuracy of ChatGPT 4o in interpreting chest X-rays (CXR) and abdominal X-rays (AXR), comparing its performance to expert radiology findings, secondary aims were diagnostic confidence and patient safety.

METHODS AND MATERIALS

A total of 500 X-rays, including 257 CXR (51.4%) and 243 AXR (48.5%), were analyzed. Diagnoses made by ChatGPT 4o were compared to expert interpretations. Confidence scores (1-4) were assigned, and responses were evaluated for patient safety.

RESULTS

ChatGPT 4o correctly identified 345 of 500 (69%) pathologies (95% CI: 64.81-72.9). For AXR, 175 of 243 (72.02%) pathologies were correctly diagnosed (95% CI: 66.06-77.28), while for CXR, 170 of 257 (66.15%) were accurate (95% CI: 60.16-71.66). The highest detection rates among CXR were observed for pulmonary edema, tumor, pneumonia, pleural effusion, cardiomegaly and emphysema, and lower rates for pneumothorax, rib fractures, and enlarged mediastinum. AXR performance was highest for intestinal obstruction and foreign bodies, and weaker for pneumoperitoneum, renal calculi, and diverticulitis. Confidence scores were higher for AXR (mean 3.45 ± 1.1) than CXR (mean 2.48 ± 1.45). All responses (100%) were considered as safe for the patient. Interobserver agreement was high (kappa = 0.920), and reliability (2 nd prompt) was moderate (kappa = 0.750).

CONCLUSION

ChatGPT 4o demonstrated moderate accuracy for the interpretation of X-rays, being higher for AXR compared to CXR. Improvements are required for its use as efficient clinical support tool.

CLINICAL RELEVANCE/APPLICATION

This study provides the evaluation of ChatGPT-4o's diagnostic performance on plain chest and abdominal X-rays. The findings highlight its potential as a clinical support tool in emergency or resource-limited settings, particularly for non-radiologists, while emphasizing the need for expert oversight due to moderate accuracy and limited reliability in complex cases.

M5B-SPCH-10 PREDICTING LYMPHOVASCULAR INVASION IN STAGE IA LUNG ADENOCARCINOMA: A CT-BASED CLASSIFICATION AND REGRESSION TREE MODEL

Chen Lihua (*Presenter*)
Yao Huang (*Abstract Co-Author*)
Junli Tao (*Abstract Co-Author*)
Daihong Liu, PhD (*Abstract Co-Author*)
Jiuquan Zhang (*Abstract Co-Author*)

PURPOSE

Lymphovascular invasion (LVI) is a significant histopathological marker associated with poor prognosis in lung cancer patients. However, there is a notable lack of reliable, non-invasive preoperative tools to accurately predict LVI. We aim to develop and validate a computed tomography (CT)-based classification and regression tree (CART) model for the preoperative prediction of LVI in patients with clinical stage IA lung adenocarcinoma (LUAD).

METHODS AND MATERIALS

The study was approved by the institutional review board of each participating hospital and conducted by the principles of the Declaration of Helsinki and the statement of TRIPOD. This multi-centre cohort study recruited patients who underwent resection and had a preoperative CT examination. The CT features were independently and visually evaluated by two thoracic radiologists who were blinded to each other. Any discrepancies were resolved by a third radiologist. An internal cohort (n = 525) is included to construct the LVI classi& 7;cation and regression tree model (LVI-CART). An external cohort (n = 115) and a public cohort (n = 57) are then used to fully validate the predictive performance of the LVI-CART. The survival rates of the patients were analysed using the Kaplan-Meier method, and the survival curves were compared using the log-rank test.

RESULTS

Univariate logistic regression analysis revealed that tumor diameter, nodule type, and pleural indentation were significantly associated with pathological LVI status (all $P < 0.05$). Variables with $P < 0.05$ in the univariate analysis were included in stepwise multivariable logistic regression, which identified tumor diameter and nodule type as independent predictors of LVI status (all $P < 0.05$). The LVI-CART model with diameter and nodule type shows acceptable performance in predicting pathological LVI, with area under the curve values of 0.719, 0.756, and 0.835 in the internal validation set, external validation set and test set, respectively. A predicted LVI positive relative to the median value in the outcomes cohort was found to be independently associated with 1-, 3-year RFS and 1-, 3-, 5-year OS (all P values < 0.05).

CONCLUSION

The LVI-CART model could be used to preoperatively predict LVI and identify patients with poor prognosis in clinical IA LUAD. The model is like to be simple and easily applicable to risk stratification.

CLINICAL RELEVANCE/APPLICATION

The LVI-CART model provides clinicians with an easy-to-use method for preoperative identification of patients with clinical stage IA lung adenocarcinoma who are LVI-positive. It also provides a framework for a comprehensive assessment of patient survival risk.

M5B-SPCH-11 MRI OUTPERFORMS CT IN RESPONSE ASSESSMENT AFTER NEOADJUVANT THERAPY FOR LOCALLY ADVANCED ESOPHAGEAL SQUAMOUS CELL CARCINOMA: A PROSPECTIVE STUDY BASED ON RECIST CRITERIA

Jin Rong Qu, MD (*Presenter*)
Binbin Han (*Abstract Co-Author*)
Wenshi Li (*Abstract Co-Author*)

PURPOSE

To compare the diagnostic performance of magnetic resonance imaging (MRI) and contrast-enhanced computed tomography (CT) in evaluating treatment response after neoadjuvant therapy (NAT) for locally advanced esophageal squamous cell carcinoma (ESCC), based on Response Evaluation Criteria in Solid Tumors (RECIST).

METHODS AND MATERIALS

This prospective cohort study (July 2019-June 2024) enrolled 108 patients with ESCC (cT2-T4a/N0-N3/M0; mean age 63.5±7.1 years; 84 males). All patients underwent MRI and contrast-enhanced CT before and after NAT prior to esophagectomy. Two radiologists independently assessed treatment response on CT and MRI images. Postoperative pathologic tumor regression grade (TRG) served as the reference standard: complete response (CR: TRG0, n=28) versus non-CR (TRG1-3, n=80), and good response (GR: TRG0-1, n=43) versus non-GR (TRG2-3, n=65). Chi-square tests and Cohen's kappa values were used to compare imaging assessments with pathological findings.

RESULTS

CT demonstrated accuracy, sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) of 64.81%, 25.00%, 77.50%, 28.00%, and 74.70%, respectively, in discriminating CR from non-CR. In contrast, MRI showed significantly superior performance: accuracy (92.59%), sensitivity (89.29%), specificity (93.75%), PPV (83.33%), and NPV (96.15%). Cohen's kappa coefficient revealed high agreement between MRI and postoperative pathology for CR assessment (?=0.815, p<0.001), while CT showed no statistically significant agreement (?=0.031, p=0.715). MR tumor regression grade (mrTRG) demonstrated excellent concordance with pathological TRG (CR/non-CR: ?=0.905; GR/non-GR: ?=0.702, p<0.001).

CONCLUSION

MRI outperforms CT in assessing treatment response after NAT for locally advanced ESCC, demonstrating high diagnostic accuracy (>92%). The mrTRG system accurately stratifies TRG, suggesting MRI as the preferred imaging modality for implementing RECIST in ESCC management.

CLINICAL RELEVANCE/APPLICATION

MRI-based RECIST assessment combined with the mrTRG system provides accurate risk stratification and individualized treatment planning for locally advanced ESCC, offering superior clinical utility and pathological concordance compared to CT.

M5B-SPCH-12 AUTOMATED INTERSTITIAL LUNG ABNORMALITY PROBABILITY PREDICTION ON CT: ASSOCIATION WITH MORTALITY IN PATIENTS WITH ESOPHAGEAL CANCER

Akinori Hata, MD, PhD (*Presenter*)
Kota Aoyagi (*Abstract Co-Author*)
Masahiro Yanagawa, MD, PhD (*Abstract Co-Author*)
Midori Ueno, MD (*Abstract Co-Author*)
Miyuki Tomiyama (*Abstract Co-Author*)
Daiki Nishigaki, PhD (*Abstract Co-Author*)
Shuhei Doi, MD (*Abstract Co-Author*)
Kazuki Yamagata, MD (*Abstract Co-Author*)
Yuka Fujita, MD (*Abstract Co-Author*)
Yukiko Tokuda, MD, PhD (*Abstract Co-Author*)
Noriyuki Tomiyama, MD, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate the diagnostic performance of automated interstitial lung abnormality (ILA) probability prediction and investigate its association with mortality in patients with esophageal cancer.

METHODS AND MATERIALS

This retrospective study included patients diagnosed with esophageal cancer between January 2011 and December 2015. ILA was visually scored on pretreatment baseline chest CT (<1 mm slice thickness) using a three-point scale (0 = non-ILA, 1 = indeterminate for ILA, 2 = ILA). Previously developed artificial intelligence (AI) models were applied to the CT images. A total of 12 AI models were used, incorporating different classification algorithms (support vector machine [SVM], random forest [RF], and convolutional neural network [CNN]) and handling of indeterminate ILA slices and cases. These models generated probability values ranging from 0 (unlikely to have ILA) to 1 (likely to have ILA). A multivariable Cox proportional hazards model, adjusting for age, sex, body mass index, smoking history, and cancer stage, was used to assess the association between AI-predicted ILA probability and five-year overall survival. The best-performing model was selected using the Akaike Information Criterion. The probabilities derived from this model were compared among the non-ILA, indeterminate for ILA, and ILA groups using the Kruskal-Wallis test.

RESULTS

A total of 452 patients (median age, 68 years; interquartile range, 61-73 years; 61 women) were included. Among them, 251 (56%) were classified as non-ILA (score 0), 118 (26%) as indeterminate for ILA (score 1), and 83 (18%) as ILA (score 2). All 12 AI-predicted probability models demonstrated a statistically significant association with shorter survival in the multivariable Cox proportional hazards model ($p < 0.05$). The best-performing model yielded a hazard ratio (HR) for mortality of 7.3 (95% confidence interval: 2.7-19.2; $p < 0.001$). The mean probability scores for the non-ILA, indeterminate ILA, and ILA groups in this model were 0.18 ± 0.07, 0.20 ± 0.07, and 0.35 ± 0.23, respectively, with significant differences among groups (all $p < 0.001$).

CONCLUSION

AI-derived ILA probability on CT was a significant predictor of shorter survival in patients with esophageal cancer. The AI-predicted probability was well correlated with visually assessed ILA classification, demonstrating its potential as a reliable, automated diagnostic tool.

CLINICAL RELEVANCE/APPLICATION

Automated AI-based ILA detection provides a reproducible and objective method for diagnosing ILA. This approach may be valuable for prognostication and patient management in esophageal cancer.

M5B-SPCH-13 AI-ASSISTED CT PATTERN CLASSIFICATION FOR NTM LUNG DISEASE: TOWARD PRECISION DIAGNOSIS USING 3D DEEP LEARNING

Liu Shu Yu, MS, RT (*Presenter*)
Pin-Yi Chiang, MD (*Abstract Co-Author*)
Yuan-Chung Cheng (*Abstract Co-Author*)
Yu-Jie Shen (*Abstract Co-Author*)
RUEYMING HWANG (*Abstract Co-Author*)
Yeun-Chung Chang, MD (*Abstract Co-Author*)
Shyh-Jye Chen, MD, PhD (*Abstract Co-Author*)
YI-CHENG HSIAO (*Abstract Co-Author*)

PURPOSE

Non-tuberculous mycobacterial lung disease (NTM-LD) presents with distinct CT patterns linked to different prognoses and treatments. As imaging volume increases, manual interpretation may not always provide timely clinical support. This study aimed to develop a 3D deep learning model to enable efficient and standardized classification of NTM-LD patterns.

METHODS AND MATERIALS

We retrospectively collected chest CT scans from patients with NTM-LD treated between 2015 and 2024 at a single tertiary medical center in Taiwan. A modified 3D EfficientNetB0 pretrained on ImageNet was used for classification. Data were randomly split (60:20:20) into training, validation, and test sets. The model was trained using cross-entropy loss and the Adam optimizer (learning rate = 1e-4) over 100 epochs (batch size = 4). Performance was continuously monitored for convergence and generalizability.

RESULTS

The dataset included 211 CT scans, categorized into fibrocavitary (n=63), bronchiectasis with cavitation (n=46), and bronchiectatic-only (n=112) subtypes. The proposed model achieved a test accuracy of 75.68%, with weighted precision, recall, and F1-score of 0.77, 0.76, and 0.76, respectively. Class-specific recall was 70% for fibrocavitary, 57% for bronchiectasis with cavitation, and 85% for bronchiectatic-only. Training accuracy exceeded 90%, while validation accuracy plateaued at approximately 75%, indicating minor overfitting. Loss curves demonstrated convergence around epoch 60.

CONCLUSION

We developed a 3D deep learning model to classify imaging patterns of NTM-LD on chest CT.Given the prognostic and therapeutic variability across NTM subtypes, accurate radiologic differentiation is essential for guiding clinical decision-making. This automated classification system may enhance diagnostic precision and promote consistency in interpretation.By supporting timely identification of imaging subtypes, the model has potential to serve as a clinical decision-support tool that informs appropriate treatment selection and improves workflow efficiency in daily radiology practice.

CLINICAL RELEVANCE/APPLICATION

This 3D deep learning-based classification model assists in distinguishing radiologic patterns of NTM-LD on chest CT, helping clinicians tailor treatment strategies based on imaging subtypes. It supports precision medicine by improving diagnostic consistency and reducing subjective interpretation.

M5B-SPER-1 POSTMORTEM CT ATTENUATION VALUES OF ORGANS IN BURNED AND NON-BURNED BODIES: A FORENSIC COMPARATIVE STUDY

Norihiro Shinkawa, MD, PhD (*Presenter*)

PURPOSE

In burned cadavers, PMCT is primarily used to detect injuries or pathologies unrelated to the fire, identify anatomical variations, surgical alterations, or medical devices used for personal identification, and determine optimal sampling sites for DNA analysis or toxicological examination. In this study, "burned bodies" refer to those discovered at fire scenes, including both true burn fatalities and cases where death occurred prior to fire exposure. Radiologists often interpret PMCT using the same criteria as in living patients. This study aims to clarify the CT attenuation values of various organs in burned cadavers.

METHODS AND MATERIALS

We analyzed 47 forensic autopsy cases with PMCT: 19 burned and 28 non-burned bodies. Severely decomposed cases were excluded. CT scans were acquired using a 64-detector-row scanner (SOMATOM Definition AS+, Siemens Medical, Erlangen, Germany), with 120 kVp and automatic exposure control (AEC). The PMCT image data consisted of 5-mm axial sections through the head and abdominal region. The window level and window width settings were the same as those used for living patients in our institution: head images with WL 30 and WW 80, and abdominal images with WL 55 and WW 350. CT attenuation values (Hounsfield Units, HU) were measured in the liver, spleen, kidneys, iliopsoas muscles, and cerebral corona radiata. Bilateral measurements were performed for all organs except the spleen. The regions of interest (ROIs) were maximized, avoiding areas with endogenous disease, trauma unrelated to burns, gas, or artifacts from the upper limbs in the trunk region. The Mann-Whitney U test was used to compare the CT values between the burned and non-burned groups.

RESULTS

The mean (±SD) CT values in burned versus non-burned groups were as follows (in HU): liver, 73±11 vs. 56±19; spleen, 52±9 vs. 46±9; kidneys, 51±9 vs. 38±8; iliopsoas muscles, 53±5 vs. 49±7; cerebral corona radiata, 42±3 vs. 42±4. Statistically significant differences ($p < 0.05$) were observed in the liver, spleen, kidneys, and iliopsoas muscles.

CONCLUSION

CT attenuation values in burned bodies were significantly higher than those in non-burned bodies for the liver, spleen, kidneys, and iliopsoas muscles. Compared to the brain, which is enclosed by the skull, abdominal organs are more susceptible to thermal effects. We hypothesize that heat exposure causes water loss and thermal coagulation of proteins, leading to increased CT values.

CLINICAL RELEVANCE/APPLICATION

Radiologists should be aware that CT attenuation values of abdominal organs may be elevated in burned cadavers. This finding also highlights the need for the development of CT imaging techniques optimized for burned bodies.

M5B-SPER-2 EFFECTS OF A HIGH-FIDELITY ON-CALL SIMULATION FOR PGY-2 DIAGNOSTIC RADIOLOGY RESIDENTS

Alind Amedi, MD (*Presenter*)
Ann Packard, MD (*Abstract Co-Author*)
Julie B. Guerin, MD (*Abstract Co-Author*)
Nathan C. Hull, MD (*Abstract Co-Author*)

PURPOSE

Preparing residents for on-call responsibilities remains one of the most important duties of a radiology training program. Programs have devised varying methods for educating residents and assessing their competence before starting call. These include didactic lectures, case conferences, and flipped-classroom models. Simulation learning has been a focus of increased interest in radiology, often for promoting procedural or interpersonal skills. We sought to develop a high-fidelity simulation of the on-call experience for our PGY-2 radiology residents. While other institutions have previously incorporated forms of simulation in their pre-call curriculum, these simulations often lack elements that could provide a higher-fidelity experience. These elements include native PACS functionality, dictation software integration, exposure to normal exams, and the introduction of workroom interruptions.

METHODS AND MATERIALS

We asked each division of radiology to collect cases that were representative of those residents might encounter on-call. Our goal was to simulate a specific call shift that begins in PGY3, where the resident has the responsibility of independently reading ultrasounds and radiographs that occur after-hours. 120 cases were collected, including normal exams. We deidentified these cases and hosted them on our native PACS. Residents were tasked with dictating preliminary reports. There was a time-limit of 3 hours and residents would be periodically interrupted by administrative staff to better simulate the call experience. Preliminary reports were graded on a score of 0-2, with full marks given to reports that correctly interpreted all major and pertinent findings. Cases were graded by a single examiner to remove inter-observer variance. Pre- and post- surveys were given to residents to assess subjective feelings of confidence and anxiety regarding taking this specific call shift. The Mann-Whitney U test was used to compare responses between pre- and post- simulation groups.

RESULTS

There was a statistically significant reduction in the anxiety of residents in reading ultrasound ($p = 0.02$) and radiographs ($p = 0.019$) on call. Residents also reported increased confidence with detection ($p = 0.035$) as well proper interpretation of major and pertinent findings on call ($p < 0.001$). 90% of residents recommended the simulation be given to future classes.

CONCLUSION

High-fidelity simulation allows radiology trainees to practice and refine clinical judgment in a realistic environment, and can result in decreased resident anxiety and increased confidence when taking call.

CLINICAL RELEVANCE/APPLICATION

This simulation can be used as a model for other training programs seeking to improve their call-related curriculum.

M5B-SPGI-1 AUTOMATED AI-ENABLED CT BIOMARKERS FOR POPULATION-BASED OPPORTUNISTIC DETECTION OF PATIENTS AT RISK FOR UNSUSPECTED ADVANCED HEPATIC FIBROSIS AND CIRRHOSIS

Ravi Chandra Yada (*Presenter*)
Meghan G. Lubner, MD (*Abstract Co-Author*)
John W. Garrett, PhD (*Abstract Co-Author*)
Lu Mao (*Abstract Co-Author*)
Ronald M. Summers, MD, PhD (*Abstract Co-Author*)
Perry J. Pickhardt, MD (*Abstract Co-Author*)

PURPOSE

Chronic liver disease affects hundreds of millions worldwide, with early intervention during fibrosis stages offering the best outcomes. Despite this opportunity, advanced disease often remains undetected until complications arise. Liver biopsy remains the gold standard for confirming fibrosis but has significant limitations including invasiveness, sampling error, cost, and poor patient acceptance. Non-invasive alternatives like elastography require prospective planning. Meanwhile, approximately 30 million CT scans including the upper abdomen are performed annually in the US for various indications. As fibrosis progresses, characteristic morphologic changes in hepatic and splenic morphology often precede clinical symptoms, potentially allowing for opportunistic detection using AI. This study aimed to determine the utility of automated AI-enabled CT biomarkers in assessing risk for hepatic fibrosis and cirrhosis.

METHODS AND MATERIALS

AI-enabled CT tools assessing liver segmental volume ratio (LSVR; ratio of Couinaud segments I-III/IV-VIII) and splenic volume were applied to 30,940 adults (mean age 51.5 years; 14,459 men, 16,481 women) who underwent abdominal CT with available retrospective FIB-4 scores within 1 year. Established high-risk thresholds of 0.347 for LSVR and 315 ml for splenic volume were applied. Cohorts were analyzed according to FIB-4 levels and correlated with clinical outcome data regarding chronic liver disease and cirrhosis.

RESULTS

Among 2,943 patients (10.3%) with both elevated LSVR and splenic volume, mean FIB-4 score was 2.97 ($p < 0.0001$), whereas among 13,759 patients (48.3%) below both thresholds, mean FIB-4 score was 0.89. Patients with elevated LSVR only (5,359; 18.8%) had mean FIB-4 score of 0.91 ($p = 0.2397$), while those with elevated splenic volume only (6,437; 22.6%) had mean FIB-4 score of 1.14 ($p < 0.0001$). Among patients below both thresholds, 5.6% had FIB-4 score >2.67, versus 46.7% among patients above both. The likelihood of having chronic liver disease recorded in the EMR (e.g., downstream from CT) was 76% for patients above both thresholds and 6.5% for those below both.

CONCLUSION

AI-enabled automated hepatosplenic CT biomarkers demonstrate strong correlation with both FIB-4 scores and clinical liver disease outcomes. Patients exceeding both LSVR and splenic volume thresholds were nearly 12x more likely to have chronic liver disease compared to those below both thresholds.

CLINICAL RELEVANCE/APPLICATION

This opportunistic screening approach could identify at-risk patients who would benefit from hepatology referral without requiring additional testing, potentially enabling timely interventions that could slow or reverse fibrosis progression before cirrhosis becomes established.

M5B-SPGI-3 ARTERIAL PHASE HYPOINTENSE VOLUME ON GADOXETIC ACID-ENHANCED MRI: A POOR PROGNOSTIC FACTOR IN HCC PATIENTS UNDERGOING HEPATIC RESECTION

Jun Gu Kang, MD (*Presenter*)
Seohyun Park (*Abstract Co-Author*)
Dasom Kim (*Abstract Co-Author*)
Hyungjin Rhee, MD, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate the prognostic significance of arterial phase hypointense volume (APHIV) measured on gadoxetic acid-enhanced MRI in patients undergoing hepatic resection for hepatocellular carcinoma.

METHODS AND MATERIALS

This retrospective study included 482 patients with Barcelona Clinic Liver Cancer(BCLC) stage 0/A HCC who underwent hepatic resection and preoperative gadoxetic acid-enhanced MRI within 3 months at a single institution between January 2009 and December 2014. Patients were temporally divided into training(n=272, 2009-2011) and validation(n=210, 2012-2014) sets by surgery date. After registering arterial and hepatobiliary phase images, an abdominal radiologist performed volumetric tumor segmentation on hepatobiliary phase images and placed a 1-cm^2 peritumoral non-tumor region-of-interest (ROI) in the on arterial phase image. APHIV was determined by the tumor volume showing lower intensity than the mean non-tumor ROI intensity in the arterial phase. Overall survival (OS) was defined by the time from surgery to death within 5 years, and early recurrence (ER) was defined by the time from surgery to intrahepatic or extrahepatic recurrence within 2 years. The optimal cutoff value for APHIV to predict survival outcomes was determined using maximally selected rank statistics in the training set. Clinical, pathological, and imaging factors were analyzed using Cox regression.

RESULTS

In the training set, an APHIV cutoff of =6.5 cm^3 was optimal for predicting both ER and OS. HCCs with APHIV =6.5 cm^3 were associated with higher serum alpha-fetoprotein (AFP) and protein induced by vitamin K absence or antagonist-II (PIVKA-II), higher albumin-bilirubin (ALBI) grade, and adverse pathological features—including larger tumor size, poorer differentiation, more frequent microvascular invasion (MVI), and larger necrotic areas—in both sets, than those with APHIV <6.5 cm^3

(all P <0.05). In the training set, APHIV =6.5 cm³ (hazard ratio [HR], 2.261; P =0.001) was an independent factor for ER along with ALBI grade 2 or 3, MVI, and arterial phase rim-like enhancement (rim-APHE), and APHIV =6.5 cm³ (HR, 3.240; P <0.001) was independently associated with OS, along with hepatitis B, ALBI grade 2 or 3, MVI, and rim-APHE. In the validation set, APHIV =6.5 cm³ was also an independent factor for ER (HR, 2.345; P =0.013) and OS (HR, 2.900; P =0.014), along with MVI.

CONCLUSION

A higher APHIV on gadoxetic acid-enhanced MRI is a novel prognostic biomarker associated with adverse clinicopathological factors and poorer ER and OS in patients undergoing hepatic resection for HCC.

CLINICAL RELEVANCE/APPLICATION

A higher APHIV is a relatively simple, objective, and non-invasive prognostic factor that may help guide tailored treatment decisions in patients with HCC.

M5B-SPGI-4 QUANTITATIVE MRI INDICATORS FOR ASSESSING RISK OF IPMN WITH CONCOMITANT VERSUS ASSOCIATED INVASIVE CARCINOMA

Akihiko Kanki, MD (*Presenter*)
Kazuya Yasokawa, MD, PhD (*Abstract Co-Author*)
Yuki Sato (*Abstract Co-Author*)
Akira Yamamoto, MD, PhD (*Abstract Co-Author*)
Yoshihiko Fukukura, MD, PhD (*Abstract Co-Author*)
Tsutomu Tamada, MD, PhD (*Abstract Co-Author*)

PURPOSE

Intraductal papillary mucinous neoplasm (IPMN) related pancreatic carcinoma includes two distinct types: IPMN with associated invasive carcinoma (IPMN-AIC), in which the IPMN itself undergoes malignant transformation, and IPMN with concomitant invasive carcinoma (IPMN-CIC), where pancreatic cancer develops independently from IPMN lesions. Current management guidelines primarily address IPMN-AIC, while strategies for IPMN-CIC remain limited due to insufficient risk prediction methods. This study aims to perform a morphological and quantitative MRI comparison among IPMN-CIC, non-invasive IPMN, and IPMN-AIC to identify novel biomarkers for risk assessment.

METHODS AND MATERIALS

Ninety-four patients who underwent abdominal 3-T MRI were classified into three groups: IPMN (n=60), IPMN-AIC (n=11), and IPMN-CIC (n=23). Morphological evaluation by MRCP assessed the number and maximum diameter of cystic lesions and the caliber of the main pancreatic duct (MPD). Quantitative evaluations included proton density fat fraction (PDFF), T2* relaxation time, and T1 relaxation time in the pancreatic parenchyma using multi-echo 3D Dixon and T1 mapping sequences. Group comparisons were analyzed using the Kruskal-Wallis test followed by the Mann-Whitney U test with Bonferroni correction.

RESULTS

No significant difference was found in the number of cystic lesions (p=0.509). The maximum cystic lesion diameter and MPD caliber were significantly larger in the IPMN-AIC group compared with the IPMN (both p<0.001) and IPMN-CIC groups (both p<0.001), while no significant differences were observed between the IPMN and IPMN-CIC groups (p=0.462 and p=1.000, respectively).No significant difference was found in T2* relaxation time across groups(p=0.530). PDFF and T1 relaxation time were significantly higher in the IPMN-CIC group than in the IPMN (p<0.001 and p<0.001) and IPMN-AIC groups (p=0.017). No significant differences were observed between the IPMN and IPMN-AIC groups (p=0.220 and p=1.000, respectively).

CONCLUSION

PDFF and T1 relaxation time within pancreatic parenchyma may be useful markers for distinguishing IPMN-CIC from IPMN-AIC and could serve as novel indicators for IPMN-CIC risk assessment.

CLINICAL RELEVANCE/APPLICATION

Pancreatic PDFF and T1 relaxation time may serve as potential biomarkers for the development of IPMN with concomitant invasive carcinoma.

M5B-SPGI-7 INADVERTENT BOWEL SAMPLING AT PERCUTANEOUS OMENTAL AND MESENTERIC CORE BIOPSY

Lutfullah Sari, MD (*Presenter*)
Francesca Rigiroli, MD (*Abstract Co-Author*)
Zeynep Nur Akyol Sari, MD (*Abstract Co-Author*)
Bettina Siewert, MD (*Abstract Co-Author*)
Olga R. Brook, MD, MBA (*Abstract Co-Author*)

PURPOSE

Assess the incidence and clinical outcomes of inadvertent bowel sampling with 17G introducer, 18G biopsy device omental and mesenteric CT and US-guided biopsy.

METHODS AND MATERIALS

In this HIPAA-compliant, IRB-approved study, consecutive patients undergoing omental and mesenteric CT and US-guided biopsy with 17G introducer, 18G biopsy device performed at a single tertiary academic institution between March 1, 2005, and March 1, 2024, were included to assess the incidence and clinical outcomes of inadvertent bowel sampling. Descriptive statistics were used.

RESULTS

Among 265 omental and mesenteric biopsies performed during the study period, there were six cases (6/265, 2.3%) with inadvertent bowel sampling identified on pathology. The median age was 83.5 years (IQR 65.6-85.3 years) in patients with inadvertent bowel sampling, and 66 years (IQR 58-74 years) in patients with inadvertent bowel sampling, p: 0.02. The median body mass index was 25.1 (IQR 23.4-28.8) in inadvertent bowel sampling group, and 28.6 (IQR 24.2-33.8) for patients without, p: 0.25. In patients with inadvertent bowel sampling, 4/6 (66.7%) of biopsies were from mesentery and 33.3% (2/6) from omentum, in contrast to the patients without inadvertent bowel sampling with a distribution of 49/259 (18.9%) mesenteric and 210/259 (81.1%) omental biopsies, p: 0.04. No patients underwent bowel preparation or were treated with antibiotics prior to or after the procedure. In retrospective review, the bowel mucosa on pathology was arising from colon in 3/6 (50%), duodenum 2/6 (34%) and distal ileum in 1/6 (17%). The median procedure length was 22.5 minutes (IQR: 20.0-25.0) in patients with inadvertent bowel sampling, and 30 minutes (IQR: 20.0-38.8) in patients without inadvertent bowel involvement, with no significant differences, p: 0.48. All patients underwent standard post-procedure observation time of one hour, during which no signs or symptoms of clinically significant bowel perforations were identified. No patients were admitted after the procedure and no patients required admission within 30 days after the procedure for bowel-related indications.

CONCLUSION

Inadvertent bowel sampling during percutaneous omental and mesenteric biopsy with 17G introducer, 18G biopsy device is a rare, but likely benign event, even in patients without bowel preparation or antibiotic coverage.

CLINICAL RELEVANCE/APPLICATION

Inadvertent bowel sampling is rare, more common in elderly patients and mesenteric biopsies, and likely benign, even without preparatory measures. However, given the potential for serious complications reported in the literature, meticulous technique remains crucial to minimize the risk.

M5B-SPGI-8 COMPARISON OF IMAGE QUALITY AND RADIATION EXPOSURE BETWEEN REDUCED-DOSE ABDOMINOPELVIC CT USING A SILVER FILTER AND DEEP LEARNING RECONSTRUCTION AND STANDARD-DOSE CT WITH ITERATIVE RECONSTRUCTION

Chuluunbaatar Otgonbaatar, MD (*Presenter*)
Jin Woo Kim (*Abstract Co-Author*)
Sung-Jin Cha, BS (*Abstract Co-Author*)
JEON SANG HYUN (*Abstract Co-Author*)
Hackjoon Shim, PhD (*Abstract Co-Author*)
Jhii-Hyun Ahn (*Abstract Co-Author*)

PURPOSE

To evaluate and compare image quality and radiation exposure between reduced-dose abdominopelvic computed tomography (CT) employing a SilverBeam filter with deep learning-based reconstruction (DLR) and standard-dose CT utilizing iterative reconstruction (IR).

METHODS AND MATERIALS

A total of 182 patients were included in this retrospective study. Standard-dose CT was acquired using a tube voltage of 100 kVp, automatic tube current modulation, and IR. Reduced-dose CT was performed with a tube voltage of 120 kVp, implementation of the SilverBeam filter, and DLR. Additionally, a contrast-enhanced (CE) boost image was generated in the reduced-dose group. Radiation dose metrics, along with both objective and subjective image quality assessments, were analyzed across different body mass index (BMI) categories.

RESULTS

The mean effective dose was significantly lower in the SilverBeam + DLR group compared to the standard-dose IR group, with an average dose reduction of 59.0% (1.87 mSv vs. 4.57 mSv). There was no significant difference in image noise between the two protocols (standard IR: 10.59 ± 1.75; SilverBeam + DLR: 10.60 ± 1.08; p = 0.99). In the obese subgroup (BMI > 25 kg/m²), signal-to-noise ratios (SNRs) of the liver, pancreas, and spleen were comparable between protocols. The SilverBeam + DLR + CE-boost images demonstrated significantly higher SNRs and contrast-to-noise ratios (CNRs) compared to both the standard-dose IR and SilverBeam + DLR alone.

CONCLUSION

Reduced-dose abdominopelvic CT utilizing a SilverBeam filter and deep learning reconstruction significantly lowers radiation exposure while maintaining image quality comparable to standard-dose IR. The addition of CE-boost further enhances contrast attenuaton, supporting the clinical feasibility of this approach for routine imaging.

CLINICAL RELEVANCE/APPLICATION

The SilverBeam protocol combined with deep learning reconstruction (DLR) achieved comparable image quality to standard-dose CT with iterative reconstruction (IR), while yielding a substantial reduction in radiation dose—averaging 59.0%—across all body mass index (BMI) categories in abdominopelvic CT.

M5B-SPGI-12 HEPATIC FAT QUANTIFICATION VIA THREE-MATERIAL DECOMPOSITION IN DUAL-LAYER CT: REPRODUCIBILITY AND INTEROBSERVER AGREEMENT

Thomas Schoemig, MD (*Presenter*)
Lina Hieronymi (*Abstract Co-Author*)
Stephan Skornitzke (*Abstract Co-Author*)
David C. Maintz, MD (*Abstract Co-Author*)
Nils Grosse Hokamp, MD, MBA (*Abstract Co-Author*)

PURPOSE

This study investigates the reproducibly and interobserver agreement of a previously published three-material decomposition (3MD) algorithm for hepatic fat quantification using dual-layer dual-energy CT (dlDECT). Prior research demonstrated good correlation in hepatic fat fraction between dlDECT and MR fat quantification. As a next step toward clinical integration, we aim to evaluate the consistency and reliability of this dlDECT-based approach.

METHODS AND MATERIALS

dasdasdIn this retrospective study, we evaluated contrast-enhanced abdominal dual-layer CT scans (IQon, Philips Healthcare) of 58 patients obtained twice within a maximum interval of 60 days (mean interval: 34.3 ± 20.2 days) for clinical indications. Patients with severe changes in clinical status, such as initiation of chemotherapy, or new findings in CT scans affecting liver perfusion were not included. Fat fraction maps were generated using the previously published 3MD algorithm for native, arterial, venous and delayed phase acquisitions. Two radiologists, with 2 and 5 years of experience in abdominal imaging, respectively, independently placed five circular ROIs per scan, four in the right and one in the left hepatic lobe, avoiding vessels. Reproducibility between the two scans and interobserver agreement were assessed using Pearson's correlation, Bland-Altman analysis, repeated measures analysis of variances (ANOVA), and intraclass coefficients (ICC).

RESULTS

The mean hepatic fat fraction across all patients with all contrast medium phases was 4.91% ±5.91 and no significant difference was found between contrast medium phases (p=0.07). Averaging across contrast phases and both readers, there was a strong correlation between measurements at the two time points (4.87% ±6.04 vs. 4.94% ±6.13, R^2=0.78) with a low mean difference of 0.34 ± 3.09 percentage points (not significant, p=0.61) indicating good reproducibility. Interobserver agreement was also excellent, with an ICC of 0.92 and a mean difference between the two readers of 0.62 ± 1.3 percentage points, consistent across different contrast phases.

CONCLUSION

The 3MD algorithm enabled through dlDECT provides reproducible and consistent hepatic fat quantification with excellent interobserver agreement, supporting its potential role in clinical practice.

CLINICAL RELEVANCE/APPLICATION

Metabolic disorders associated with hepatic steatosis are increasingly prevalent. While MRI and ultrasound are currently considered the gold standards for hepatic fat assessment, novel dual-energy CT technologies using 3MD algorithm offer promising, reliable alternatives for quantifying hepatic fat fractions in clinical settings.

M5B-SPGI-13 BEYOND CT LIMITATIONS: COLON MRI UNLOCKS ACCURATE IMMUNOLOGICAL COMPLETE RESPONSE EVALUATION IN MSI-H COLORECTAL CANCER

Zhen Guan (*Presenter*)
Ying-shi Sun, PhD (*Abstract Co-Author*)

PURPOSE

This study establishes MRI as a superior imaging modality for evaluating immunological complete response (iCR) in microsatellite instability-high (MSI-H) colon cancer patients undergoing immunotherapy, addressing the critical limitations of CT in accurately assessing treatment response and guiding clinical decisions.

METHODS AND MATERIALS

We conducted a prospective single-center study enrolling 43 consecutive MSI-H colon cancer patients receiving neoadjuvant immunotherapy between 2023-2024, utilizing paired 3T MRI (with DWI sequences) and CT scans to quantitatively compare image quality (CNR, ERD), tumor characteristics (T2WI signal, DWI patterns). And

response criteria, including MRI detected immunological complete response (mr-iCR) and CT detected immunological complete response (ct-iCR), against endoscopic and pathological gold standards for complete response assessment.

RESULTS

MRI demonstrated significantly superior performance to CT, with higher contrast-to-noise ratio (4.71±2.03 vs 1.32±0.72, p<0.001), sharper tumor margins (ERD 2.94±2.22 vs 5.23±1.91, p<0.001), and improved diagnostic accuracy (81.4% vs 51.2%), while correctly identifying 85% of pathological complete responses and reducing false positives by 62% compared to CT assessment.

CONCLUSION

Colon MRI provides technically superior and clinically more accurate response assessment than CT in MSI-H colon cancer immunotherapy, offering objective quantitative biomarkers for immunological complete response that can reliably guide treatment decisions and potentially enable non-operative management for complete responders.

CLINICAL RELEVANCE/APPLICATION

This MRI-based assessment protocol addresses a critical clinical need in immuno-oncology by enabling reliable non-operative monitoring of immunotherapy response, reducing overtreatment through precise iCR identification, and providing a validated alternative to CT with superior soft-tissue contrast, with ongoing validation further establishing its role in personalized treatment strategy for MSI-H colon cancer patients.

M5B-SPGI-14 COMBINATION OF RADIOMIC FEATURES AND RESECTABLE ASSESSMENT BASED ON CONTRAST-ENHANCED CT PROVIDES AN OPTIMAL OPTION TO TREAT BORDERLINE RESECTABLE PANCREATIC CANCER

Bin Wang (*Presenter*)
Wei Wei (*Abstract Co-Author*)

PURPOSE

To select the optimal treatment of borderline resectable pancreatic cancer (BRPC) via combining radiomic features and resectable assessment based contrast-enhanced CT.

METHODS AND MATERIALS

A total of 261 patients (median age, 49 years; IQR, 36-72 years; 166 male and 95 female) with BRPC who underwent abdominal enhanced CT from January 2019 to April 2022 were enrolled for the study, including 168 patients with surgery and 93 patients with surgery after neoadjuvant therapy. Seventy percent of the cases were randomly selected for the training dataset, and 30% of the cases were independently used for testing. We retrospectively analyzed clinical data (gender,age, gender, preoperative CA125, CA19-9) and imaging resectable assessment (tumor size, location, distal common bile duct amputation/dilation, lymph vascular space invasion (LVSI), wrapping angle between lesion and superior mesenteric artery (SMA), pancreatic parenchyma atrophy). Radiomic features were extracted from portal venous-phase CT of the BRPC lesion. LASSO regression algorithm and mRMR were used for feature dimension reduction. Multivariable logistic regression was used to build radiomics model, clinical model, and integrated model. The receiver operating characteristic (ROC) curve, decision curve, and nomogram were plotted to assess the differentiating performance of the three models.

RESULTS

Pathological grade, tumor location, tumor size(>3cm) LVSI, and wrapping angle between lesion and SMA indicated significant differences (P<0.1) Pathological grade (P=0.000) and LVSI(P=0.017) were the independent factors to select the optimal clinical treatment. The area under the ROC curve (AUC) of the clinical model, radiomics model, and integrated model was 0.75, 0.70, and 0.80 in the training dataset and 0.67, 0.58 and 0.70 in the testing dataset, respectively. The nomogram indicated that radiomic features helped to select treatment method and showed a better efficiency. DCA curve indicated that the integrated model yielded a higher benefit than the clinical model in the threshold range of 0.1~0.8.

CONCLUSION

The treatment strategy for patients with BRPC was accurately predicted by the combination of radiomic features and resectable assessment, and the combination could help to make treatment choice.

CLINICAL RELEVANCE/APPLICATION

The combination of imaging features and resectability assessment can accurately predict treatment strategies for BRPC patients, aiding in the selection of optimal therapy for clinically borderline resectable pancreatic cancer (BRPC) cases, thereby improving patient survival rates and quality of life.

M5B-SPGU-1 DIFFERENTIATING BENIGN VS MALIGNANT RENAL CYSTS IN HEREDITARY LEIOMYOMATOSIS AND RENAL CELL CANCER (HLRCC) SYNDROME UTILIZING QUALITATIVE MRI SIGNATURES

Ali Sheikhy, MD (*Presenter*)
Aryan Zahergivar, MD (*Abstract Co-Author*)
Mahshid Golagha, MD (*Abstract Co-Author*)
Xiaobai Li (*Abstract Co-Author*)
W. Marston Linehan, MD (*Abstract Co-Author*)
Ashkan A. Malayeri, MD (*Abstract Co-Author*)

PURPOSE

Patients with Hereditary Leiomyomatosis and Renal Cell Cancer (HLRCC) face an aggressive renal carcinoma that often mimics benign cysts on imaging leading to potentially unnecessary surgeries. We aimed to identify MRI features that reliably distinguish benign from malignant complex renal cysts in this high-risk cohort, with the goal of safely reducing unneeded surgical interventions.

METHODS AND MATERIALS

In this retrospective study, we identified 42 HLRCC patients (mean age 46 ± 14 years; 22 men, 20 women) who underwent partial or radical nephrectomy between June 2002 and May 2022. Seventy-six histologically confirmed renal lesions were reviewed independently by two abdominal radiologists blinded to pathology. Recorded features included lesion size (maximum 3D diameter), location, internal composition, cyst-wall characteristics (septations, nodules), enhancement patterns (including combined areas of enhancement on T1-weighted nephrogenic-phase images), and diffusion characteristics (ADC, b-2000). Inter-reader agreement was quantified by Cohen's ?. Univariable GEE logistic regression (exchangeable correlation, binomial logit) identified candidate predictors ($p < 0.10$). Those predictors entered a multivariable GEE model with backward elimination guided by sequential Wald tests ($p < 0.05$) and QIC.

RESULTS

Of 76 lesions, 44 (58%) were benign and 32 (42%) malignant. Twelve MRI features demonstrated at least moderate inter-reader agreement (? > 0.4). Univariable GEE screening yielded eight significant predictors of malignancy: combined nephrogenic-phase enhancement area, endophytic/exophytic location, nodular presence, number of septations, septation caliber, Septation T1-nephrogenic enhancement, b500/800 signal, and non-solid T2 signal. The final multivariable GEE (Reader 1) included nodules, combined enhancement area, and endophytic/exophytic configuration (AUC 0.86); for Reader 2 these same three features achieved AUC 0.91. At a predicted-probability threshold of 0.13, the nomogram identified all malignant lesions and would have spared 57% of patients with benign cysts from unnecessary surgery.

CONCLUSION

Key qualitative MRI features robustly distinguish benign from malignant complex renal cysts in HLRCC patients. By applying a predicted-probability cutoff of 0.13, this approach maintains 100% sensitivity for malignancy while potentially avoiding surgery in 57% of benign cases, markedly reducing unnecessary interventions.

CLINICAL RELEVANCE/APPLICATION

Applying these MRI criteria with a 0.13 risk threshold may reduce unnecessary surgeries in over half of benign cases while maintaining 100% sensitivity for malignancy, thereby improving patient management in this high-risk cohort.

M5B-SPGU-2 COMPARING THE NOVEL TARGET AND PI-FAB SCORING SYSTEMS FOR THE EVALUATION OF THE LOCAL RECURRENCE OF PROSTATE CANCER AFTER HIFU

Michael Phillipi (*Presenter*)
Shayan Saeed (*Abstract Co-Author*)
Ashima Kundu, BS (*Abstract Co-Author*)
Saira Arora (*Abstract Co-Author*)
Christopher Liu (*Abstract Co-Author*)
Kasha Chen (*Abstract Co-Author*)
Yinuo Zhang (*Abstract Co-Author*)
Justin Glavis-Bloom, MD (*Abstract Co-Author*)
Akash C. Joshi, MD (*Abstract Co-Author*)
James Shi, MD (*Abstract Co-Author*)
Amir Imanzadeh, MD (*Abstract Co-Author*)
Roozbeh Houshyar, MD (*Abstract Co-Author*)

PURPOSE

Focal high-intensity focused ultrasound (HIFU) has recently emerged as a safe, noninvasive treatment for prostate cancer. However, HIFU transforms the appearance of prostatic tissue. To better assess prostatic tissue after treatment with focal ablation for the recurrence of prostate cancer, two novel scoring systems have been developed: the Transatlantic Recommendations for Prostate Gland Evaluation with Magnetic Resonance Imaging After Focal Therapy (TARGET) and Prostate Imaging after Focal Ablation (PI-FAB). However, evidence of their diagnostic accuracy to detect recurrence in patients treated with HIFU is limited. In this study, we aim to compare the diagnostic accuracy of radiologists using the TARGET versus PI-FAB scoring systems, as well as inter-reader agreement with both.

METHODS AND MATERIALS

Patients with and without the local recurrence of prostate cancer who underwent HIFU and received both post-treatment multiparametric MRI (mpMRI) and biopsy were included. Two board-certified radiologists independently reviewed mpMRI scans to grant each case a TARGET and PI-FAB score. A TARGET score of 5 and a PI-FAB score of 3 were considered positive for recurrence. Histopathologic analysis was used as the reference standard to assess radiologist accuracy. The sensitivity, specificity,

accuracy, positive predictive value (PPV), and negative predictive value (NPV) for both the TARGET and PI-FAB scoring systems were calculated. Inter-reader agreement was assessed using quadratic weighted Cohen's kappa.

RESULTS

Of the 48 cases reviewed, 33 were identified to have local recurrence of prostate cancer on biopsy. Our results demonstrated that for each case a participating radiologist assigned a TARGET score of 5 (considered positive for recurrence), a PI-FAB score of 3 was also assigned by that participant, and vice-versa for both radiologists. Thus, the overall specificity (80.8%), sensitivity (40.0%), PPV (84.9%), and NPV (33.3%) were identical for both scoring systems. One radiologist achieved an accuracy of 58.3% with both scoring systems, while the other had an accuracy of 43.8%. The inter-reader agreement with both TARGET and PI-FAB was 0.407.

CONCLUSION

Both radiologists achieved perfect intra-rater concordance when grading cases for local recurrence using the TARGET and PI-FAB systems. Despite this consistency, neither scoring system achieved a high diagnostic accuracy in detecting the local recurrence of prostate cancer following HIFU treatment.

CLINICAL RELEVANCE/APPLICATION

Our findings underscore the need for improved imaging criteria to reliably detect local prostate cancer recurrence in patients treated with HIFU.

M5B-SPGU-4 EARLY DIFFUSION-WEIGHTED MRI CHANGES AS PREDICTIVE BIOMARKER AFTER SINGLE-DOSE ABLATIVE RADIATION THERAPY IN LOCALIZED UNFAVOURABLE PROSTATE CANCER

Paolo N. Franco, MD (*Presenter*)
Cammillo R. Talei Franzesi (*Abstract Co-Author*)
Davide G. Gandola, MD (*Abstract Co-Author*)
Cesare Maino, MD (*Abstract Co-Author*)
Rocco Corso, MD (*Abstract Co-Author*)
Davide Ippolito, MD (*Abstract Co-Author*)

PURPOSE

To investigate the diagnostic value of diffusion-weighted (DWI) MRI early changes, 1 hour after treatment, in patients with organ-confined unfavourable prostate cancer (PCa) treated with Single-Dose Ablative Radiation Therapy (SDART), in comparison with biochemical markers.

METHODS AND MATERIALS

We prospectively enrolled 30 patients with intermediate unfavourable or high-risk organ-confined PCa treated with SDART of 21 Gy on the entire prostate (with boost up to 24 Gy on the focal lesion) associated with hormone therapy. Each patient was examined with a 3T scanner four times: 1-2 weeks before RT for treatment planning (t0); 1 hour after treatment (t1); 3 months after treatment (t2); 2 years after treatment (t3). Regions of interest (ROIs) were plotted on ADC maps and T2 HR sequences on neoplasm lesions, benign peripheral zone and the entire prostate gland. Patients' laboratory data (PSA and testosterone levels) was collected.

RESULTS

Apparent diffusion coefficient (ADC) values significantly increased in neoplastic lesions at t1 (+22%) and at t2 and t3 (+43% and +53%, respectively). On the other hand, no significant changes were observed at the level of the benign peripheral zone and the entire prostate gland. On T2 sequences, signal intensity progressively decreased at the benign peripheral zone (t1: -1%; t2: -33%; t3: -42%) and the entire prostate gland (t1: - 6%; t2: -24%; t3: -31%), while no significant changes were observed at the level of the lesion. 28 patients (93.3%) had a complete biochemical response.

CONCLUSION

The study findings showed high diagnostic value of DWI imaging and a good correlation between early (t1) changes in ADC values after SDART and later (t2 and t3) tumour response (both biochemical and imaging) in patients with unfavourable PCa. Early DWI changes can represent a useful parameter to evaluate treatment response and predict patients' outcomes.

CLINICAL RELEVANCE/APPLICATION

Early diffusion-weighted MRI changes observed just one hour after single-dose ablative radiotherapy offer a non-invasive imaging biomarker correlated with long-term biochemical response. This early marker could support timely treatment evaluation and guide clinical decision-making in patients with localized high-risk prostate cancer.

M5B-SPGU-5 MULTI-READER EVALUATION OF THE PROSTATE IMAGING QUALITY SCORE SYSTEM VERSION 2 AND ITS CLINICAL APPLICATION

Yue Cheng (*Presenter*)
Zhenghan Yang (*Abstract Co-Author*)
Liting Shen (*Abstract Co-Author*)
Yao Niu (*Abstract Co-Author*)
Qian Liao (*Abstract Co-Author*)

PURPOSE

Currently, while emphasizing the importance of high-quality images for appropriate interpretation of prostate MRI and subsequent management decisions, various quality scoring methods have emerged in succession, among which the Prostate Imaging Quality (PI-QUAL) Scoring System is the most widely used. Several studies have revealed some inconsistencies and limitations in PI-QUAL. Therefore, an updated version of PI-QUAL was proposed in May 2024, which applies to prostate MRI performed with or without intravenous contrast medium using a simplified 3-point scale focused on critical technical and qualitative image parameters. Thus far, the clinical application of PI-QUAL V2 has not been investigated and verified. Therefore, the aim of our analysis was: (1) to assess the inter-reader agreement in PI-QUAL V2; (2) to investigate the differences in diagnostic performance for clinically significant prostate cancer (csPCa) between different quality scores.

METHODS AND MATERIALS

This retrospective study included 581 patients who underwent prostate MRI exams and had definitive pathological reports between January and December 2023. All histopathological specimens were evaluated, and an ISUP Grade Group = 2 was considered as csPCa. Four radiologists independently assigned PI-QUAL V2 scores to each patient, with one of the readers re-scoring after a three-month interval. Cohen's and Fleiss' Kappa were used to determine inter-reader agreement, and the area under the receiver operating characteristics curve (AUC-ROC) was used to compare diagnostic performance. A $p < 0.05$ was considered statistically significant.

RESULTS

The study comprised 581 individuals (median [IQR] age, 70 [66-75] years). The consistency was moderate for T2WI, DWI, and PI-QUAL V2, substantial for DCE. For PI-RADS V2.1 categorization tasks, the proportion of PI-RADS 3 gradually decreased with improving image quality, and a statistical difference was found between PI-QUAL 1 and 3 ($p < 0.001$). However, regardless of whether PI-RADS =3 or =4 was used as the "suspicious for cancer" threshold, there was no significant difference in overall diagnostic performance for csPCa among different PI-QUAL V2 scores (AUC 0.741-0.844).

CONCLUSION

PI-QUAL V2 plays a positive role in inter-reader reproducibility and radiologists' MRI diagnosis. Regarding the limited value of PI-QUAL V2 in overall diagnosis of csPCa, further exploration with larger sample sizes and studies may be needed in the future.

CLINICAL RELEVANCE/APPLICATION

While simplifying the scoring system, PI-QUAL V2 retains high inter-reader agreement. A suboptimal PI-QUAL V2 score may undermine radiologists' confidence in image interpretation, resulting in a decreased detection rate of clinically significant prostate cancer.

M5B-SPGU-6 ENHANCED PREOPERATIVE DETECTION OF PERIRENAL FAT INVASION IN RENAL CELL CARCINOMA: INTEGRATING CT AND RADIOMICS

Hyojeong Lee, MD, PhD (*Presenter*)
Taekmin Kim, MD, PhD (*Abstract Co-Author*)
Sang Youn Kim (*Abstract Co-Author*)

PURPOSE

To evaluate conventional CT imaging features and develop a radiomics-based model for predicting perirenal fat invasion (PFI) in renal cell carcinoma (RCC), with the intent of enhancing preoperative staging accuracy.

METHODS AND MATERIALS

This retrospective case-control study included patients with pathologically proven PFI and size-matched non-PFI controls who underwent nephrectomy between January 2016 and December 2020. Two radiologists independently evaluated qualitative imaging features and measured quantitative parameters. Furthermore, 107 radiomics features were extracted from semiautomatically segmented tumors using Pyradiomics. Feature selection, based on interobserver agreement, correlation analysis, and analysis of variance, facilitated the construction of a conventional-radiomics model that integrates conventional CT features with selected radiomics features.

RESULTS

The study comprised 86 participants in PFI group (66 men, mean age: 63.3±11.1 years) and 169 in non-PFI group (119 men, mean age: 58.8±12.1 years). Multivariate analysis of conventional features identified four independent predictors of PFI: lobulated shape (odds ratio [OR]=2.03, p = 0.042), irregular margin (OR=3.40, p = 0.007), perirenal fascial thickening (OR=4.20, p < 0.001), and contact length (>154.2 mm; OR=3.82, p = 0.019). The combination of these predictors exhibited moderate diagnostic performance (sensitivity, 61.6%; specificity, 79.3%; accuracy, 73.3%). The conventional-radiomics model incorporating five selected radiomics features demonstrated superior performance (area under the curve [AUC]=0.979) with statistically significant improvements in sensitivity (91.9%), specificity (95.9%), and accuracy (94.5%).

CONCLUSION

The integration of quantitative CT parameters and radiomics with conventional imaging features yielded enhanced predictions of PFI in RCC.

CLINICAL RELEVANCE/APPLICATION

This study identified four independent imaging predictors and developed a conventional-radiomics model, achieving an impressive area under the curve of 0.979 for predicting perirenal fat invasion. The enhanced diagnostic model aids in more accurate preoperative staging of renal cell carcinoma, ultimately improving surgical decision-making and patient prognostication.

M5B-SPGU-7 MR FINGERPRINTING (MRF) FOR THE EVALUATION OF CHRONIC ALLOGRAFT NEPHROPATHY: A PROSPECTIVE STUDY WITH HISTOPATHOLOGIC CORRELATION

Kaustav Bera, MD (*Presenter*)
Dheeman Futela, MBBS (*Abstract Co-Author*)
Pranit Chotai (*Abstract Co-Author*)
Meghan Kapp (*Abstract Co-Author*)
Yerneni Himabindu (*Abstract Co-Author*)
Zoe Stewart Lewis (*Abstract Co-Author*)
Mark A. Griswold, PhD (*Abstract Co-Author*)
Chris A. Flask, PhD (*Abstract Co-Author*)
Yong Chen (*Abstract Co-Author*)
Sreeharsha Tirumani, MD (*Abstract Co-Author*)

PURPOSE

Kidneys are the most commonly transplanted organ worldwide. All renal allografts will develop chronic dysfunction and eventually fail, which is referred to as chronic allograft nephropathy (CAN). The current standard of care to diagnose and monitor CAN is invasive allograft biopsy as there is no reliable, non-invasive testing alternative. In this prospective study, we aim to determine if there is a correlation between the MRF-derived quantitative T1 and T2 maps of renal allograft cortex and medulla with renal function and the histopathologic fibrotic changes in CAN patients.

METHODS AND MATERIALS

Seven kidney transplant patients underwent both MRF and allograft biopsy (M:F 4:3, Mean age - 57, Median time from transplant - 3 months). Inclusion criteria were age >18 years, >3 months post-transplant and scheduled for transplant kidney biopsy within one month after MRI. Coronal T1 and T2 maps were acquired using breath-hold kidney MRF. Respiratory-triggered diffusion-weighted imaging and arterial spin labeling MRI were further applied to measure apparent diffusion coefficient (ADC) and renal blood flow (RBF), respectively. Freehand region of interest (ROI)-based measurements were then made in the cortex and medulla in the upper, inter polar and lower pole regions of transplant kidney to obtain quantitative parameters (T1, T2, ADC and RBF). Clinicopathologic data was extracted from electronic medical records, including renal biopsy Banff scores. Statistical analysis was performed to determine correlation between quantitative parameters and Banff scores.

RESULTS

Distribution of the Banff scores are shown in Figure. Preliminary evaluation using Spearman rank correlation showed that T2cortex had strong negative correlation with composite chronic Banff lesions (ct,ci,cv,cg) [r=-.81; p=.05]. Among individual Banff lesions, T2cortex had strong negative correlation with intimal fibrosis (cv; r=-..90; p=.04). Additionally, ADC values correlated positively with interstitial inflammation (i; r=.83;p=.04) while RBF had negative correlation with interstitial fibrosis (ci; r=-.89; p=.04). Meanwhile, eGFR at time of biopsy was not correlated with any of the Banff lesion categories (p>.05). T2cortex was also strongly negatively correlated with eGFR (r=-.81, p=.05). Allosure was not correlated with Banff lesions or MRF parameters.

CONCLUSION

Our preliminary evaluation suggests that MRF derived quantitative T1, T2 maps correlate strongly with chronic Banff lesions derived from the “gold standard” histopathology of transplant renal biopsies.

CLINICAL RELEVANCE/APPLICATION

MRF is a potential non-invasive imaging technique to predict CAN in kidney transplant patients.

M5B-SPHN-3 IDENTIFYING MICROSTRUCTURAL ALTERATIONS FOR OCCULT METASTATIC LYMPH NODES WITH IN-VIVO ADVANCED DIFFUSION-RELAXATION MR SPECTROSCOPY

Yingwei Wu, MD, PhD (*Presenter*)

PURPOSE

To explore the feasibility of using in-vivo diffusion-T2 (D-T2) MR spectroscopy to noninvasively identify OLNM by characterizing microstructural peak morphology changes in lymph nodes.

METHODS AND MATERIALS

A prospective study enrolled 57 oral tongue squamous cell carcinoma (OTSCC) patients and 25 healthy controls. D-T2 MR spectroscopy was performed using multi-b-value and multi-TE DR-CSI sequences to generate normalized spectra. Lymph nodes were categorized into benign (BLN, from healthy controls), occult metastatic (OLNM, MR-negative but pathology-positive), and clinically metastatic (CLNM, MR-positive and pathology-confirmed). Apparent diffusion coefficient (ADC), T2 values, and spectral peak characteristics were analyzed.

RESULTS

Among 79 lymph nodes (38 BLN, 16 OLNM, 25 CLNM), ADC and T2 values showed limited discriminative power ($p > 0.05$). However, D-T2 spectra consistently revealed three characteristic peaks (A-C).BLNs displayed a saucer-like spectrum with sharp Peak A (short T2) and broad flat Peak B (medium-to-long T2).OLNMs showed a 23.4% decrease in Peak A fraction, and a notable spatial separation between Peaks A and B. Peak B became rounder and shifted upward and rightward, indicating microstructural alterations not visible on conventional MRI. CLNMs exhibited further Peak A reduction (31.7%), and Peak B developed a distinct double-angle morphology with upward and rightward deflections, respectively.

CONCLUSION

D-T2 MR spectroscopy reveals distinctive spectral peak morphology in OLNM, which remains undetectable by conventional imaging. This noninvasive method holds promise as a novel diagnostic tool for early detection of occult metastases in head and neck cancer.

CLINICAL RELEVANCE/APPLICATION

This study demonstrates that in-vivo diffusion-T2 MR spectroscopy enables noninvasive identification of OLNMs by revealing distinctive peak morphology alterations—particularly the separation of Peaks A and B and upward-rightward shift of Peak B. These spectral signatures could serve as early diagnostic biomarkers for OLNM, guiding more accurate clinical decision-making and potentially reducing the need for invasive diagnostic procedures or overtreatment.

M5B-SPHN-4 COMPARATIVE STUDY OF NON-ENHANCED 3D-FLAIR AND CONTRAST-ENHANCED 3D-FLAIR SEQUENCES IN THE DIAGNOSIS OF ENDOLYMPHATIC HYDROPS USING 5T MRI

Mengqiu Liu (*Presenter*)
Ying Liu (*Abstract Co-Author*)
Jiang Fan (*Abstract Co-Author*)

PURPOSE

To evaluate the diagnostic value of non-enhanced 5T MRI 3D-FLAIR sequences for endolymphatic hydrops.

METHODS AND MATERIALS

Fourteen patients (7 males, 7 females; mean age 59.05±8.04 years) clinically suspected of Meniere's disease underwent 5T inner ear MRI with gadolinium contrast. All patients underwent pre-contrast conventional inner ear MRI, internal auditory canal hydrography, and 3D-FLAIR sequences (parameters: TR: 10000.00 ms, TI: 2500.00 ms, TE: 455.40 ms, slice thickness: 0.5 mm, flip angle: 54.00°). Four hours after double-dose contrast injection, contrast-enhanced 3D-FLAIR and thin-slice T1WI fat-suppressed sequences were performed. Two head and neck radiologists with 10 years of experience independently reviewed the images; discrepancies were resolved by consensus.

RESULTS

Using contrast-enhanced 3D-FLAIR as the reference standard, all 14 patients exhibited varying degrees of endolymphatic hydrops: 7 had vestibular hydrops, 14 had cochlear hydrops, 2 had concurrent vestibular neuritis, and 2 had labyrinthitis. Non-enhanced 3D-FLAIR detected 7 cases of vestibular hydrops, 13 cases of cochlear hydrops, and hyperintensity in 1 vestibular neuritis case but failed to visualize labyrinthitis. The diagnostic concordance rates for non-enhanced 3D-FLAIR were 100% for vestibular hydrops and 92.9% (13/14) for cochlear hydrops.

CONCLUSION

Non-enhanced 5T 3D-FLAIR demonstrates high diagnostic accuracy for endolymphatic hydrops and may partially replace contrast-enhanced sequences. For patients suspected of Meniere's disease without hydrops on non-enhanced 3D-FLAIR, contrast-enhanced imaging is recommended to exclude labyrinthitis or vestibular neuritis.

CLINICAL RELEVANCE/APPLICATION

Meniere's disease

M5B-SPHN-6 RELIABILITY ASSESSMENT OF MANUAL AND ARTIFICIAL INTELLIGENCE TECHNIQUES IN ANALYZING SKELETAL FACIAL ASYMMETRY

Wojciech Kazimierczak, MD, PhD (*Presenter*)
Natalia Kazimierczak (*Abstract Co-Author*)
Pawel Nowicki (*Abstract Co-Author*)
Natalia Chwarscianek (*Abstract Co-Author*)
Zbigniew Serafin (*Abstract Co-Author*)

PURPOSE

To compare artificial intelligence (AI)-driven web-based platform and manual measurements for analysing facial asymmetry in craniofacial CT examinations.

METHODS AND MATERIALS

The study included 95 craniofacial CT scans from patients aged 18-30 years. The degree of asymmetry was measured based on AI platform-predefined anatomical landmarks: sella (S), condylion (Co), anterior nasal spine (ANS), and menton (Me). The concordance between the results of automatic asymmetry reports and manual linear 3D measurements was calculated. The asymmetry rate (AR) indicator was determined for both automatic and manual measurements, and the concordance between them was calculated. The repeatability of manual measurements in 20 randomly selected subjects was assessed. The concordance of measurements of quantitative variables was assessed with interclass correlation coefficient (ICC) according to the Shrout and Fleiss classification.

RESULTS

Erroneous AI tracings were found in 16.8% of cases, reducing the analysed cases to 79. The agreement between automatic and manual asymmetry measurements was very low (ICC < 0.3). A lack of agreement between AI and manual AR analysis (ICC type 3 = 0) was found. The repeatability of manual measurements and AR calculations showed excellent correlation (ICC type 2 > 0.947).

CONCLUSION

The results indicate that the rate of tracing errors and lack of agreement with manual AR analysis make it impossible to use the tested AI platform to assess the degree of facial asymmetry.

CLINICAL RELEVANCE/APPLICATION

Accurate assessment of skeletal facial asymmetry is critical for diagnosing craniofacial discrepancies and planning orthodontic and orthognathic interventions. This study evaluates and compares the reliability of traditional manual analysis with emerging AI-driven approaches, providing valuable insights into their clinical utility.

M5B-SPHN-8 COMPUTED TOMOGRAPHIC FINDINGS PREDICTIVE OF SUCCESSFUL DRAINAGE OF PERITONSILLAR ABSCESSES

Shaun Aciu, MD (*Presenter*)
Andrew Li (*Abstract Co-Author*)
Huaqing Zhao, PhD (*Abstract Co-Author*)
Neelu Jain, MD (*Abstract Co-Author*)

PURPOSE

Prompt diagnosis of a peritonsillar abscess (PTA) is critical to inform clinical management as bedside drainage and/or medical therapy are the mainstay of treatment to prevent complications such as airway compromise. Diagnosis of PTA is typically accomplished by CT scanning after infusion of intravenous contrast. There is a lack of research into the radiologic markers that are predictive of successful PTA drainage. In this study, we sought to identify those factors.

METHODS AND MATERIALS

Following IRB approval, we retrospectively analyzed the CT scans of all patients older than 18, who presented to our Emergency Department from January 2013 to December 2023 with PTA for whom a CT neck was obtained. Characteristics of the PTA obtained on each CT included the following: size dimensions in three planes with volume calculation, Hounsfield Units (HU), presence or absence of rim enhancement, continuous vs discontinuous rim enhancement, extension of PTA to the patient midline, laterality (left or right). The review was blinded to all clinical data including patient demographics, medical history, procedures performed, and clinical course. A multivariable analysis was run to determine which factors were predictive of successful PTA drainage. A post hoc analysis was performed to determine if radiologic features predicted physical exam findings.

RESULTS

One hundred thirty-two patients met inclusion criteria of which 72 were males, with an overall mean age of 41 years. There were 139 peritonsillar abscesses included in the final analysis (7 patients with bilateral PTA). Patients who had successful PTA drainage had larger abscesses (PTA mean volume 5.95 vs. 2.78 cm 3 , p < 0.001), continuous ring enhancement (75.00% vs 50.91%, p = 0.003). If an abscess reached midline on imaging, there was no statistically significant association with clinical findings of soft palate effacement, trismus, or uvular deviation.

CONCLUSION

CT parameters were useful in predicting successful PTA drainage. Larger abscess size and continuous ring enhancement were statistically significant predictors and can be used to guide management.

CLINICAL RELEVANCE/APPLICATION

Radiologist may be able to help guide treatment for peritonsillar abscess based on radiographic features of contrast enhanced CT neck.

M5B-SPIN-1 AUTOMATED DETECTION OF CRITICAL RESULTS IN RADIOLOGY REPORTS: PUBMEDBERT VS. ZERO-SHOT PROMPTING APPROACH

Victor Agwu, MD, MS (*Presenter*)
Eshan Joshi (*Abstract Co-Author*)
Aanya Khatri (*Abstract Co-Author*)
Dave A. Roy, MD (*Abstract Co-Author*)
Jeannie K. Kwon, MD, MBA (*Abstract Co-Author*)
Yin Xi, PhD (*Abstract Co-Author*)
Yee Seng Ng, MD (*Abstract Co-Author*)

PURPOSE

Radiology reports often contain critical results that necessitate prompt communication to ensure patient safety, as mandated by the Joint Commission and the American College of Radiology. Manual identification of critical results by radiologists is time-intensive and variable, prompting interest in automation to improve efficiency and support quality assurance. Advances in natural language processing have enabled high-precision automated extraction of text. This study compares PubMedBERT, a domain-specific language model, with a zero-shot prompting approach using Llama 3.1, an open-source LLM, for detecting critical results in pediatric radiology reports.

METHODS AND MATERIALS

This retrospective case-control study included 3,798 de-identified pediatric radiology reports collected from the PACS over a five-year period (2018 - 2023). Report impressions were reviewed for 14 predefined critical results, per institutional standards. Non-critical reports served as controls. PubMedBERT was fine-tuned on 80% of the reports and tested on the remaining 20%. Final predictions were based on the highest category probability >0.5; otherwise, "No critical result identified" was assigned. A zero-shot prompting method using Llama 3.1-8B-instruct with a structured prompt strategy was also applied to the test set. All outputs were dichotomized into "Critical result identified" or "No critical result identified". Model performance was assessed using sensitivity, specificity, and per-finding F1 scores (harmonic mean of sensitivity and positive predictive value), with 95% bootstrap confidence interval. McNemar’s test was used for comparisons.

RESULTS

Of the 754 test reports, 190 included at least one predefined critical result and 564 had none. PubMedBERT achieved 96% sensitivity and 79% specificity, while Llama 3.1 achieved 97% sensitivity and 90% specificity for the detection of any critical result ($p = 0.8$ and $p < 0.001$, respectively). Zero-shot prompting with Llama 3.1 demonstrated higher F1 scores than PubMedBERT across all individual critical results. Performance in rare categories was limited by small sample sizes.

CONCLUSION

PubMedBERT and Llama 3.1 performed comparably in detecting any of the predefined critical results; however, Llama 3.1 showed superior detection of individual critical results without needing fine-tuning. These findings underscore the utility of compact, open-source LLMs as a resource-efficient and scalable solution for automated critical result detection in radiology reports.

CLINICAL RELEVANCE/APPLICATION

Scalable open-source large language models enable automated critical result detection without task-specific training, streamlining radiology communication workflows and compliance monitoring.

M5B-SPIN-2 FROM FASTER FRAMES TO FLAWLESS FOCUS: DEEP LEARNING HASTE IN POST-OPERATIVE SINGLE SEQUENCE MRI

Clarissa Hosse (*Presenter*)
Uli Fehrenbach, MD (*Abstract Co-Author*)
Johannes Kolck, MD (*Abstract Co-Author*)

PURPOSE

This study evaluates the feasibility of a novel deep learning-accelerated half-Fourier single-shot turbo spin-echo sequence (HASTE-DL) compared to the conventional HASTE sequence (HASTE S) in postoperative single-sequence MRI for the detection of fluid collections following abdominal surgery. As small fluid collections are difficult difficult to visualize using other techniques, HASTE-DL may offer particular advantages in this clinical context.

METHODS AND MATERIALS

A retrospective analysis was conducted on 76 patients (mean age 65 ± 11.69 years) who underwent abdominal MRI for suspected septic foci following abdominal surgery. Imaging was performed using 3-T MRI scanners, and both sequences were analyzed in terms of image quality, contrast, sharpness, and artifact presence. Quantitative assessments focused on fluid collection detectability, while qualitative assessments evaluated visualization of critical structures. Inter-reader agreement was measured using Cohen's kappa coefficient, and statistical significance was determined with the Mann-Whitney U test.

RESULTS

HASTE-DL achieved a 46% reduction in scan time compared to HASTE S , while significantly improving overall image quality ($p < 0.001$), contrast ($p < 0.001$), and sharpness ($p < 0.001$). The inter-reader agreement for HASTE-DL was excellent (? = 0.960), with perfect agreement on overall image quality and fluid collection detection (? = 1.0). Fluid detectability and characterization scores were higher for HASTE-DL, and visualization of critical structures was significantly enhanced ($p < 0.001$). No relevant artifacts were observed in either sequence.

CONCLUSION

HASTE-DL offers superior image quality, improved visualization of critical structures, such as drainages, vessels, bile and pancreatic ducts, and reduced acquisition time, making it an effective alternative to the standard HASTE sequence, and a promising complementary tool in the postoperative imaging workflow.

CLINICAL RELEVANCE/APPLICATION

The deep learning-accelerated HASTE-DL sequence provides significantly improved image quality and reduced acquisition time compared to the conventional HASTE sequence, enhancing the detection and characterization of postoperative fluid collections. This makes HASTE-DL a valuable tool for rapid, high-quality imaging in patients with suspected postoperative complications, potentially improving diagnostic confidence and guiding timely clinical management.

M5B-SPIN-3 MULTI-ENERGY SPECTRAL PHOTON-COUNTING CT FOR LIVER LESION CLASSIFICATION: A MULTICENTER STUDY

Friedrich Pietsch (*Presenter*)
Abhinay Krishna Vellala (*Abstract Co-Author*)
Florian Haag, MD (*Abstract Co-Author*)
Alexander Hertel, MD (*Abstract Co-Author*)
Javier Contreras Yametti, MD (*Abstract Co-Author*)
Anushree M. Burade, MBBS (*Abstract Co-Author*)
Parisa Kaviani, MD (*Abstract Co-Author*)
Stefan O. Schoenberg, MD, PhD (*Abstract Co-Author*)
Mannudeep K. Kalra, MD (*Abstract Co-Author*)
Matthias F. Froelich, MD (*Abstract Co-Author*)

PURPOSE

To assess the diagnostic performance of radiomics-based machine learning in differentiating benign from malignant hepatic lesions using Photon-Counting CT scans, and to investigate model generalizability across multiple spectral reconstructions.

METHODS AND MATERIALS

This retrospective, multi-center study included patients with confirmed hepatic lesions who underwent contrast-enhanced photon-counting CT. Lesions were segmented automatically using a 3D nnU-Net model and manually reviewed. Volumetric segmentations were used to extract radiomic features on a lesion basis from nine image reconstructions: 40 keV, 50 keV, 70 keV, 90 keV, 110 keV, 140 keV, 180 keV, Virtual Non-Contrast (VNC), and Iodine Density Maps (IDM). A patient-based classification analysis was conducted by training multiple machine learning models separately for each reconstruction, with lesion-level predictions aggregated to the patient level. The best-performing model (Random Forest) was further evaluated by assessing classification performance across all train-test reconstruction combinations.

RESULTS

The study cohort comprised 378 patients (median age: 62 years; 40.5% male), including 190 with benign and 188 with malignant hepatic lesions. The Random Forest Model trained on 180 keV achieved the highest classification performance, with an AUC of 0.878 and accuracy of 85.7%. All training energy levels achieved similar mean AUCs (range: 0.75-0.83), indicating consistent model transferability. However, evaluation performance varied across test levels. Models tested on 110 keV, 140 keV, 180 keV, and VNC showed the highest stability (median AUC = 0.84), while 40 keV, 50 keV, and IDM resulted in lower and more variable AUCs.

CONCLUSION

Radiomics-based machine learning enables reliable differentiation between malignant and benign hepatic lesions on PCCT. This study demonstrates the feasibility of applying such models across multiple spectral reconstructions. While training on different energy levels resulted in comparable average AUCs, the choice of test level substantially influenced performance: higher energy levels and VNC reconstructions consistently yielded more accurate and stable results. These findings support the integration of multi-energy PCCT radiomics into oncologic lesion assessment workflows, particularly when high-energy reconstructions are available.

CLINICAL RELEVANCE/APPLICATION

Radiomics-based lesion classification on photon-counting CT is feasible across multiple spectral domains. The consistent performance observed at higher energy levels and Virtual Non-Contrast reconstructions support their preferential use for stable, cross-spectral application of machine learning models in hepatic oncology.

M5B-SPIN-4 DUAL-SEQUENCE MRI RADIOMICS WITH A SUPPORT VECTOR MACHINE FOR PREDICTING POST-PANCREATITIS DIABETES IN PATIENTS WITH METABOLIC SYNDROME

Yanting Li (*Presenter*)

PURPOSE

To evaluate the clinical utility of a support-vector-machine (SVM) model that combines clinical variables with dual-sequence MRI radiomics for predicting post-pancreatitis diabetes mellitus after acute pancreatitis (PPDM-A) in patients with metabolic syndrome (MetS).

METHODS AND MATERIALS

This retrospective study enrolled 121 consecutive MetS patients who experienced a first episode of acute pancreatitis (January 2016 - February 2021). According to follow-up, 50 developed PPDM-A (MetS-PPDM-A) and 71 did not (MetS-nPPDM-A). Patients were randomly assigned (7:3) to training and test cohorts. Metabolic indices (BMI, fasting glucose, lipid profile, blood pressure) and MRI scans—fat-suppressed T2-weighted imaging (T2WI) and late-arterial-phase contrast-enhanced T1-weighted imaging (CE-T1WI)—were collected. Regions of interest were manually delineated on both sequences; radiomic features were extracted and reduced with variance thresholding, k-best selection, and LASSO regression. Three SVM classifiers were built: (i) a clinical model, (ii) a dual-sequence radiomics model, and (iii) a combined model. Discrimination was quantified by the area under the receiver-operating-characteristic curve (AUC); DeLong's test compared AUCs. Incremental performance was evaluated with integrated discrimination improvement (IDI), and net clinical benefit with decision-curve analysis (DCA).

RESULTS

n the training cohort, AUCs for the clinical, radiomics, and combined models were 0.792, 0.859, and 0.927, respectively; in the test cohort they were 0.739, 0.842, and 0.927. The combined model significantly outperformed the clinical model in both cohorts (training $p = 0.002$; test $p = 0.023$). Compared with the radiomics model, the combined model performed better in the training cohort ($p = 0.040$) but not in the test cohort ($p = 0.113$). IDI confirmed incremental discrimination for the combined approach, and DCA demonstrated consistently greater net benefit across all reasonable risk thresholds.

CONCLUSION

An SVM-based model that fuses clinical parameters with radiomic features from T2WI and late-arterial CE-T1WI achieves high accuracy for early prediction of PPDM-A in MetS patients. The model offers a reliable tool for individualized risk stratification and has substantial potential for clinical application.

CLINICAL RELEVANCE/APPLICATION

It predicts the risk of diabetes in patients with acute pancreatitis in the state of metabolic syndrome, and can detect and prevent diabetes early

M5B-SPIN-5 CT-BASED SWIN TRANSFORMER MODEL COMBINED WITH 3D U-NET FOR PREDICTING SPREAD THROUGH AIR SPACES IN CLINICAL STAGE I LUNG ADENOCARCINOMA: COMPARISON WITH VARIOUS DEEP LEARNING MODELS AND CLINICAL-SEMANTIC MODEL

Xiao-Ling Ma (*Presenter*)

PURPOSE

Spread through air spaces (STAS) is a unique tumor invasion pattern and a well-established independent prognosticator for lung adenocarcinoma, assisting in risk stratification and directing surgical options. This study aims to develop and validate a deep learning signature for noninvasive prediction of spread through air spaces (STAS) in clinical stage I lung adenocarcinoma and compare its predictive performance with various deep learning models and conventional clinical-semantic model.

METHODS AND MATERIALS

A total of 386 patients with pathologically-confirmed stage I lung adenocarcinoma in Center 1 were retrospectively enrolled in training cohort. Besides, 127 eligible patients from Center 2 constituted the independent validation cohort. The 3D U-Net was employed to achieve tumor automatic segmentation. The Swin Transformer architecture was adopted to develop a deep learning signature predictive of STAS. Furthermore, ResNet-50, EfficientNet and ConvNeXt were also applied for modeling denoted as Model ResNet-50 , Model EfficientNet and Model ConvNeXt to compare the efficacy of different deep learning methods in predicting STAS. Clinicopathological data were collected and CT semantic features were evaluated. Multivariate logistic regression analyses were conducted to construct a clinical-semantic model.

RESULTS

The proposed deep learning signature achieved an AUC of 0.869 (95% CI: 0.831, 0.901) in training cohort and 0.837 (95% CI: 0.831, 0.901) in validation cohort, surpassing clinical-semantic model both in training and validation cohort (all P <0.01). Encouragingly, Swin Transformer based deep learning signature achieved significantly higher AUC than Model ResNet-50 , Model EfficientNet and Model ConvNeXt in training cohort (0.869 vs. 0.800, 0.797 and 0.783; all P < 0.001), as well as than Model EfficientNet and Model ConvNeXt in validation cohort (0.837 vs. 0.775 and 0.795; P = 0.025 and 0.027). Deep learning signature showed an improvement in predictive performance than Model ResNet-50 in validation cohort, but it did not reach statistical significance (0.837 vs. 0.799, P = 0.087).

CONCLUSION

The end-to-end deep learning signature based on Swin Transformer combined with 3D U-Net automatic segmentation offers a promising predictive performance, surpassing clinical-semantic model and other deep learning models in predicting STAS.

CLINICAL RELEVANCE/APPLICATION

The deep learning signature based on Swin Transformer harbors the potential as a noninvasive tool for preoperative estimation of STAS, thereby directing surgical strategy and facilitating individual therapeutic scheduling.

M5B-SPIN-6 AN AI-BASED DISEASE CLASSIFICATION TOOL FOR SPINE X-RAYS

Vikash Gupta, PhD (*Presenter*)

PURPOSE

Deep learning approaches, particularly convolutional neural networks, have emerged as powerful tools for automated disease detection in medical imaging, offering promising solutions to assist radiologists in their diagnostic workflow. So far, very few spinal disease classification tools are available to the research community [1]. In this paper we are leveraging DenseNet121 for classifying spine diseases using the VinDr-SpineXR [2] dataset. In the future, we intend to expand this work for disease localization.

METHODS AND MATERIALS

DenseNet-121 [3] is a powerful convolutional neural network architecture known for its dense connectivity pattern, where each layer is directly connected to every other layer in a feed-forward fashion. This unique structure allows for improved information flow throughout the network, leading to better feature reuse, reduced parameter count, and enhanced gradient flow. We used this model for spine x-ray classification due to its ability to maintain and propagate fine-grained features throughout the network. We trained the model for 100 epochs, with a batch size of 32 and a learning rate of 0.001. We minimized the cross-entropy loss using an Adam optimizer. The images in the dataset were normalized and resized to 256 X 256. The dataset consisted of 8389 training images from 4000 studies. The trained model was tested on 2077 testing images.

RESULTS

The results show very high accuracy on the test data. We achieved an AUC score above 0.95 for all the categories. See figure 1 for more details.

CONCLUSION

In this work, we have shown a highly accurate disease classification algorithm based on a large dataset provided by [1]. We are working on disease localization as our next logical step in this research. We would like to point out that, in this experience we find managing and training a large number of narrow AI models much more efficient than training a single large foundation models. We are working on a suite of disease localization models which can then be deployed in a clinical workflow.

CLINICAL RELEVANCE/APPLICATION

This system enhances diagnostic support and workload distribution through an agent-based orchestration system. The architecture employs a cascading analytical pipeline, where initial classification triggers disease-specific localization models via automated routing. This distributed approach offers superior scalability and efficiency compared to large language models, while maintaining granular control over individual diagnostic tasks. The modular design facilitates continuous integration of new models and independent optimization, aligning with distributed computing paradigms and addressing clinical deployment constraints.

M5B-SPIN-7 AN ANATOMICAL LANDMARK-BASED INTENSITY PROFILE ANALYSIS FOR KNEE RADIOGRAPH CROPPING

Seyed Mohammadreza Chavoshi, MD (*Presenter*)
Theodorus Dapamede, MD, PhD (*Abstract Co-Author*)
Hari Trivedi, MD (*Abstract Co-Author*)
Keana Aitcheson (*Abstract Co-Author*)
Frank Li, PhD (*Abstract Co-Author*)
Aawez Mansuri, BS, MS (*Abstract Co-Author*)
Rohan Satya Isaac (*Abstract Co-Author*)
Janice M. Newsome, MD (*Abstract Co-Author*)
Judy W. Gichoya, MBChB, MS (*Abstract Co-Author*)

PURPOSE

To develop and evaluate an explainable image processing approach for knee radiograph cropping based on anatomical landmarks, providing an alternative to black-box machine learning methods while maintaining comparable performance for downstream assessment.

METHODS AND MATERIALS

We implemented an anatomical feature-based algorithm to crop the left and right knees from bilateral knee radiographs using classical image processing techniques including adaptive thresholding, edge detection, and intensity profile analysis. The approach was evaluated against the cropping performance of a convolutional neural network and a support vector machine. Cropping performance was evaluated using two complementary strategies. First, we assessed spatial accuracy by comparing each method's output to ground truth annotations on 1,000 manually cropped bilateral knee radiographs (2,000 individual knees) randomly selected from our institutional database, using Intersection over Union (IoU) and Dice similarity scores. Second, we tested the downstream utility of the cropped images of each method by training a ConvNeXt model for Kellgren-Lawrence grade (KLG) prediction on knee radiographs from the NIH Osteoarthritis Initiative dataset.

RESULTS

Our approach successfully cropped 1,999/2,000 knee images (99.95% completion rate), compared to 100% for the deep learning method and 96.1% for the SVM-based approach. For downstream KLG prediction, our method achieved 69.38% accuracy and 0.874 kappa score, comparable to the deep learning approach (70.43%, 0.880) and SVM method (68.94%, 0.872). Spatial accuracy metrics showed our method achieved mean IoU of 0.976 (±0.025) and Dice score of 0.988 (±0.014), closely approaching the deep learning (IoU: 0.983 ±0.017, Dice: 0.991 ±0.009) and surpassing the SVM (IoU: 0.971 ±0.053, Dice: 0.985 ±0.031). Visual comparison of the challenging cases demonstrated that our method maintains clinically relevant joint structures even in lowest-performing crops.

CONCLUSION

Our anatomical feature-based approach offers comparable performance to deep learning methods while providing full explainability, reduced computational requirements, and adaptability to different imaging datasets without retraining. The processing speed of our method significantly outperforms deep learning approaches, particularly when handling large datasets, making it more suitable for large-scale studies and time-sensitive clinical applications.

CLINICAL RELEVANCE/APPLICATION

This transparent, fast and computationally efficient approach enables knee cropping in resource-limited clinical settings without GPU requirements. Its explainable nature provides understandable process, critical for clinical adoption in various datasets.

M5B-SPIN-8 INTRAVENOUS CONTRAST MEDIUM IMPACTS CT-BASED MUSCLE QUALITY BUT NOT QUANTITY ANALYSIS: A LARGE-ANIMAL STUDY WITH HUMAN VALIDATION

Luca Salhofer, MD (*Presenter*)
Gregor Jost, PhD (*Abstract Co-Author*)
Mathias Holtkamp, MD (*Abstract Co-Author*)
Marcel Opitz, MD (*Abstract Co-Author*)
Sebastian Zensen, MD (*Abstract Co-Author*)
Rene Hosch, MSc, BSc (*Abstract Co-Author*)
Johannes Christian Harmes, MD (*Abstract Co-Author*)
Lale Umutlu, MD (*Abstract Co-Author*)
Michael Forsting, MD (*Abstract Co-Author*)
Felix Nensa, MD (*Abstract Co-Author*)
Hubertus Pietsch, VMD, PhD (*Abstract Co-Author*)
Johannes Haubold, MD (*Abstract Co-Author*)

PURPOSE

CT-based body composition analysis (BCA) has emerged as a valuable tool to extract new imaging biomarkers such as sarcopenia or myosteatosis. Myosteatosis can be assessed by muscle radiodensity analysis and the quantification of Inter- and Intramuscular Adipose Tissue (IMAT). Despite its potential, the integration of BCA into routine clinical practice has been hindered by concerns over the comparability of Non-contrast and contrast-enhanced CT scans. This study assessed the influence of various contrast phases on a fully automated, volumetric BCA.

METHODS AND MATERIALS

10 Göttingen minipigs were subjected to a Non-contrast (NC) and five contrast-enhanced ([CE], Early Arterial, Late Arterial, Vascular Portal Venous, Parenchymal Portal Venous, Late) CT scans on three occasions. For human validation, 114 tri-phasic (NC, Arterial, Venous) aortic CT scans were analyzed. An open-source and validated BCA network (Body and Organ Analysis [BOA]) extracted the following features as volumes: Muscle, Subcutaneous Adipose Tissue (SAT), IMAT, Visceral Adipose Tissue (VAT), and Total Adipose Tissue (TAT). Statistical significance was assessed by a one-way ANOVA with Tukey's multiple comparisons or Kruskal-Wallis with Dunn's post-hoc tests.

RESULTS

In the animal model, volumetric analysis of all BCA features in both NC and CE scans showed no significant changes. However, there was a tendency toward reduced IMAT volumes after CM injection. Muscle radiodensity was significantly higher following CM administration compared to the NC scan (NC: 51.1 HU (1.9 HU); Late: 56.6 HU (2.4 HU), $p < 0.001$). In the human validation, there was also a tendency toward reduced IMAT after CM injection (NC: 1651 ml (1254-2250 ml); Arterial: 1567 ml (1120-2073 ml); Venous: 1463 ml (1047-1970 ml); $p = 0.10$). Human muscle radiodensity deviated by -4.86% (-8.04-0.37%) in the Arterial phase and 7.65% (3.35-15.5%) in the Venous phase, compared to the NC scan.

CONCLUSION

Volumetric BCA provides consistent results for quantifying Muscle, VAT, and SAT volume. Myosteatosis metrics, both muscle radiodensity and IMAT, are susceptible to interference by CM.

CLINICAL RELEVANCE/APPLICATION

The consistent results of Muscle, VAT, and SAT volume by fully automated, volumetric CT-based BCA across NC and multiple CE phases foster its integration into clinical workflows and may enable longitudinal monitoring. However, CM alters muscle radiodensity and IMAT volume. Therefore, standardized imaging protocols or phase-specific correction factors are crucial when using CT-derived myosteatosis metrics to evaluate muscle quality for prognosis, therapy guidance, or treatment response.

M5B-SPIN-9 MULTI-ORGAN RADIOMICS PHENOTYPING REVEALS LUNG AND LIVER AS KEY PROGNOSTIC MARKERS IN ADVANCED NSCLC TREATED WITH IMMUNOTHERAPY

Taofik Ahmed Suleiman, MSc, BEng (*Presenter*)
Pushkar Mutha (*Abstract Co-Author*)
Mendel Lebowitz (*Abstract Co-Author*)
Juyoung Lee (*Abstract Co-Author*)
GOURAV MODANWAL (*Abstract Co-Author*)
Mohammadhadi Khorrami, PhD (*Abstract Co-Author*)
Anant Madabhushi, PhD (*Abstract Co-Author*)

PURPOSE

Radiomics-based prognostic models for non-small cell lung cancer (NSCLC) have traditionally focused on tumor features, with limited exploration of the prognostic role of nearby organs and tissues. However, organs such as the lung and liver may reflect systemic physiological states and immune status, potentially influencing disease progression and treatment response independently from tumor characteristics. This study investigated whether radiomic features from the lung and liver were independently associated with overall survival (OS) in patients with advanced-stage NSCLC treated with immunotherapy.

METHODS AND MATERIALS

Baseline CT scans from 231 patients with Stage III-IV NSCLC across three immunotherapy-treated cohorts were retrospectively analyzed. Regions of interest included organs (lungs, liver, spleen, airway) as well as tissues (subcutaneous fat, torso fat, and skeletal muscle). A standardized segmentation pipeline was applied: LungMask was used for lung segmentation, TotalSegmentator was used for liver, spleen, and fat/muscle regions, and NaviAirway was used for airway extraction. From these segmentations, 15 handcrafted radiomic features (shape, intensity, and texture) were extracted per organ, resulting in 105 features. The dataset was split into 70% training and 30% testing sets. Highly correlated features (Pearson $r > 0.95$) were first removed. Feature selection was performed using the Boruta algorithm and

bootstrapped Cox proportional hazards modeling (with ElasticNet regularization) across 50 iterations to identify most stable and discriminative features. Association between the radiomic features and OS was evaluated using C-index, hazard ratios (HR), p-values, and Kaplan-Meier (KM) survival analysis.

RESULTS

Liver and lung features were consistently identified as the topmost strongly associated factors with OS across 50 bootstrap iterations. In contrast, features from the airway, spleen, skeletal muscle, subcutaneous fat, and torso fat did not present an association with OS. KM analysis based on median risk score threshold within a 5-year survival window demonstrated significant survival-based stratification in the test cohorts (HR = 2.99; 95% CI: 1.26-7.11; p = 0.013).

CONCLUSION

Radiomic features of the liver and lung, independent of tumor characteristics, were found to be associated with OS in patients with advanced stage NSCLC undergoing immunotherapy. These initial results warrant additional multi-site independent validation.

CLINICAL RELEVANCE/APPLICATION

Multi-organ radiomic phenotyping on standard-of-care CT imaging could complement tumor-specific biomarkers to enhance survival prediction and treatment response assessment in NSCLC patients undergoing immunotherapy

M5B-SPIN-10 FEASIBILITY OF VARIATIONAL AUTOENCODER-BASED CLASSIFICATION OF PERIPHERAL ARTERY DISEASE LESIONS USING CLINICAL 3T UTE MRI

Eniko Pomozi, MD (*Presenter*)

PURPOSE

Peripheral artery disease (PAD) involves complex lesions with both soft and hard components, requiring accurate tissue assessment for effective treatment planning. Previous work demonstrated the potential of a convolutional variational autoencoder (VAE) for classification of PAD lesions using 9.4T MRI and multi-contrast pseudo-histological imaging (T2-weighted + UTE), enabling precise separation of concentric/eccentric calcifications and soft/hard occlusions. Imaging was extended to 7T MRI, showing that multi-contrast datasets (T1w, T2w, UTE) could be effectively encoded and classified by VAE. However, both approaches rely on ultra-high-field scanners, long acquisition times, and research-specific protocols. The purpose of the present study is to bring this methodology into the clinical setting.

METHODS AND MATERIALS

A total of 797 arterial cross-sections were obtained from 5 amputated lower limbs of patients with chronic limb-threatening ischemia (CLTI). The cross-sections were generated by imaging the harvested arterial segments using a 3T clinical MRI scanner (Siemens Healthineers) using a dedicated UTE sequence with total scan time under 15 minutes. Axial images perpendicular from a user-defined centerline were from UTE data were the only input into a custom 2D convolutional VAE, trained to encode image features into the 2D latent space and to classify lesions by a tissue score proportional to lumen occlusion. The tissue score defined by emphasizing the spatial separation of the images in latent space by their Euclidian distance.

RESULTS

The VAE successfully separated soft and hard lesion components using UTE images alone. Classification outputs closely aligned with visual assessments of plaque morphology. Compared to prior ex vivo 9.4T and 7T-based models using multi-contrast input, this 3T UTE-only approach maintained comparable performance with substantially reduced acquisition time and scanner burden. Tissue scores ranged from 1.26 to 0 for mostly occluded to patent tissues.

CONCLUSION

UTE MRI alone at 3T enables effective AI-based classification of PAD lesions using a variational autoencoder. This approach removes the dependency on longer, research-grade protocols and offers a rapid, clinically feasible imaging solution for pre-interventional planning. These findings support the broader adoption of AI-driven PAD lesion assessment in standard care.

CLINICAL RELEVANCE/APPLICATION

Clinical 3T UTE MRI combined with a variational autoencoder enables rapid, automated classification of PAD lesion components, offering shorter imaging time and more precise decision planning.

M5B-SPIN-11 EVALUATING LARGE LANGUAGE MODELS FOR ASCITES SEVERITY LABELING IN RADIOLOGY REPORTS

Robert D. Boutin, MD (*Presenter*)
Arjun Jain (*Abstract Co-Author*)
Asad Aali (*Abstract Co-Author*)
Andrew Johnston, MD, MBA (*Abstract Co-Author*)
Carl F. Sabottke, MD (*Abstract Co-Author*)
Luke S. Yoon, MD (*Abstract Co-Author*)
Jason Hom, MD (*Abstract Co-Author*)
Laura Derry (*Abstract Co-Author*)
David Svec (*Abstract Co-Author*)
Akshay Chaudhari, PhD (*Abstract Co-Author*)

PURPOSE

Radiology reports contain rich clinical detail, but current natural language processing (NLP) methods struggle to extract nuanced, structured findings at scale—especially for tasks requiring ordinal severity labels rather than binary classification. One such task is qualitative ascites severity grading, an important imaging feature in diagnosing and managing abdominal pathologies such as liver disease, malignancy, and systemic illness. This study evaluates whether a large language model (LLM) can accurately classify ascites severity from free-text radiology reports as a proxy for expert annotation.

METHODS AND MATERIALS

We developed a zero-shot ascites severity classifier using DSPy (an automated prompt optimization framework) with LLaMA 3.1 8B. The LLM used rule-based text cues—such as "no free fluid" for no ascites—to assign severity levels from free-text abdominal CT reports.The model was applied to 200 de-identified reports from a tertiary care center, evenly stratified across four severity levels (none, small, moderate, large). Each report was independently reviewed by a board-certified body radiologist and a body imaging fellow using a standardized rubric incorporating report findings and imaging appearance.

RESULTS

Expert inter-rater agreement yielded a linear-weighted Cohen's Kappa of 0.772. The LLM achieved Kappa scores of 0.716 (vs. Reader 1) and 0.652 (vs. Reader 2), with exact matches in 67% and 59% of cases, respectively. Over 93% of disagreements with Reader 1 and 89% with Reader 2 were off by only one severity level, suggesting most misclassifications were clinically minor. Additionally, 83% and 77% of the LLM's misclassifications overestimated severity compared to Reader 1 and Reader 2, respectively, indicating an upward bias that may be correctable.

CONCLUSION

This study showed that large language models can approximate expert interpretation in assigning ordinal severity labels from radiology reports, addressing a key challenge in extracting structured clinical detail at scale. Despite operating in a zero-shot setting and using only free-text input, the model demonstrated strong agreement with human readers, highlighting its promise for scalable, reliable annotation without image access.

CLINICAL RELEVANCE/APPLICATION

Automatically labeling free-text radiology reports with high fidelity enables scalable dataset curation, which is critical for both training high-performance AI models and continuously monitoring their behavior. This approach is easily adaptable to other imaging findings, paving the way for safer and more reliable integration of AI into clinical radiology workflows.

M5B-SPIN-12 TEXTURE-BASED SUPER-RESOLUTION GAN FOR SYNTHESIZING 3T T1-WEIGHTED MRI FROM 1.5T SCANS

Sk Rahatul Jannat, PhD, MS (*Presenter*)
Ketki Kinkar (*Abstract Co-Author*)
Bino A. Varghese, PhD (*Abstract Co-Author*)
Dighvijay Giri (*Abstract Co-Author*)
Nasim Sheikh-Bahaei (*Abstract Co-Author*)
Jeiran Choupan (*Abstract Co-Author*)
Kirsten Lynch (*Abstract Co-Author*)
Steven Cen, PhD (*Abstract Co-Author*)

PURPOSE

Develop a texture-based super-resolution GAN model to evaluate its effectiveness in generating synthetic whole-brain 3T T1-weighted (T1W) images from 1.5T MRI scans.

METHODS AND MATERIALS

This study used data from the Alzheimer's Disease Neuroimaging Initiative (ADNI) to evaluate super-resolution methods on 163 subjects with both 1.5T and 3T MRI scans from GE, Siemens, and Philips, excluding cross-manufacturer cases to avoid confounding from reconstruction differences. All 1.5T images were realigned to their 3T counterparts using SPM12 for precise comparison. We introduced a novel Texture-GAN model that incorporates GLCM-based texture features—specifically "Contrast "into the GAN loss function. This model was compared against Five other approaches: Bicubic, Lanczos, Efficient Sub-pixel CNN (ESPCN), SRGAN and TCGAN. Performance was evaluated using PSNR, SSIM and a custom metric, Intensity Difference in Points (IDP), which quantifies pixel-wise differences between 1.5T and 3T images to assess resolution enhancement.

RESULTS

TextureGAN and TCGAN showed notable improvement in IDP compared to Bicubic, Lanczos, SRGAN, ESPCN, and the original 1.5T images. Pixel-wise comparisons of axial T1-weighted slices between 1.5T and 3T scans revealed that TextureGAN and TCGAN substantially reduced pixel disparities relative to the original 1.5T images. We have counted the number of pixels with >25% intensity difference. To control repeated measurement error, we used data from 9 subjects who underwent two same-day 1.5T scans. The average pixel difference from these repeated scans was treated as baseline noise with 1.45% of pixels reached >25% intensity difference. TextureGAN and TCGAN had only 2.07% and 2.05% pixels with >25% intensity different from 3T scans respectively which is about 2% lower than the original 1.5T-3T difference, and close to the baseline noise of 1.45%. We also evaluated SSIM and PSNR with consistent results for all the super-resolution models.

CONCLUSION

Our experiment showed a significant enhancement in super-resolution's capacity to generate synthetic 3T images from 1.5T scans using TextureGAN and TCGAN.

CLINICAL RELEVANCE/APPLICATION

This approach offers a cost-effective alternative to 3T MRI, especially beneficial for patients with implants who cannot undergo high-field imaging.

M5B-SPIR-1 BUBBLE ENHANCED THERMALLY INSULATING HYDROGEL FOR HYDRODISSECTION DURING PERCUTANEOUS CRYOABLATION

Miles B. Conrad, MD (*Presenter*)
Subhajit Pal (*Abstract Co-Author*)
Isabelle Pummill (*Abstract Co-Author*)
Clarissa Jacobo Hernandez (*Abstract Co-Author*)
Jisoo Shin (*Abstract Co-Author*)
Sparshika Chhaperia (*Abstract Co-Author*)
Vinayak Tuteja (*Abstract Co-Author*)
Daniel Shi (*Abstract Co-Author*)
Phillip Messersmith (*Abstract Co-Author*)

PURPOSE

Cryoinjury to adjacent healthy tissues remains a significant limitation of percutaneous cryoablation, a minimally invasive and targeted tumor ablation technique. Although hydrodissection with fluids such as saline or dextrose is employed to displace tissues and minimize thermal injury, the thermal insulating properties of these solutions are limited. This study proposes a novel, thermally insulating, injectable hydrogel to enhance tissue protection via hydrodissection during percutaneous cryoablation.

METHODS AND MATERIALS

To facilitate minimally invasive injection, shear-thinning alginate-based hydrogels were developed by dynamically crosslinking alginate with boronic acid-functionalized multi-arm polyethylene glycol or other biopolymers. Additional ionic crosslinks were incorporated to enhance the hydrogel's stability under physiological conditions. Furthermore, CO2 microbubbles were introduced through in situ generation by reacting hydrochloric acid with sodium bicarbonate to enhance the thermal insulation properties of the developed hydrogels.

RESULTS

The dual crosslinked hydrogels exhibited shear-thinning and rapid recovery properties due to the dynamic covalent nature of the network, facilitating precise localization after injection. Moreover, the microbubble-enhanced hydrogel demonstrated exceptional thermal insulation and exhibited a gradient from the surface of the cold bath, -60? at 0 mm, -6.2? at 5 mm, and 3.7? at 10 mm. This indicates effective thermal shielding (53.8? across the first 5 mm distance) and significantly outperforms standard hydrodissection fluids. The developed hydrogel shows excellent biocompatibility, tunable degradability, and stability at ambient conditions.

CONCLUSION

Together, the mechanical, thermal, and biological properties of the developed hydrogel confirm the potential of the designed hydrogels as effective hydrodissectants, facilitating tissue displacement while minimizing thermal injury during percutaneous cryoablation.

CLINICAL RELEVANCE/APPLICATION

Future research will focus on validating clinical applicability through comprehensive in vivo studies assessing thermal shielding efficacy, migration over clinically relevant timeframes, and evaluations of the safety profile.

M5B-SPIR-2 LUNG RADIOFREQUENCY ABLATION USING AN18-GAUGE RADIOFREQUENCY ELECTRODE: FEASIBILITY, SAFETY, AND TREATMENT OUTCOMES

Kosuke Matsuda (*Presenter*)
Haruyuki Takaki, MD, PhD (*Abstract Co-Author*)
Hiroshi Kodama, MD (*Abstract Co-Author*)
Atsushi Ogasawara (*Abstract Co-Author*)
Reona Wada, MD, PhD (*Abstract Co-Author*)
Yasukazu Kako (*Abstract Co-Author*)
Sayuri Nishimoto (*Abstract Co-Author*)
Koichiro Yamakado, MD, PhD (*Abstract Co-Author*)

PURPOSE

Although lung radiofrequency ablation (RFA) is a useful therapeutic option for the treatment of malignant lung tumors, adverse events occur and some of them can be fatal. The use of thinner RF electrode may reduce the risk of adverse events. This retrospective study compared the safety and efficacy between lung RFA using 18-gauge (G) electrodes and that using 17-G electrodes.

METHODS AND MATERIALS

Lung RFA was performed to treat lung tumors from March 2024 to April 2025 in 61 patients with 175 lung tumors. Technical feasibility, therapeutic response and safety after lung RFA were evaluated in 57 patients having lung tumors 25 mm or smaller in a maximum diameter. Thirty-six patients (21 female /15 male) with 83 tumors were treated by using 18-G RF electrode (VIVARF system, Century Medical, Inc, Tokyo, Japan), and 32 patients (16 female /16 male) with 81 tumors by using 17-G RF electrode (VIVARF system in 76 tumors, Cooltip RFA system, Covidien Japan, Tokyo, Japan, in 5 tumors). The mean tumor size was 9.2 ± 3.8 mm in the 18-G group, and 10.6 ± 5.0 mm (p=0.054) in the 17-G group.

RESULTS

RFA was successfully technically performed in 98.8% (82/83 tumors) of tumors in the 18-G group, and 98.8% (80/81 tumors) of tumors in the 17-G group (p= 0.99). The overall incidence of adverse events did not differ significantly between the 18-G and 17-G groups (75.0% vs. 73.8%, p=0.88). However, the incidence of grade-2 or

-3 pneumothorax requiring drainage was significantly lower in the 18-G group (13.3% vs. 27.9%, p<0.05). The local tumor progression rates were similar between the 18-G and 17-G groups [0% (0/83) vs. 2.5% (2/81), p=0.15] during the follow-up of 177 ± 91 days in the 18-G group and 342 ± 70 days in the 17-G group.

CONCLUSION

Lung RFA with an 18-G RF electrode reduces the risk of clinically significant pneumothorax while maintaining equivalent therapeutic efficacy compared to lung RFA with 17-G RF electrode.

CLINICAL RELEVANCE/APPLICATION

Lung RFA using an 18-G RF electrode reduces clinically significant pneumothorax without compromising treatment efficacy, offering a safer and more patient-friendly approach in clinical practice.

M5B-SPIR-3 DIFFUSION MRI AS THE LEADING TECHNIQUE FOR TARGETED PROSTATE BIOPSY GUIDANCE

Ludovica Laschena, MD (*Presenter*)
Emanuele Messina, MD (*Abstract Co-Author*)
Antonella Borrelli, MD (*Abstract Co-Author*)
Luca De Giacomo (*Abstract Co-Author*)
Maurizio Del Monte (*Abstract Co-Author*)
Valeria Panebianco, MD (*Abstract Co-Author*)

PURPOSE

To explore the potential role of DWI in identifying the "core" of lesions in the prostate peripheral zone and to assess whether targeting biopsies specifically on the DWI-defined “lesion’s core” can improve the diagnostic performance in detecting clinically significant prostate cancer (csPCa).

METHODS AND MATERIALS

Prospective single center study; patients with MRI suspicious of PCa (PI-RADS 5, 4 and PI-RADS 3 with PSA-density =0.15) with a mismatch between DWI and T2 in terms of lesion extension, undergoing transrectal-fusion-targeted-biopsy(TBx). During the pre-biopsy segmentation phase performed by an experienced uro-radiologist, the “lesion-core” was indicated as the most restricting area on DWI, while the “penumbra” as the exceeding area visible on T2WI. During the procedure, 2 biopsy cores were sampled from the “lesion-core” (DWI-defined), while 2 cores from the “penumbra”(T2WI-defined); they were separately stored.For clinically significant PCa-DR, contingency tables were tested (Pearson’s chi-squared). To compare the outcomes, we compared the number of positive cores and the percentage of positive tissue within cores. ROC-curves were implemented.

RESULTS

54 patients underwent TBx. 75 biopsy-targets were identified. 17/54 (31.5%) overall patients resulted negative for PCa. Among “lesion-cores”, csPCa-DR was 43/75(57.3%), while among “penumbra” 25/75(33.3%) (p=0.02); on 18/75(24%) of “penumbra-areas” we found inflammatory changes. The percentage of positive tissue within cores resulted different, with better performance on “lesion-core” (median percentage of 61.6%) vs “penumbra” (median percentage of 38.7%)(p<0.01). We witnessed higher Gleason Score within “lesion-cores”, compared to “penumbra”(p=0.03).

CONCLUSION

These results show significant differences between the “lesion-core” and “penumbra”. Indeed, this of DWI-defined “lesion-core” allowed us to achieve a better biopsy performance in terms of DR and percentage of positive tissue within cores. Therefore, DWI should be used as main sequence during the TBx, identifying the “lesion-core”.

CLINICAL RELEVANCE/APPLICATION

This study demonstrates that targeting the "lesion-core"(DWI-defined), improves the detection rate of csPCa during MRI-targeted biopsy. Compared to the broader T2-defined “penumbra”areas, the DWI-defined core yielded a higher proportion of positive biopsy cores, greater tumor burden within those cores, and higher Gleason Scores. Clinically, these findings support prioritizing DWI as the primary sequence for lesion characterization and biopsy guidance in suspicious prostate lesions, potentially leading to more accurate diagnoses, reduced overdiagnosis of indolent disease, and optimized patient management.

M5B-SPIR-5 A COMPARATIVE META-ANALYSIS AND TRIAL SEQUENTIAL ANALYSIS ON PERCUTANEOUS THERMAL ABLATION VS PARTIAL NEPHRECTOMY FOR THE TREATMENT OF STAGE 1 RENAL CELL CARCINOMA:RESULTS FROM 49 STUDIES AND 30,944 PATIENTS

Dimitrios-Marios Chalmoukis, MD (*Presenter*)
Andreas K. Papadopoulos, MD, MSc (*Abstract Co-Author*)

PURPOSE

Accumulating evidence support the notion that partial nephrectomy (PN) and percutaneous thermal ablation (pTA) offer similar overall survival (OS), while the latter is linked to a better safety profile. We undertook a systematic review and meta-analysis with the aim to compare the two techniques, among patients with stage 1 Renal Cell Carcinoma (RCC). Additionally, we sought to address the consistency of the currently available literature.

METHODS AND MATERIALS

Following the PRISMA guidelines, PubMed, Embase and the Cochrane Library were systematically searched for published reports comparing PN and pTA. Comparative studies reporting OS and/or complication rates were considered eligible. Random effect meta-analyses and trial sequential analyses (TSA) were performed.

RESULTS

Eligible were 49 studies encompassing a total of 30,944 patients (pTA/PN, 6,571/24,373). All grades of complication rates were significantly higher for patients undergoing PN Vs pTA (Risk Ratio [RR], 1.78; 95% CI, 1.47 to 2.16, and RR, 1.9; 95% CI 1.27 to 2.71, p -value<0.001, respectively). TSA indicated that no additional trials were needed to reach this conclusion. OS was shown to be similar for patients undergoing either pTA or PN both at 1-year (RR 0.68; 95% CI 0.45 to 1.03, p -value>0.05) and 5-years (RR 0.76; 95% CI 0.58 to 1.01, p -value>0.05). For 1- and 5- year OS, TSA analysis revealed that -at a minimum- an additional 4,335 and 63,720 patients, respectively, might be needed for stable conclusions.

CONCLUSION

Our results indicate that there is no difference in OS between pTA vs PN; a significant number of additional large-scale studies would be needed to detect an identifiable potential difference. However, we found pTA to be associated with a superior safety profile when compared to PN, with future studies being unlikely to alter this conclusion.

CLINICAL RELEVANCE/APPLICATION

This study shows that while partial nephrectomy and percutaneous thermal ablation offer similar overall survival for stage 1 RCC, the latter has a significantly better safety profile.

M5B-SPIR-6 POST-HOC ANALYSIS OF THE COVER-ALL TRIAL: THERMAL ABLATION OUTCOMES IN PATIENTS WITH COLORECTAL LIVER METASTASES

Noreen Siddiqi, MD (*Presenter*)
Jessica A. Marques Silva, MD (*Abstract Co-Author*)
Iwan Paolucci, PhD (*Abstract Co-Author*)
Caleb Oconnor (*Abstract Co-Author*)
A. Kyle Jones, PhD (*Abstract Co-Author*)
Kristy K. Brock, PhD (*Abstract Co-Author*)
Bruno C. Odisio, MD, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate oncologic outcomes of software-based versus visual assessment of minimal ablative margins (MAM) in patients with colorectal liver metastases (CLM) undergoing thermal ablation.

METHODS AND MATERIALS

This post hoc analysis used data from patients with CLM enrolled in the COVER-ALL randomized phase 2 trial (NCT04083378), conducted at a single center between June 2020 and October 2023. Patients underwent CT-guided percutaneous thermal ablation with the goal of achieving =5 mm MAM. Fifty patients were randomized 1:1 to software-based (experimental) or visual (control) MAM assessment using Pocock-Simon dynamic allocation. Following a planned interim analysis confirming superiority of the software-based method, enrollment to the control arm was halted, and subsequent 50 patients were assigned to the experimental group. Only CLM cases were included. Outcomes included post-ablation MAM, 2-year local tumor progression (LTP), LTP-free survival, overall survival, and intra-/extrahepatic progression-free survival. Follow-up will be completed by October 2025. Time-to-event analyses were performed using Kaplan-Meier and Fine-Gray methods. Adverse events were recorded per CTCAE.

RESULTS

Eleven patients were included in the control group (mean age 54.6 years, 91% male; median tumor diameter 1.8 cm [IQR 1.3-2.2]) and 40 patients were included in the entire experimental group (mean age 54.0 years, 55% male; median tumor diameter 1.5 cm [1.2-1.9]). The mean MAM was 2.5 mm in the control group versus 7.4 mm in the experimental group. Median follow-up was 22.7 months overall (25.1 months control vs. 21.0 months experimental). Local tumor progression occurred in 1/11 (9.1%) control vs. 1/40 (2.5%) entire experimental group. One grade 2 adverse event occurred in the experimental group (1/40, 2.5%). No grade 4-5 events or treatment-related deaths were reported.

CONCLUSION

In this subset of CLM patients, software-based MAM assessment was safe and, with a low LTP rate. These findings support the integration of AI-driven tools in ablation planning for CLM, aligned with updated NCCN guidelines endorsing ablation as an alternative to resection for small lesions.

CLINICAL RELEVANCE/APPLICATION

This study reinforces the clinical value of software-based MAM assessment for guiding thermal ablation in CLM. Its adoption may help standardize margin evaluation, improve tumor control, and support NCCN-endorsed practice of ablation as a curative-intent option for small resectable CLMs.

M5B-SPIR-7 COMPARATIVE ANALYSIS OF ULTRASOUND GUIDED MICROWAVE ABLATION VERSUS PAROTIDECTOMY FOR BENIGN PAROTID TUMORS

Min Zhuang (*Presenter*)
Man Lu, PhD (*Abstract Co-Author*)

PURPOSE

To compare the clinical efficacy of ultrasound-guided microwave ablation (MWA) and parotidectomy in treating benign parotid tumors.

METHODS AND MATERIALS

A total of 40 patients with benign parotid tumors treated in our hospital from 2021 to 2023 were enrolled and divided into two groups based on treatment modality: the MWA group (n=18) and the surgery group (n=22). Perioperative indicators, cosmetic score changes, and complication rates were compared between the two groups.

RESULTS

No statistically significant difference in recurrence rates was observed between the two groups at 6 months and 1 year post-treatment (P>0.05). The MWA group exhibited shorter operative time, smaller surgical scars, reduced hospital stays, and less intraoperative blood loss compared to the surgery group (P<0.05). The complication rate in the MWA group was significantly lower than that in the surgery group (P<0.05). Post-treatment cosmetic scores in the MWA group showed a significant decrease and continued to improve over time, although 2 patients with larger pre-treatment tumors exhibited no notable improvement at the 1-year follow-up. In contrast, the surgery group demonstrated immediate cosmetic score reduction, but 5 cases developed noticeable facial depression and asymmetry.

CONCLUSION

Compared to parotidectomy, ultrasound-guided MWA for benign parotid tumors results in smaller scars, shorter hospitalization, and fewer postoperative complications. For patients with smaller tumors, MWA can prevent surgery-induced facial depression and asymmetry, yielding superior clinical outcomes.

CLINICAL RELEVANCE/APPLICATION

Ultrasound-guided MWA presents a minimally invasive alternative to traditional parotidectomy for benign parotid tumors, particularly in small to medium-sized tumors.

M5B-SPMK-1 GRADING CERVICAL NEURAL FORAMINAL STENOSIS VIA 3T MRNERVE/BONE FUSION IMAGING COMPARED WITH T2-WEIGHTED IMAGING

Dongmei Jiang (*Presenter*)
Yuwei Pan (*Abstract Co-Author*)
Shuyi Lei (*Abstract Co-Author*)
Dejun She (*Abstract Co-Author*)
Yingying Xie (*Abstract Co-Author*)
Dairong Cao, MD (*Abstract Co-Author*)

PURPOSE

To investigate the value of 3T MR nerve/bone fusion imaging in grading cervical neural foraminal stenosis (CNFS).

METHODS AND MATERIALS

58 healthy participants and 23 patients with suspected cervical radiculopathy were prospectively enrolled. MR nerve and bone sequences including 3D-T2-weighted fast field echo (3D-T2-FFE) and fast field echo resembling a CT using restricted echo-spacing (FRACTURE) were performed. The agreements of overall image quality, image artifacts, the width of cervical neural foramen (WCNF) and the width of extraforaminal nerve root (WENR) were assessed on 3D-T2-FFE/FRACTURE fusion image in healthy participants. The detection rate, visibility score of extraforaminal nerve root (ENR), and the CNFS grade were compared for patients between 3D-T2-FFE/FRACTURE fusion image and T2WI. The correlation between CNFS grade and the neck disability index (NDI) and numerical pain scale (NPS) was assessed.

RESULTS

The agreements were moderate to good for overall image quality and image artifacts (?=0.614-0.867), and good to excellent for WCNF and WENR (ICC=0.755-0.931) . The detection rate of ENR on 3D-T2-FFE/FRACTURE fusion (184/184, 100%) was higher than that on T2WI (116/184, 63.04%). The visibility score for ENR was also higher on 3D-T2-FFE/FRACTURE fusion. The proportion of grade 1 and grade 2 on T2WI was higher than that on 3D-T2-FFE/FRACRURE fusion. The overall CNFS grade on T2WI was slightly higher than that on 3D-T2-FFE/FRACRURE fusion. The intra-reader and inter-reader agreement for CNFS grading was substantial to nearly perfect on 3D-T2-FFE/FRACTURE fusion (?=0.774-0.837), and moderate on T2WI (?=0.436-0.624). The correlation between the CNFS grade based on 3D-T2-FFE/FRACTURE fusion and NDI (? = 0.4317, P<0.05) /NPS (? = 0.4212, P < 0.05) was moderate, respectively. But no correlation was found between CNFS grade based on T2WI and NDI/NPS (P > 0.05).

CONCLUSION

Compared with T2WI, 3D-T2-FFE/FRACTURE fusion provides a more reliable and reproducible evaluation of the severity of CNFS. The CNFS grade based on 3D-T2-FFE/FRACTURE fusion is associated with clinical symptoms.

CLINICAL RELEVANCE/APPLICATION

3D-T2-FFE/FRACTURE fusion provides a more reliable evaluation of the severity of CNFS. The CNFS grade based on 3D-T2-FFE/FRACTURE fusion is associated with clinical symptoms. 3D-T2-FFE/FRACTURE fusion imaging may facilitate a one-stop-shop and radiation-free approach to comprehensively evaluate CNFS.

M5B-SPMK-2 HIGH RESOLUTION MRI EVALUATING PRE-SURGERY PLANNING IN NON-MELANOMA SKIN CANCER

XIAOQIONG LI (*Presenter*)
Yueyou Peng (*Abstract Co-Author*)
Yanfeng Meng, MD, PhD (*Abstract Co-Author*)

PURPOSE

To assess the value of high-resolution MRI (HR-MRI) in pre-surgery evaluation of non-melanoma skin cancer.

METHODS AND MATERIALS

The study enrolled patients with non-melanoma skin cancer and underwent Mohs micrographic surgery (MMS) from January 2022 to April 2025. Patients who eligible for MRI were performed skin HR-MRI on a 3T scanner before surgery. The MRI sequence included T1WI, T2WI, T2WI fat suppression(FS-T2), and T1 dynamic contrast enhancement (DCE). DCE scan was conducted utilizing a gadolinium-based contrast agent, via a high-pressure injector at a flow rate of 2 ml/s into the elbow vein. The dosage of the contrast agent was 0.1 mmol/kg. Following the injection of contrast agent, five consecutive dynamic enhanced images were acquired, with a time resolution of 76s per phase. Tumor characteristics including size, shape, invasion, signal intensity, and enhancement curve were assessed by two radiologists. Patients received both MRI and surgery were assigned in Group 1, while those who received surgery only were assigned in Group 2. The number of post-surgery tissue sections, positive tumor margins on histopathology sections, and cases requiring secondary surgery were recorded. A Chi-square test was employed to compare the differences of tumor invasion levels between MRI and pathology findings.

RESULTS

A total of 134 cases were enrolled, in which 76 cases in Group 1 and 59 cases in Group 2. There were 54 basal cell carcinoma (BCC) and 22 squamous cell carcinoma (SCC) cases in Group1. The observation results between the two radiologists showed no statistical difference. T1WI showed hypointensity or isointensity for both BCC and SCC, while T2WI and FS-T2 showed hyperintensity. T2WI effectively showed the relationship between tumors and nearby structures, while FS-T2 highlighted tumor contours. DCE scans were performed for 15 BCC and 3 SCC cases, revealing plateau or washout patterns for BCC and plateau patterns for SCC. In Group 1, the positive rates for pathological sections and secondary resections were 12.6% and 25%, respectively, compared to 23.1% and 44.1% in Group 2. Group 1 showed a lower secondary resection rate than Group 2. There was a high consistency between tumor invasion levels observed by HR-MRI and pathological results in the group 1 (p>0.75).

CONCLUSION

Skin HR-MRI is valuable for non-melanoma skin cancers, providing accurate pre-surgery tumor scope assessment and reducing the secondary surgeries rate.

CLINICAL RELEVANCE/APPLICATION

MMS is most commonly used for skin tumorectomy with a high possibility of secondary surgery without HR-MRI. MRI clearly depicts the size of tumor and the invaded layer. The application of HR-MRI pre-surgery precisely determine the surgical range and reduce the possibility of secondary operations.

M5B-SPMK-4 GENERATION OF SYNTHETIC PET/MR FUSION IMAGES FROM MR IMAGES USING A COMBINATION OF GENERATIVE ADVERSARIAL NETWORKS AND CONDITIONAL DENOISING DIFFUSION PROBABILISTIC MODELS BASED ON SIMULTANEOUS 18F-FDG PET/MR IMAGE DATA OF PYOGENIC SPONDYLODISCITIS

IKCHAN JEON, MD, PhD (*Presenter*)

PURPOSE

This study aims to generate synthetic PET/MR fusion images from MR images using a combination of generative adversarial networks (GANs) and conditional denoising diffusion probabilistic models (cDDPMs) based on simultaneous 18F-fluorodeoxyglucose (18F-FDG) PET/MR image data.

METHODS AND MATERIALS

We used paired spinal sagittal T2FS and PET/T2FS fusion images of simultaneous 18F-FDG PET/MR imaging examination in patients with PSD, which were employed to generate synthetic PET/T2FS fusion images from T2FS images using a combination of Pix2Pix (U-Net generator + Least Squares GANs discriminator) and cDDPMs algorithms. In the analyses of image similarity between the real and synthetic PET/T2FS fusion images, we adopted the values of mean peak signal to noise ratio (PSNR), mean structural similarity measurement (SSIM), mean absolute error (MAE), and mean squared error (MSE) for quantitative analysis, while the discrimination accuracy by three spine surgeons was applied for qualitative analysis.

RESULTS

Total 2082 pairs of T2FS and PET/T2FS fusion images were obtained from 172 examinations on 94 patients, which were randomly assigned to training, validation, and test data sets in 8:1:1 ratio (1664, 209, and 209 pairs). The quantitative analysis revealed PSNR of 30.634 ± 3.437, SSIM of 0.910 ± 0.067, MAE of 0.017 ± 0.008, and MSE of 0.001 ± 0.001, respectively. The values of PSNR, MAE, and MSE significantly decreased as FDG uptake increase in real PET/T2FS fusion image, with no significant correlation on SSIM. In the qualitative analysis, the overall discrimination accuracy between real and synthetic PET/T2FS fusion images was 47.4%.

CONCLUSION

The combination of Pix2Pix and cDDPMs demonstrated the potential for cross-modal image generation from MR to PET images, with reliable quantitative and qualitative image similarities.

CLINICAL RELEVANCE/APPLICATION

Cross-modality image generation from magnetic resonance (MR) to positron emission tomography (PET) using the generative model can be expected to have complementary effects by addressing the limitations and maximizing the advantages inherent in each modality.

M5B-SPMK-5 MRI-BASED OSSEOUS TUMOR REPORTING AND DATA SYSTEM (OT-RADS): CLINICAL EXPERIENCE OF PROSPECTIVE IMPLEMENTATION AND DIAGNOSTIC ACCURACY

Garrett Croley (*Presenter*)
Atul K. Taneja, MD,PhD (*Abstract Co-Author*)
Flavio Duarte Silva, MD, PhD (*Abstract Co-Author*)
Avneesh Chhabra, MD, MBA (*Abstract Co-Author*)

PURPOSE

To evaluate the clinical performance and diagnostic accuracy associated with the prospective implementation of the MRI-based Osseous Tumor Reporting and Data System (OT-RADS) in comparison to the traditional descriptive reports.

METHODS AND MATERIALS

Following prospective implementation of the OT-RADS scoring in the electronic dictation system, several fellowship-trained musculoskeletal radiologists classified the bone tumors routinely using this system. This retrospective auditing and analysis included 352 consecutive patients evaluated using OT-RADS from July 2021 to May 2024. Inclusion criteria encompassed patients aged 14-100 years with osseous lesions of the extremities, thoracic or abdominopelvic walls evaluated by MRI, confirmed by surgery, biopsy, and/or follow-up for benign lesions. Data on patient demographics, imaging findings, lesion characteristics, biopsy results, treatment modalities, and clinical outcomes were collected. Diagnostic accuracy was statistically evaluated using McNemar's test.

RESULTS

The cohort included 352 patients (60.2% females, mean age 54.7 ± 15.7 years). Most lesions (66.1%) were managed conservatively. Surgical and chemotherapy interventions each accounted for 8.4%. Biopsy was performed selectively (18.8%). OT-RADS I,II, III were 4.8%, 46.1% and 18.2%, respectively. Suspicion categories for malignancy (OT-RADS IV-VI) collectively comprised 36.1% of cases. Clinical outcomes were favorable, with improvement in 60.8% of patients. OT-RADS demonstrated superior overall accuracy (95.4%) compared to descriptive reporting (88.0%) ($p<0.0001$), especially in biopsy-confirmed cases (OT-RADS 84.6% vs. descriptive 61.5%; $p<0.0001$). In addition, OT-RADS accuracy remained consistently higher across all categories: grouped analysis showed using McNemar tests demonstrated significant differences favoring OT-RADS for both benign (II-III) ($p = 0.003$) and malignant lesions (IV-V) ($p < 0.001$), as well as in OT-RADS IV ($p = 0.0078$) and V ($p = 0.0156$) when analyzing the subgroups separately.

CONCLUSION

OT-RADS provides significantly improved diagnostic accuracy compared to the traditional descriptive reporting both for benign and malignant bone tumors These findings highlight further validation of the scoring system for broader applicability to stratify lesion risk, guide appropriate clinical management, and positively impact patient outcomes.

CLINICAL RELEVANCE/APPLICATION

The implementation of OT-RADS significantly enhances diagnostic accuracy in osseous tumor evaluation, enabling standardized lesion stratification and more informed clinical decision-making, ultimately improving patient care pathways.

M5B-SPNMMI-1 THE DIFFERENCES OF CEREBRAL HYPERPERFUSION IN PATIENTS WITH MOYAMOYA DISEASE AND ATHEROSCLEROTIC OCCLUSIVE CEREBROVASCULAR DISEASE EVALUATED BY ^{99M}TC-ECD SPECT ONE DAY AFTER REVASCULIZATION SURGERY

Koichiro Kaneko, MD, PhD (*Presenter*)
Kengo Yoshimitsu, MD, PhD (*Abstract Co-Author*)
Michinobu Nagao, MD, PhD (*Abstract Co-Author*)
Shuji Sakai, MD, PhD (*Abstract Co-Author*)

PURPOSE

To examine the relation between postoperative cerebral hyperperfusion (CHP) and preoperative cerebral blood flow (CBF) SPECT findings in patients with moyamoya disease (MMD) and atherosclerotic occlusive cerebrovascular disease (AOCD).

METHODS AND MATERIALS

99mTc-ethyl cysteinate dimer SPECT studies were performed for 100 cerebral hemispheres in the 77 MMD/AOCD patients one day after revascularization surgery. We calculated the pre-postoperative regional CBF (rCBF) ratio and postoperative increase rate (IR) in frontal, temporal, and parietal lobes using a three-dimensional stereotaxic region of interest (ROI) template. We compared the patterns, severities of CHP, and major complications among the adult onset MMD (AMMD), pediatric onset MMD (PMMD), and AOCD patients. We also investigated the association among CHP, preoperative rCBF ratio, and cerebrovascular reactivity (CVR) for acetazolamide activation.

RESULTS

A total of 300 ROIs were analyzed in 100 revascularized hemispheres. CHP (?30% in IR) occurred in 27 hemispheres mainly with frontal lobe dominant pattern (19/27), and the incidence (19.0%) was significantly higher than those of temporal and parietal lobe dominant pattern (4.0% in each, $p < 0.001$). Severe CHP (?50 % in IR) more frequently occurred in the AMMD patients than in the PMMD and AOCD patients (21.5% vs. 2.9%, $p = 0.01$), and major complications occurred only in the 2 AMMD patients with severe CHP. In the ROC analyses, preoperative rCBF ratio more correctly differentiated the regions with mild/severe or severe CHP from those without CHP than CVR (area under curves of 0.84 vs. 0.67, 0.81 vs 0.73, respectively) in the MMD patients, while neither preoperative rCBF ratio nor CVR did not significantly correlated in the AOCD patients. The AMMD and AOCD patients showed significantly lower preoperative rCBF ratio in all lobes than the PMMD patients ($p < 0.0001$ for all), while the all types of patients showed similar CVR. In the 13 subsequent CBF SPECT studies for the patients with definite or equivocal CHP beyond postoperative day 2, rCBF reduced in 12 hemispheres while one hemisphere developed to severe CHP.

CONCLUSION

CHP in the frontal lobe occurred more often and with greater severity in AMMD patients. Reduction of preoperative CBF was more closely associated with CHP than CVR in MMD patients, and non-activated ECD SPECT was suitable for pre/postoperative CBF evaluation.

CLINICAL RELEVANCE/APPLICATION

CHP after revascularization surgery was mainly observed in the frontal lobe of AMMD patients. CHP tended to be more severe in AMMD patients than in PMMD or AOCD patients. Reduced preoperative CBF more accurately predicted the occurrence of CHP than CVR in the MMD patients.

M5B-SPNMMI-2 INITIAL RESULTS OF ^{68}GA-BED003 FAP-TARGETED PET/MRI TO ASSESS THE EXTENT OF ENDOMETRIOSIS

Jonas Brandt (*Presenter*)
Philipp Backhaus, MD (*Abstract Co-Author*)
David Ventura (*Abstract Co-Author*)
Stephanie Eltrop (*Abstract Co-Author*)
Philipp Schindler, MD (*Abstract Co-Author*)

PURPOSE

Endometriosis is a common gynecologic disorder often associated with chronic pelvic pain, infertility and reduced quality of life. Conventional imaging modalities such as transvaginal ultrasound and MRI may underestimate the extent of disease, particularly in deep infiltrating endometriosis (DIE). Fibroblast activation protein (FAP) is highly expressed in remodeling endometrium and has been implicated in endometriosis lesions. This study investigates the feasibility of integrating FAP-targeted PET with MRI to improve endometriosis detection.

METHODS AND MATERIALS

In this retrospective study, nine premenopausal women with confirmed endometriosis (test group) and nine premenopausal women without known endometriosis (reference group) underwent PET/MRI or PET/CT with 68 Ga-OncoFAP (now under development as 68 Ga-BED003). 7 patients in the test group underwent PET/MRI, while 2 patients in the test group and all patients in the reference group underwent PET/CT. Standard MRI sequences were combined with PET and tracer uptake was assessed semi-quantitatively. Lesions were categorized based on a modified #ENZIAN segmentation. Clinical assessment or laparoscopy (when available) served as the reference standard. Statistical comparisons of tracer uptake and lesion counts between groups were performed using the Mann-Whitney U test.

RESULTS

In the test group, at least one endometriosis-related finding was identified in 6 of 7 patients who received PET/MRI when only MRI was evaluated, compared to all patients when combined PET/MRI was reviewed. In the test group, PET/MRI identified 45 of 91 segments (49.5%) as likely endometriotic compared with 17 of 91 segments (18.7%) with MRI alone. PET/CT and PET/MRI datasets showed focal tracer uptake in 44 of 108 segments (40.7%) in the test group, significantly higher than the 14 of 108 segments (13.0%) in the reference group ($p<0.01$). Combined PET/MRI improved lesion conspicuity for peritoneal and tubo-ovarian locations. Mean

uterine SUV max was not significantly different between groups (p=0.489). In patients who underwent laparoscopy, PET/MRI findings largely correlated with surgical results.

CONCLUSION

These initial findings suggest that 68 Ga-BED003 FAP-directed PET/MRI may improve the detection and characterization of endometriosis, particularly in anatomically challenging regions where conventional MRI is limited. As a potential adjunct to existing imaging strategies, 68 Ga-BED003 FAP-PET/MRI may refine noninvasive assessment and guide personalized management of endometriosis.

CLINICAL RELEVANCE/APPLICATION

Larger prospective studies are warranted to validate these findings, establish standardized imaging protocols, and determine the diagnostic accuracy of this novel technique.

M5B-SPNPM-1 ACADEMIC AND NON-ACADEMIC RADIOLOGIST COMPENSATION AND CLINICAL PRODUCTIVITY TRENDS OVER THE LAST DECADE

Dheeman Futela, MBBS (*Presenter*)
Ajay Malhotra, MD, MMM (*Abstract Co-Author*)

PURPOSE

Physician shortages have been reported across multiple specialties, particularly in radiology, as imaging utilization increases. Despite increased imaging volumes, collections and unit prices may not keep up with increased workloads. This study aimed to assess recent trends in financial compensation and clinical productivity of radiologists in academic and nonacademic settings.

METHODS AND MATERIALS

We studied deidentified data from the Medical Group Management Association for both Diagnostic and Interventional (DR and IR) physicians in academic and nonacademic practices from 2014 to 2023. Median, 25th and 75th percentiles, and mean values were analyzed for compensation, collections, and work relative value units (wRVUs). Compensation and productivity data were compared by radiology subspecialty (DR versus IR), practice type (academic versus nonacademic provider), geographical region of the United States, and practice size. Trends were analyzed with linear regression and by comparing growth rates with market inflation.

RESULTS

The Medical Group Management Association Survey data for 2023 included responses from 3,769 radiologists (2,883 in DR and 886 in IR). In 2023, nonacademic radiologists had greater total median compensation than academic faculty in both DR (by 27%) and IR (by 32%). From 2014 to 2023, median compensation increased faster for academic DR physicians (3.2% annually) than for nonacademic DR physicians (1.9% annually). In 2023, DR physicians produced greater median wRVUs than IR physicians (by 53% for nonacademic and 46% for academic radiologists) with higher collections, but IR physicians had higher compensation (by 16% in nonacademic and 10% in academic settings). Over the last decade, IR physician compensation increased by 3.9% and 3.4% annually for nonacademic and academic IR physicians, respectively, whereas median wRVUs trended downward (by -1.5% for nonacademic and -2.4% for academic physicians) with declining collections (by -4.4% annually for nonacademic and -2.1% for academic physicians).

CONCLUSION

Over the last decade, the salary gap between academic and nonacademic radiologists has narrowed. Physician compensation has increased at a faster pace in IR, despite relatively lower clinical productivity and declining collections.

CLINICAL RELEVANCE/APPLICATION

This study shows compensation and clinical productivity trends over the last decade to inform both practice managers and newly graduating or early career radiologists. Using this data could help in address staffing, ensuring access to care for patients, and negotiations for subsidies, or additional sources of funding, especially in the face of decreasing reimbursements.

M5B-SPNPM-2 ROLEX, KODAK, AND THE RADIOLOGY VIRTUAL READING ROOM: NAVIGATING DISRUPTIVE INNOVATION ACROSS INDUSTRIES

Khushboo Jhala, MD, MBA (*Presenter*)

PURPOSE

The traditional radiology reading room has long been a hub for image interpretation and interdisciplinary collaboration. However, the COVID-19 pandemic prompted workflow restructuring to minimize in-person interactions, leading to the development of virtual reading rooms (VRRs). This talk reviews the ongoing digital evolution of VRRs in a post-PACS, post-COVID era, updating our 2020 utility hypothesis with insights from 2025. By examining how industries have adapted to disruptive digital innovations, radiology can apply these lessons to shape its role in multidisciplinary care.

METHODS AND MATERIALS

This Institutional Review Board-exempt study assessed VRR usage at a large academic center. Focus groups conducted one year after VRR inception gathered feedback from radiologists and consulting providers regarding VRR effectiveness, communication preferences, and future utilization. Predictive utilization was based on workflow characteristics and provider question types. Automated user data were analyzed using chi-squared tests, and regression analysis evaluated correlations between predictive utilization and actual engagement from 2020 to 2022. Utilization was reassessed in 2025.

RESULTS

VRR engagement remained steady despite easing social distancing (average daily users: 73 in 2020 vs. 65 in 2022, P=0.09). Divisions with standardized workflows, such as subspecialties (body, neuro), maintained the highest VRR usage. Divisions with disrupted workflows, like the ED, faced challenges due to inconsistent staffing. Communication preferences varied: focused questions were handled by phone, while multidisciplinary discussions favored VRR or in-person consultations. Predictive utilization from 2020 correlated with actual engagement in 2022 ($R^2=0.88$, P=0.002 for radiology workflow; $R^2=0.75$, P=0.004 for provider question type). By 2025, there were no active drop-in VRRs, though 235 users engaged with the technological platform for daily one-to-one consultations, education, and scheduling.

CONCLUSION

Virtual Reading Room platforms mark a transformative shift in radiology workflows, offering a sustainable model for interdisciplinary collaboration in the post-COVID era. This talk underscores the critical importance of technological innovation adaptability and strategic implementation in enhancing patient care, radiology's value proposition, and practice efficiency. It draws valuable insights from industries that have navigated similar "disruptive innovation" challenges, such as the experiences of companies like Rolex and Kodak.

CLINICAL RELEVANCE/APPLICATION

Virtual reading room platforms can enhance interdisciplinary collaboration, improve workflow efficiency and patient care.

M5B-SPNPM-3 USING THE A3 FRAMEWORK TO INCREASE MAMMOGRAPHY SCREENING PERCENTAGES IN PATIENT POPULATIONS LIVING IN AREAS WITH HIGH NEIGHBORHOOD DEPRIVATION

Lewis A. Jordan, MD,MPH (*Presenter*)
Tyler M. Prout, MD (*Abstract Co-Author*)
Dania Daye, MD,PhD (*Abstract Co-Author*)
Robin Lankton (*Abstract Co-Author*)
Mai A. Elezaby, MD (*Abstract Co-Author*)
Anand K. Narayan, MD, PhD (*Abstract Co-Author*)

PURPOSE

Quality improvement initiatives use data-driven, rigorous approaches to plan, execute, and study the delivery of healthcare. There have been limited studies using quality improvement methods to address health disparities. We describe the initial results of an initiative to increase mammography screening percentages in patient populations living in high levels of neighborhood deprivation using the A3 Framework.

METHODS AND MATERIALS

A3 Framework is a quality improvement tool to identify problems, synthesize data, and propose solutions to achieve goals. A3 framework for a multicenter academic medical center in the Upper Midwest is outlined by FOCUS-PDCA: F - Find process to improve, O - Organize stakeholders, C - Clarify current state, U - Understand sources of variation that contribute to the problem, S - Select change ideas, P - Plan and do the improvement, C - Check results, A - Act. Quantitative data was derived from the EMR to determine if women living in areas with high neighborhood deprivation have received a screening mammogram following intervention. PDCA cycle - improve mammography screening percentage by 5% in women living in the 5 highest deciles of neighborhood deprivation, as measured by the Area Deprivation Index.

RESULTS

A3 Framework starting in 2022 yielded the following initial results: F - Increase percentage of patients aged 50-74 years who have undergone mammography screening within the last two years. O - Multidisciplinary team of managers, directors, students, and physicians including surgeons, radiologists, and primary care doctors. C - Decreased screening mammography percentages in medically underserved patient populations, SMART Goal: We will increase mammography percentages by 5% by December 2023 for medically homed patients within the health system accountable care organization. U - Clinical staff time has been limited time for outreach, Patients don’t realize they're due for mammograms, Access issues including scheduling and transportation. S -Hire Outreach Coordinators for culturally responsive outreach. PDCA - Mammography screening percentages increased from 65% to 71% for women living in the highest 5 deciles of neighborhood deprivation by December 2023, while mammography screening percentages increased from 73% to 76% for women living in the lowest 5 deciles of neighborhood deprivation.

CONCLUSION

A3 Framework was associated with achieving target improvements in mammography screening percentages in patient populations living in areas with high neighborhood deprivation.

CLINICAL RELEVANCE/APPLICATION

Structured quality improvement methods can be used to drive quantitative improvements in imaging outcomes for medically underserved patient populations.

M5B-SPNR-2 LONGITUDINAL ANALYSIS OF TOTAL WHITE MATTER HYPERINTENSITIES IN PATIENTS UNDERGOING CARDIAC SURGERY: PRELIMINARY FINDINGS FROM THE PASCAL STUDY

Moreno Zanardo, PhD (*Presenter*)
Martina Anguissola (*Abstract Co-Author*)
Chiara Arduino (*Abstract Co-Author*)
Vlasta Bari (*Abstract Co-Author*)
Giacomo Bortolussi (*Abstract Co-Author*)
Beatrice Cairo (*Abstract Co-Author*)
Pavandeep Singh (*Abstract Co-Author*)
Paolo Vitali, MD,PhD (*Abstract Co-Author*)

PURPOSE

White matter hyperintensities (WMH) are common MRI findings in patients undergoing cardiac surgery and may reflect cerebrovascular vulnerability. For these preliminary results, the PASCAL study investigates short-term WMH evolution in relation to postoperative cerebrovascular events in patients undergoing surgery with cardiopulmonary bypass (CPB).

METHODS AND MATERIALS

The first thirty-seven consecutive adult patients undergoing elective cardiac surgery with CPB were included. The cohort consisted of 25 males (68%) and 12 females (32%) with a median age of 65 years (interquartile range, IQR: 56-70). Brain MRI was performed preoperatively and within a median of 7 days postoperatively (IQR: 6-8 days). WMH segmentation was performed automatically using Brain Health (Quantib® ND in Europe) manufactured for DeepHealth by Quantib B.V. software platform. Total and regional WMH volumes and lesion counts were extracted. Patients were classified as subcortical stroke if new or enlarging WMH lesions were detected on follow-up MRI.

RESULTS

Eight patients (22%) were classified in the subcortical stroke group and 29 (78%) in the no-subcortical stroke group. Median lesion count increased slightly from 19 to 20. The overall median WMH volume change was +0.10 mL. No statistically significant difference in total volume was observed pre- vs. post-surgery ($p=0.541$), nor between subcortical stroke and no-subcortical stroke groups ($p=0.251$). However, subcortical stroke patients showed significantly greater lesion burden in specific regions at follow-up. In particular, deep WMH volume was higher in the subcortical stroke group compared to the no-subcortical stroke group (0.855 mL vs. 0.150 mL, $p<0.001$), as well as deep WMH new lesion volume (0.110 mL vs 0.010 mL, $p<0.001$) and deep WMH enlarging lesion volume (0.570 mL vs. 0.050 mL, $p<0.001$). Moreover, differences were found also for the juxtacortical WMH volume (0.185 mL vs. 0.010 mL, $p<0.001$).

CONCLUSION

Although total WMH burden remained stable in the short term following cardiac surgery, patients with early postoperative lesion progression exhibited significantly increased deep and juxtacortical WMH volumes, both preoperatively and in terms of new and enlarging lesions. Regional WMH patterns may indicate cerebrovascular fragility and help identify patients at risk for postoperative brain injury.

CLINICAL RELEVANCE/APPLICATION

These findings support the potential utility of regional WMH analysis, particularly in deep white matter, as a marker of cerebrovascular vulnerability. Incorporating WMH metrics into preoperative assessment may improve risk stratification. Future integration of cerebral autoregulation indices is expected to further enhance predictive modeling.

M5B-SPNR-3 DIFFUSION TENSOR IMAGE ANALYSIS ALONG THE PERIVASCULAR SPACE (DTI-ALPS) DERIVED GLYMPHATIC INDEX CORRELATIONS IN PROFESSIONAL FIGHTERS

Dhanush J. Amin, MD,MBBS (*Presenter*)
Gaurav Nitin Rathi, MS (*Abstract Co-Author*)
Charles Bernick (*Abstract Co-Author*)
Virendra Mishra, PhD (*Abstract Co-Author*)

PURPOSE

Sports-related TBIs account for 1.2-30.3% of all TBI cases in the USA, with boxing and martial arts being major contributors. Repeated head impacts (RHI) have been indicated as a risk factor for neurodegenerative and neuropsychiatric disorders. The recently discovered glymphatic system, vital for clearing brain waste like amyloid-ß and tau proteins, are shown to be affected in participants experiencing cognitive decline. The glymphatic system is evaluated using Diffusion Tensor Imaging (DTI) through the Along the Perivascular Space (ALPS) method, by measuring the ALPS index. We hypothesized that RHI will affect the glymphatic system causing lower ALPS in cognitively impaired fighters as compared to non-impaired fighters and total ALPS will show a significant correlation with the total number of knockouts in the impaired fighters.

METHODS AND MATERIALS

This longitudinal study included 280 male professional fighters (boxers and MMA) and 20 age-matched healthy controls. Recorded variables included age, race, and intracranial volume. 95 fighters were identified as impaired fighters based on neuropsychological testing of processing and psychomotor speed. 3T Verio Siemens MRI scanner with a 32-channel head coil was used. 71 directions DTI was acquired with b = 0 and b = 1000s/mm 2 . Using FSL software, diffusion metric images were generated, including FA and directional diffusivity maps along the x-, y-, and z-axes. Using the diffusivity values along the direction of the perivascular space compared with those of projection fibers and association fibers on a slice at the level of the lateral ventricle body, we computed DTI-ALPS. PALM in FSL was used to compare DTI-

ALPS among the groups and understand the correlation between the DTI-ALPS index and the total number of knockouts. The results were considered at familywise error corrected p-value <0.05.

RESULTS

The non-impaired fighters had a significantly lower right and total glymphatic index as compared to the impaired fighters. The relationship between the glymphatic index and the knock-out history was significantly different between the two groups and that the impaired fighters had a non-significant negative correlation with the total number of knockouts.

CONCLUSION

Contrary to our hypothesis, though our results show that impaired fighters had a significantly higher glymphatic index, it deteriorated significantly with the total number of knockouts.

CLINICAL RELEVANCE/APPLICATION

Understanding RHI's impact on the glymphatic system is crucial for early detection and management of neurodegenerative risk in contact sport athletes. This study uses the DTI-derived ALPS index as a noninvasive biomarker to assess glymphatic dysfunction and guide early intervention.

M5B-SPNR-4 PROGNOSTIC VALUE OF CT CONTRAST STAINING AFTER ENDOVASCULAR THERAPY IN BASILAR ARTERY OCCLUSION STROKE

Matthias P. Fabritius, MD (*Presenter*)
Paul Reidler, MD (*Abstract Co-Author*)
Daniel Puhr-Westerheide, MD (*Abstract Co-Author*)
Jens Ricke, MD, PhD (*Abstract Co-Author*)
Wolfgang G. Kunz, MD, MBA (*Abstract Co-Author*)

PURPOSE

Contrast staining signifies prolonged tissue absorption of iodinated contrast media following endovascular therapy (EVT) for large vessel occlusion stroke, indicating blood-brain barrier disruption. With EVT becoming the standard for treating basilar artery occlusion (BAO) stroke, considering the substantial variability in outcomes, our study aimed to determine the prognostic significance of post-interventional contrast staining in BAO stroke cases.

METHODS AND MATERIALS

We included BAO patients who received postinterventional noncontrast CT within 24h after EVT. Expert radiologists confirmed the presence of contrast staining on CT and its volume was quantified. Functional outcomes were assessed on the modified Rankin (mRS) scale at 90 days and unfavorable outcome was defined as mRS =4. A multivariable LASSO-penalized logistic regression analysis was used to determine association of contrast staining and other clinical and imaging parameters with functional outcome.

RESULTS

Forty-two patients fulfilled the inclusion criteria (15 female, 35,7%). Contrast staining on postinterventional CT was present in 18 patients (42.9%) with a median [interquartile range / IQR] volume of 7.9 mL [3.7-14.6]. Patients with contrast staining had a worse outcome with higher mRS after 90 days (median [IQR]: 6 [4-6] vs. 2 [1-4], p<0.001). Multivariable LASSO analysis revealed significant association of contrast staining with clinical outcome.

CONCLUSION

Contrast staining on postinterventional CT after EVT for BAO is a strong predictor of unfavorable functional outcome, outperforming other pre- and post-interventional imaging parameters.

CLINICAL RELEVANCE/APPLICATION

Our finding could help identify patients who may benefit from closer and more intensive monitoring at an early stage, potentially improving overall outcomes. Moreover, early identification of a poor prognosis is highly relevant for transparent communication with patients' families and for aligning expectations regarding further treatment strategies and goals of care.

M5B-SPNR-7 CORRELATION ANALYSIS BETWEEN THE ENHANCEMENT INTENSITY OF T2 FLAIR IN BRAIN METASTASES AND VASCULAR PERMEABILITY PARAMETERS INDYNAMIC CONTRAST-ENHANCED MRI

YU ZHANG (*Presenter*)
Zong Fang Li (*Abstract Co-Author*)

PURPOSE

To investigate the correlation between the degree of contrast-enhanced T2-weighted fluid-attenuated inversion recovery (CE-T2 FLAIR) enhancement and dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) parameters in patients with brain metastases.

METHODS AND MATERIALS

This retrospective analysis included 43 patients (80 cerebral metastatic lesions) pathologically or follow-up confirmed at our institution between January 2018 and July 2024. All participants underwent standardized MRI protocols: T1-weighted imaging (T1WI), T2-weighted imaging (T2WI), T2-FLAIR, DCE-MRI, CE-T2 FLAIR, and contrast-enhanced T1WI (CE-T1WI). DCE-MRI parameters were systematically quantified, including volume transfer constant (Ktrans) and reflux rate constant (Kep). Concurrently, lesion enhancement characteristics on CE-T2 FLAIR were evaluated using two metrics: contrast ratio (CR) and percentage increase (PI). Lesions were classified into three groups based on the degree of enhancement on CE-T2 FLAIR compared to CE-T1WI: Group A (CE-T2 FLAIR hyperenhancement), Group B (both enhancements were similar), and Group C (CE-T2 FLAIR hypoenhancement).

RESULTS

A total of 80 metastatic lesions were categorized into Group A (n=17), Group B (n=45), and Group C (n=18). Group A demonstrated significantly higher CR and PI values and lower Ktrans and Kep values compared to Groups B and C (all P <0.05). Group B showed higher CR and PI but lower Ktrans and Kep than Group C (all P <0.05). The maximum lesion diameter (TD) was significantly smaller in Groups A and B compared to Group C (both P <0.05), with no significant difference between Groups A and B (P>0.05). Ktrans and Kep were negatively correlated with CR (r =-0.467 and-0.526, respectively; both P <0.001) and PI (r =-0.658 and -0.716, respectively; both P <0.001).

CONCLUSION

Vascular permeability plays a pivotal role in the differential enhancement observed betweenCE-T2 FLAIR and CE-T1WI. Our findings demonstrate that CE-T2 FLAIR exhibits superior sensitivity in detecting brain metastases with low vascular permeability, which may be underrepresented on CE-T1WI. Incorporating CE-T2 FLAIR into standard neuroimaging protocols can enhance diagnostic confidence, particularly in the assessment of subtle or early-stage metastatic lesions.

CLINICAL RELEVANCE/APPLICATION

Integrating CE-T2 FLAIR into standard MRI protocols can enhance the diagnostic detection of brain metastases, particularly those with low vascular permeability that may be missed on CE-T1WI. This approach may improve early lesion identification, guide treatment planning, and ultimately contribute to better clinical outcomes in patients with metastatic brain tumors.

M5B-SPNR-8 PROTON BEAM THERAPY-ASSOCIATED RADIATION CHANGES IN THE SUBEPENDYMAL PERIVENTRICULAR REGION - A MIMICKER OF RECURRENT TUMOR?

Rajeev Herekar, DO (*Presenter*)
Kirby Quinn, MD (*Abstract Co-Author*)
Russ A. Kuker, MD (*Abstract Co-Author*)
Natalya Nagornaya, MD (*Abstract Co-Author*)
Gaurav M. Saigal, MBBS (*Abstract Co-Author*)

PURPOSE

Proton beam radiation treatment (PBT) is a relatively recent form of therapy for brain cancers. PBT, like other forms of radiation therapies, can result in post radiation changes that are visible on imaging. PET/CT or MR Perfusion are the imaging tests of choice to help differentiate between post radiation changes and recurrent tumor. In this study, we demonstrate a relatively unknown effect of proton therapy predominantly seen in the periventricular regions of the brain, resulting in false positive MR Perfusion and/or PET/CT findings.

METHODS AND MATERIALS

Sixty-one patients with resected high grade oligodendroglioma or astrocytoma who received PBT and had follow-up MRI Perfusion and/or PET/CTs were evaluated.

RESULTS

Of the evaluated patients, thirty-one demonstrated nodular enhancement in and around the surgical bed on follow-up MR studies. Of these, 13 patients demonstrated positive correlates on MR Perfusion and/or PET/CT studies suggesting recurrence, and subsequently underwent biopsy. Of these, 8 cases were true positives for tumor whereas the other 5 were false positives (negative for tumor recurrence). Four additional patients who did not undergo biopsy of the suspected recurrence were deemed to be false positives due to decrease/resolution of enhancement on follow-up imaging. Of note, the enhancement seen in all of the 9 false positive cases was periventricular/subependymal in location. Of the 8 true positive cases, none showed enhancement in the periventricular region ($p<0.05$).

CONCLUSION

Non-tumor periventricular enhancement can be seen on follow-up imaging in patients who have undergone PBT following glioma resection, and can be falsely positive on MR perfusion and/or PET CT. The cause is not entirely clear but might be related to the higher sensitivity of the subependymal region to PBT resulting in an intense inflammatory reaction. Such a finding should be treated with caution and followed up with short interval imaging rather than surgery. Further studies are needed to investigate the mechanistic differences between PBT and other radiation therapies, regarding their propensity to affect the periventricular region.

CLINICAL RELEVANCE/APPLICATION

When seen, periventricular enhancement following PBT therapy in the post operative setting for glioma patients should be further evaluated with short interval follow up imaging as opposed to surgery.

M5B-SPNR-9 PREDICTING MOLECULAR TYPES OF ADULT-TYPE DIFFUSE GLIOMAS BASED ON MRI REPORTS WITH LARGE LANGUAGE MODELS

Yaewon Park, MD, PhD (*Presenter*)
Pae Sun Suh, MD (*Abstract Co-Author*)
Kyunghwa Han, PhD (*Abstract Co-Author*)
Kyu Sung Choi, MD, PhD (*Abstract Co-Author*)
Minjae Kim (*Abstract Co-Author*)
Ji Eun Park, MD, PhD (*Abstract Co-Author*)
Na-Young Shin, MD (*Abstract Co-Author*)
Sung Soo Ahn, MD (*Abstract Co-Author*)
Seung Hong Choi, MD, PhD (*Abstract Co-Author*)
Ho Sung Kim, MD, PhD (*Abstract Co-Author*)
Seung-Koo Lee, PhD (*Abstract Co-Author*)
Jong Hee Chang (*Abstract Co-Author*)
Se Hoon Kim, MD (*Abstract Co-Author*)
Martha Foltyn-Dumitru, MD, MSc (*Abstract Co-Author*)
Philipp Vollmuth, MD,MBA (*Abstract Co-Author*)
Byung-Hoon Kim (*Abstract Co-Author*)

PURPOSE

To evaluate the performance of large language models (LLMs) in predicting molecular types of adult-type diffuse gliomas according to the 2021 WHO classification using MRI radiology reports.

METHODS AND MATERIALS

This retrospective study included 2,201 patients diagnosed with adult-type diffuse gliomas (294 oligodendrogliomas, 300 IDH-mutant astrocytomas, and 1,608 IDH-wildtype glioblastomas) between July 2005 and March 2024 from four hospitals in Asia and Europe. Six different LLMs were assessed: GPT-4o-mini, GPT-4.1-mini, Llama 3.1 8b, Llama 3.1 70b, Qwen2.5 7b, and Deepseek-r1 8b. The performance of LLMs in classifying molecular types was compared based on the provision of relevant knowledge of glioma imaging findings (knowledge-based vs. naïve prompt). The impact of radiologists' subspecialization in neuro-oncology, report quality, length, and reporting language on LLMs' performance was also evaluated.

RESULTS

LLMs achieved significantly higher (naïve vs. knowledge-based; GPT-4o-mini, 76.6% vs. 78.3%, $P < 001$; Qwen2.5 7b, 75.9% vs. 79.5%, $P < .001$; deepseek-r1 8b, 66.0% vs. 73.2%, $P <.001$) or comparable accuracy (GPT-4.1-mini, 78.7% vs. 78.6%; Llama 3.1 70b, 78.0% vs. 78.1%) using knowledge-based prompt compared to naïve prompt, except for Llama 3.1 8b (65.4% vs. 44.6%, $P<.001$). Differences in accuracy were more pronounced in smaller size LLMs. Additionally, the accuracy was significantly higher with reports by neuro-oncology specialists and high-quality reports in all LLMs ($P<.001$).

CONCLUSION

LLMs may provide preoperative information on tumor types of adult-type diffuse gliomas from MRI reports by providing relevant knowledge in the prompt. Informative and descriptive reports could further enhance LLMs' performance.

CLINICAL RELEVANCE/APPLICATION

Our findings highlight the potential supportive role of large language models in predicting molecular types of gliomas, underscoring the importance of informative and descriptive reports in enhancing their performance.

M5B-SPNR-10 DISTINCT BRAIN ATROPHY PATTERNS IN LEWY BODY DISEASE: THE IMPACT AND INTERACTION OF COMORBID NEUROPATHOLOGIES REVEALED BY VOXEL-BASED MORPHOMETRY

Shohei Inui, MD, PhD (*Presenter*)
Keita Sakurai, MD, PhD (*Abstract Co-Author*)

Osamu Abe, MD, PhD (*Abstract Co-Author*)

PURPOSE

To investigate the impact of neuropathological comorbidities—including Alzheimer's disease neuropathological change (AD-NC), TAR DNA-binding protein 43 (TDP-43), argyrophilic grain disease (AGD), and small vessel disease (SVD)—on brain atrophy patterns in Lewy body disease (LBD) patients using voxel-based morphometry (VBM).

METHODS AND MATERIALS

From 2013-2023, 34 patients diagnosed with LBD at autopsy underwent comprehensive neuropathological assessments using hematoxylin-eosin, Klüver-Barrera, and Gallyas-Braak staining methods. Immunohistochemical analyses included phosphorylated tau, ß-amyloid, phospho-TDP-43, and phosphorylated a-synuclein. Antemortem MRI scans (3D-T1WI, T2WI, susceptibility-weighted imaging) were obtained using a 1.5 T MRI system (MAGNETOM Aera®, Siemens). Small vessel disease was graded using a simple scoring system based on Fazekas scale, lacunar infarcts, and microbleeds (score range: 0-3). Voxel-wise correlations of gray matter (GM) atrophy with each neuropathological comorbidity were analyzed, adjusting for age, sex, MRI-to-death interval, intracranial volume, and SVD severity.

RESULTS

Neuropathological examination revealed co-occurring pathologies: AD-NC (n=11), TDP-43 (n=13), AGD (n=8), and MRI-identified SVD (n=25). VBM analyses demonstrated distinct atrophy patterns: AD-NC correlated significantly with extensive GM volume reductions in bilateral anterior, temporal, parietal lobes, and posterior cingulate; TDP-43 pathology correlated with focal atrophy in the right amygdala and hippocampus; AGD correlated with atrophy predominantly in bilateral temporal lobes, notably anterior temporal poles; SVD scores correlated with GM atrophy in anterior lobes, cerebellum, and temporal regions, distinctly sparing temporal regions typically involved in neurodegeneration.

CONCLUSION

This study demonstrates distinct atrophy patterns in LBD patients associated with specific neuropathological comorbidities. AD-NC is linked to widespread GM atrophy, while AGD and TDP-43 show more localized temporal lobe involvement. SVD-related atrophy differs notably, sparing typical neurodegeneration-related regions. Recognizing these patterns can enhance diagnostic accuracy and understanding of disease progression in LBD.

CLINICAL RELEVANCE/APPLICATION

Identifying characteristic MRI patterns associated with neuropathological comorbidities in LBD aids in early recognition, differential diagnosis, and tailored management, emphasizing the importance of comprehensive imaging and neuropathological evaluation.

M5B-SPNR-11 ALTERED CEREBROSPINAL FLUID DYNAMICS AND NEURAL RECOVERY IN POST-STROKE APHASIA: INSIGHTS FROM GBOLD-CSF COUPLING

Chao Zhang, MD (*Presenter*)
Hu HU Sr, MD (*Abstract Co-Author*)
Kai Xu, MD, PhD (*Abstract Co-Author*)

PURPOSE

To investigate whether rehabilitation in patients with post-stroke aphasia (PSA) enhances global blood-oxygen-level-dependent (gBOLD)-cerebrospinal fluid (CSF) coupling, a potential biomarker of glymphatic clearance, and to examine its association with language recovery.

METHODS AND MATERIALS

Twenty patients with PSA and thirty-five healthy controls (HCs) underwent multimodal MRI, including resting-state functional MRI and standardized language assessment using the Chinese version of the Western Aphasia Battery (WAB). Fourteen PSA patients completed both baseline and one-month post-treatment scans following a standardized speech-language therapy program. gBOLD signals were extracted from gray matter regions defined by the Harvard-Oxford cortical and subcortical atlases, and CSF signals were derived from the bottom fMRI slice adjacent to the cerebellum. A priori power analysis was conducted in MATLAB using Cohen's d to confirm adequate sample size. Group comparisons and linear regression analyses were performed to assess associations between imaging metrics and language performance.

RESULTS

Power analysis confirmed that the sample size was sufficient to achieve 80% power at a = 0.05. The gBOLD and CSF signals exhibited a characteristic negative peak with a lag of approximately +4 seconds, consistent with prior studies. WAB scores significantly improved in PSA patients after therapy ($P < 0.05$). Baseline gBOLD-CSF coupling was significantly reduced in PSA patients compared to HCs ($P < 0.01$), and showed significant improvement following rehabilitation ($P < 0.05$). Notably, baseline coupling strength predicted improvement in word fluency ($ß = -0.016$, $P = 0.0018$, $R^2 = 0.570$).

CONCLUSION

Rehabilitation enhances gBOLD-CSF coupling in PSA patients, indicating improved glymphatic function. This coupling may serve as a functional biomarker reflecting neurovascular and metabolic recovery following stroke.

CLINICAL RELEVANCE/APPLICATION

GBOLD-CSF coupling reflects dynamic interactions between cerebrospinal fluid and brain activity. It may provide a noninvasive marker for monitoring post-stroke recovery and evaluating the effectiveness of rehabilitation in patients with post-stroke aphasia.

M5B-SPNR-13 RADIOMICS PREDICTION OF MGMT PROMOTER METHYLATION IN ADULT DIFFUSE GLIOMAS: A COMBINATION OF STRUCTURAL MRI, DCE AND DTI

Zhengyang Zhu, MD (*Presenter*)
Huiquan Yang, PhD (*Abstract Co-Author*)
Mengying Xu, MD (*Abstract Co-Author*)
Xin Zhang (*Abstract Co-Author*)
Bing Zhang, PhD (*Abstract Co-Author*)

PURPOSE

To assess the predictive value of radiomics features extracted from Structural MRI, dynamic contrast enhanced (DCE), and diffusion tensor imaging (DTI) in detecting O6-methylguanine-DNA methyltransferase (MGMT) promoter methylation in patients with diffuse gliomas.

METHODS AND MATERIALS

Retrospective MRI data of 110 patients were enrolled in this study. The training dataset included 88 patients (mean age 52.84±14.71, 47 females). The test dataset included 22 patients (mean age 50.64±12.58, 12 females). A total of 2782 radiomic features were extracted from Structural MRI, DCE and DTI within two region of interests (ROIs). Feature section was conducted using Pearson correlation and least absolute shrinkage and selection operator. Principal component analysis was utilized for dimensionality reduction. Support vector machine was employed for model construction. Two radiologists with 1 year and 5 years of experience evaluated the MGMT status in the test dataset as a comparison with the models. The chi-square test and independent samples t-test were used for assessing the statistical differences in patients' clinical characteristics.

RESULTS

On the training dataset, the model Structural MRI + DCE achieved the highest AUC of 0.906. On the test dataset, the model Structural MRI + DCE + DTI achieved the highest AUC of 0.868, outperforming two radiologists.

CONCLUSION

The radiomics models have obtained promising performance in predicting MGMT promoter methylation status. Adding DCE and DTI features can provide extra information to structural MRI in detecting MGMT promoter methylation.

CLINICAL RELEVANCE/APPLICATION

This research may help radiologists evaluate the sensitivity to TMZ and prognosis of glioma patients.

M5B-SPNR-14 FRACTAL ANALYSIS OF MRI-BASED INTRATUMOR AND PERITUMORAL EDEMA IN PREDICTING RECURRENCE/PROGRESSION IN HIGH-GRADE MENINGIOMAS

Xianwang Liu, MD (*Presenter*)

PURPOSE

To investigate the feasibility of fractal analysis of MRI-based intratumor and peritumoral edema in predicting recurrence/progression in high-grade meningiomas.

METHODS AND MATERIALS

We retrospectively analyzed 65 patients with pathologically confirmed high-grade meningiomas. According to the follow-up results, they were divided into a recurrence/progression group (n=20, P/R) and a non-recurrence/progression group (n=45, nP/R). Fractal features (fractal dimension and lacunarity) were extracted from the intratumor, peritumoral edema, and the whole tumor (intratumor+peritumoral edema), respectively. Fractal features were recorded and compared between the two groups. Diagnostic performance was identified by the receiver operating characteristic curves.

RESULTS

P/R exhibits higher fractal dimension and lacunarity of the intratumor, peritumoral edema, and the whole tumor, compared to nP/R (all $p<0.05$). The fractal dimension of the whole tumor showed the highest AUC of 0.820 among all the fractal parameters. The combined variable integrating fractal features from intratumor and peritumoral edema yielded optimal diagnostic performance with an AUC of 0.877.

CONCLUSION

Fractal analysis of MRI-based intratumor and peritumoral edema is a promising potential biomarker, which may be helpful in noninvasive predicting the recurrence/progression in high-grade meningiomas.

CLINICAL RELEVANCE/APPLICATION

Accurate prediction of recurrence/progression in high-grade meningiomas holds significant clinical value. Fractal analysis of MRI-derived intratumoral and peritumoral edema features provides quantitative characterization of these aggressive tumors. The combined fractal signature integrating both regions demonstrated optimal diagnostic performance.

M5B-SPNR-15 MRI-BASED RADIOMICS COMBINED WITH ELASTIC MODULUS FOR PREOPERATIVE PREDICTION OF MENINGIOMA CONSISTENCY: A PILOT STUDY

Chaoyang Wang (*Presenter*)
Jianguo Xu (*Abstract Co-Author*)

PURPOSE

Meningioma is the most common primary intracranial tumor, often treated surgically. Recent studies have shown that tumor consistency affects resection extent, surgical planning, and morbidity risk. Several studies have attempted preoperative prediction using imaging, but definitions of consistency were inconsistent and often based on subjective or semi-quantitative criteria. This lack of an objective standard limits generalizability. We propose using elastic modulus (EM), a physical parameter reflecting tissue stiffness, as an objective reference. EM has been applied in assessing normal tissues and tumors. This study aims to develop a radiomics model to preoperatively predict meningioma consistency using EM.

METHODS AND MATERIALS

This retrospective study included 98 patients with pathologically confirmed meningioma. The excised tumors were tested using a tensile tester to calculate the elastic modulus (EM); tumors were then classified into low EM (<10 kPa) and high EM (=10 kPa) groups. Patients were randomly divided into training (n=68) and testing (n=30) cohorts.Contrast-enhanced T1-weighted MRI scans were reviewed by a neurosurgeon and a radiologist. Regions of interest (ROIs) were manually segmented on each slice using 3D Slicer. To reduce inter-scanner variability, N4ITK bias correction and histogram matching were applied. Radiomics features were extracted using PyRadiomics. Features with an intraclass correlation coefficient (ICC) <0.75 were excluded. The remaining features were z-score standardized.Predicting models were developed using logistic regression, random forest, and support vector machine. Model performance was assessed using AUC, sensitivity, specificity, PPV, NPV, and accuracy. Decision curve analysis was conducted to evaluate clinical utility.

RESULTS

In total, 851 radiomics features were extracted from each lesion, and three features were considered important. The SVM demonstrated the best performance, with an AUC of 0.850 (95% CI: 0.753-0.947) and accuracy of 0.765 in the training cohort, and AUC of 0.804 (95% CI: 0.628-0.980) and accuracy of 0.800 in the testing cohort. The DCA also showed SVM model has potential clinical utility.

CONCLUSION

MRI-based radiomics models may provide good performance for preoperatively predicting the consistency of meningioma based on elastic modulus.

CLINICAL RELEVANCE/APPLICATION

This study provides an objective, imaging-based method to predict meningioma stiffness, potentially improving the precision and safety of tumor resection.

M5B-SPNR-16 MRI-BASED DEEP LEARNING FOR PATHOLOGY PREDICTION IN ADULT-TYPE DIFFUSE GLIOMA

Yangyang Li (*Presenter*)
Xiaoming Hong (*Abstract Co-Author*)
Zhizheng Zhuo (*Abstract Co-Author*)
Renlong Zhang (*Abstract Co-Author*)
Yaou Liu, MD,PhD (*Abstract Co-Author*)

PURPOSE

Pathology evaluation of adult diffuse gliomas (ADGs) is crucial for tumor classification and treatment planning, which typically requires tissue obtained through invasive biopsy. A comprehensive consensus is still lacking on whether MRI-based deep learning can predict the pathology of ADGs and how well it performs. In this study, we

aimed to develop an MRI-based molecular neuropathology system (MRI-MNP) to predict two histological features— WHO grading and Ki-67 proliferation — as well as nine molecular pathological biomarkers, including IDH, 1p/19q, ATRX, CDKN2A/B, TERT, +7/-10, EGFR, TP53 and MGMT.

METHODS AND MATERIALS

We collected T1-weighted (T1w), T2-weighted (T2w), fluid attenuated inversion recovery (FLAIR), and T1 contrast enhanced (T1ce) images, with clinical data from 11,513 ADG patients across 20 datasets of 29 medical centers. These MR images (2D, 2.5D or 3D), with tumor masks, positional vectors, radiomics features, and demographics data were fed into deep learning models to predict histopathological and molecular features. We usd different network architectures, with different input compositions, and pretrained weights. Finally, we presented the MRI-MNP outputs in a structured report format as a clinical reference, and evaluated the performance in facilitating clinical neuroradiologists diagnosis.

RESULTS

Based on area under the curve (AUC), we revealed that WHO grade IV (AUC 0.852), Ki-67 proliferation (AUC 0.823), IDH mutation (AUC 0.825), 1p/19q codeletion (AUC 0.819), and +7/-10 alteration (AUC 0.805) can be effectively predicted. WHO Grading II/III/IV (AUC 0.754), CDKN2A/B homozygous deletion (AUC 0.773), and TERT promoter mutation (AUC 0.715), EGFR amplification (AUC 0.713) can be moderately predicted. In contrast, ATRX mutation, MGMT promoter methylation, and TP53 mutation can be poorly predicted (AUC<0.6). We developed a structured report to support clinical translation. With the assistance of MRI-MNP, neuroradiologists' diagnostic performance in tumor classification and pathological features improves. The ViT model utilizing 2.5D input with pretrained weights achieved the highest AUC among all architectures evaluated.

CONCLUSION

This is the first international multicenter study to develop a multimodal MRI-based system for comprehensive prediction of histopathological and molecular features in ADGs.

CLINICAL RELEVANCE/APPLICATION

MRI-MNP offers a viable alternative to traditional tissue biopsy, reducing patient risk, lowering healthcare costs, and conserving medical resources. It outputs structured reports that can be integrated into clinical practice, and significantly enhance the diagnostic performance of neuroradiologists.

M5B-SPNR-17 DIFFERENTIATING TUMOR RECURRENCE AND PSEUDOPROGRESSION IN POSTOPERATIVE GLIOMAS USING PSEUDO-CONTINUOUS ARTERIAL SPIN LABELING (PCASL) TECHNIQUE

Peiquan Liu (*Presenter*)
Yujie Chen (*Abstract Co-Author*)
Ning Zheng (*Abstract Co-Author*)
Jiaxuan Zhang (*Abstract Co-Author*)
Zhu Wenzhen, MD, PHD (*Abstract Co-Author*)

PURPOSE

To assess whether the pCASL technique and its radiomics features can enhance the differentiation between Tumor Recurrence(TR) and Pseudoprogression(PsP) in postoperative glioma patients.

METHODS AND MATERIALS

This retrospective study collected MRI data (T1WI, T2WI, T2flair, T1WI+C, pCASL) and clinical information from 123 glioma patients (WHO CNS5 grades 2-4) treated at Tongji Hospital, Wuhan. 97 patients were selected based on new/enlarged enhancing lesions post-radiotherapy/chemotherapy and good image quality. Among them, 56 had recurrence, and 41 had PsP confirmed by surgery or follow-up. PsP was defined as stable or regressing enhancing lesions over 6 months, while TR was defined as lesion progression with clinical worsening or confirmed recurrence. pCASL images were processed for CBF mapping, followed by normalization. The largest lesions were outlined, and ROI mean values calculated. Statistical analysis included Mann-Whitney U test and ROC curve analysis. Radiomics features were extracted from CBF maps, with ICC < 0.75 features excluded. Lasso was used for further feature selection. Machine learning models (SVM, logistic regression, random forest, Gaussian Naive Bayes) were developed and validated.

RESULTS

No statistically significant differences were found between the TR and PsP groups in terms of age, gender, and WHO classification in both the internal comparison within the training and independent testing sets, as well as in the separate comparisons between the two groups. The Mann-Whitney U test showed a significant difference in mean CBF values between TR and PsP groups (P < 0.001). ROC analysis revealed an AUC of 0.859 (95% CI: 0.778-0.927), sensitivity of 0.839, specificity of 0.829, PPV of 0.870, and NPV of 0.791(Figure 4_A-B). Following selection, 7 features were retained. Among the four machine learning models tested, the logistic regression yielded the best performance with an AUC of 0.946, sensitivity of 0.812, specificity of 0.857, PPV of 0.867, and NPV of 0.800 (Figure 4_C-D).

CONCLUSION

pCASL and its radiomics model accurately differentiate TR and PsP in postoperative glioma patients, with CBF as a key distinguishing parameter for prognosis.

CLINICAL RELEVANCE/APPLICATION

Postoperative differentiation of high-grade glioma recurrence and pseudoprogression is of significant clinical importance for patient management. Measuring rCBF using PCASL technique can provide valuable insights in this regard.

M5B-SPNR-18 PREDICTION OF DIFFERENT ETIOLOGICAL SUBTYPES OF ACUTE ISCHEMIC STROKE USING A COMBINED MRI BASED RADIOMICS AND CLINICAL MODEL

Ainikaerjiang Aihemaiti (*Presenter*)
Tuxunjiang Pahati (*Abstract Co-Author*)
Yunling Wang (*Abstract Co-Author*)

PURPOSE

To investigate the application value of a combined model integrating MRI-based radiomics and multiparameter features in the subtype classification.of acute ischemic stroke(AIS)between small artery occusion(SAO)and cradioembolism(CE)

METHODS AND MATERIALS

A retrospective study was conducted on 731 AIS patients admitted to the neurology department of a hospital from April 2023 to April 2024, with MRI diffusion-weighted imaging (DWI) performed. After applying inclusion and exclusion criteria, 384 patients were enrolled and randomly divided into a training set (n=268) and a test set (n=116) at a 7:3 ratio. Differences in clinical and imaging features between the two groups were analyzed. MRI-DWI images were segmented using ITK-SNAP software to delineate hyperintense infarct regions. Radiomics feature extraction and dimensionality reduction were performed to identify optimal features associated with AIS subtypes. Z-score normalization was applied for standardization. Three models were constructed: a clinical model, a radiomics model, and a combined clinical-radiomics model. Receiver operating characteristic (ROC) curves and area under the curve (AUC) were used to evaluate model performance in distinguishing SAO and CE subtypes

RESULTS

The radiomics model achieved an AUC of 0.9268 in the training set and 0.8786 in the test set. The clinical model yielded AUCs of 0.9186 (training) and 0.8483 (test). The combined clinical-radiomics model demonstrated superior performance, with AUCs of 0.9919 (training) and 0.909 (test). Statistically significant differences in AUC were observed among the models (P<0.05).

CONCLUSION

The combined model integrating DWI-based radiomics and clinical features effectively predicts SAO and CE subtypes of AIS, providing accurate and quantifiable objective evidence to support clinical decision-making

CLINICAL RELEVANCE/APPLICATION

The integration of clinical and radiomics models provide an automated solution for clinicians to implement etiologic staging diagnosis, and provide a reference value for patient prognosis and good medical decision-making, which can help clinicians choose appropriate diagnostic and management methods.

M5B-SPNR-19 INVESTIGATING GLYMPHATIC FUNCTION IN HIV USING RESTING-STATE FMRI: ASSOCIATIONS WITH COGNITION AND IMMUNOLOGICAL STATUS

Ke Xue (*Presenter*)
Fei Shan (*Abstract Co-Author*)
Yuxin Shi, PhD (*Abstract Co-Author*)
Zhiyong Zhang (*Abstract Co-Author*)
Yi Zhan, MD (*Abstract Co-Author*)

PURPOSE

To investigate glymphatic dysfunction in people living with HIV (PLWH) and its associations with immunological status and cognitive function, utilizing the coupling strength of global blood-oxygen-level-dependent (gBOLD) and cerebrospinal fluid (CSF) inflow signals as a non-invasive marker

METHODS AND MATERIALS

Seventy-five PLWH and 52 healthy controls (HCs) underwent a battery of neuropsychological tests, MoCA test and resting-state functional magnetic resonance imaging (rs-fMRI) to assess cognitive function and gBOLD-CSF coupling. Data of CD4 counts were collected. Demographic information and neuropsychological performance between PLWH and HCs were compared. A general linear model assessed group differences in gBOLD-CSF coupling strength, adjusting for age, sex, and education. Partial correlation analyses were performed to examine the associations of neurological tests and clinical data with gBOLD-CSF coupling, controlling for age, sex, and education. Multivariate regression analysis was utilized to further evaluate the associations of gBOLD-CSF coupling with cognition.

RESULTS

PLWH exhibited significantly weaker gBOLD-CSF coupling than HCs ($p = 0.018$) and revealed impairments in attention/working memory, speed of information processing, and abstract/executive function (all $p<0.05$). Importantly, the reduced strength of gBOLD-CSF coupling was associated with deficits in MoCA scores ($r=-0.332$, $p=0.004$), verbal fluency ($r=0.245$, $p=0.038$), attention/working memory ($r=0.240$, $p=0.042$), speed of information processing ($r=0.245$, $p=0.038$), and abstract/executive function ($r=0.241$, $p=0.042$) in PLWH, while no significant associations were observed in HCs (all $p>0.05$). Multivariate regression analysis showed gBOLD-CSF coupling was the sole independent predictor for speed of information processing (ß=0.410, $p=0.031$) and MoCA scores (ß=-0.399, $p=0.037$). Weaker gBOLD-CSF coupling was correlated with lower nadir and current CD4 counts ($r=-0.379$, $p=0.019$; $r=-0.321$, $p=0.049$, respectively).

CONCLUSION

Reduced gBOLD-CSF coupling in PLWH suggests glymphatic dysfunction and was correlated with cognitive performance and HIV-related immunological status, underscoring its potential as a biomarker for cognitive disturbances in HIV.

CLINICAL RELEVANCE/APPLICATION

gBOLD-CSF coupling could serve as a useful tool for monitoring glymphatic dysfunction in PLWH, offering potential as a biomarker for cognitive impairment and immune suppression.

M5B-SPOB-1 DEVELOPING INTERPRETABLE MACHINE LEARNING MODEL FOR DIFFERENTIATING UTERINE SARCOMA AND ATYPICAL LEIOMYOMA USING MRI AND RADIOMICS FEATURES

Zhong Yang (*Presenter*)
Chao Wei (*Abstract Co-Author*)

PURPOSE

This study aims to develop interpretable machine learning (ML) models based on magnetic resonance imaging (MRI) and radiomics features for differentiating uterine sarcoma (US) and atypical leiomyoma (ALM) preoperatively.

METHODS AND MATERIALS

This retrospective study enrolled 47 patients with US and 113 patients with ALM, who were randomly allocated into training (n=112) and test (n=48) cohorts. Two independent radiologists assessed 10 MRI features derived from pelvic MRI examinations. Radiomic features were extracted from axial T2-weighted imaging (T2WI) and axial diffusion-weighted imaging (DWI) sequences. Univariable and multivariable logistic regression analyses were performed to identify statistically significant MRI features. The least absolute shrinkage and selection operator (LASSO) regression was implemented to select optimal radiomic features, and the radiomic score (radscore) was calculated via linear combination of selected features. Five ML models were constructed by integrating significant MRI features and radscore. Receiver operating characteristic (ROC) curves were generated to evaluate model performance, with predictive efficacy quantified by the area under the curve (AUC). Decision-curve and calibration-curve analyses assessed clinical utility, while the SHapley Additive exPlanation (SHAP) was applied to interpret the optimal model, enhancing transparency in feature contribution.

RESULTS

The selected MRI features comprised signal intensity on T2WI, border, uterine endometrial cavity, and apparent diffusion coefficient (ADC) value. Four radiomic features were ultimately selected to compute the radscore. These features and radscore were utilized to construct five ML models: Logistic regression (LR), Random forest (RF), Extreme gradient boosting (XGBoost), Support vector machine (SVM), and Gaussian Naive Bayes (GNB). The XGBoost model demonstrated superior performance in both the training cohort (AUC: 0.991; 95% CI: 0.978-1.000) and test cohort (AUC: 0.909; 95% CI: 0.822-0.995). Decision-curve and calibration-curve analyses further validated the model's clinical applicability. The SHAP analysis elucidated the XGBoost model's prediction process at both local and global scales, identifying the ADC value as the most discriminative feature for distinguishing US from ALM.

CONCLUSION

Interpretable ML models integrating MRI and radiomic features demonstrated robust predictive efficacy in distinguishing US from ALM.

CLINICAL RELEVANCE/APPLICATION

These models assist clinicians in devising precise, personalized therapeutic strategies while offering transparent insights into individual feature contributions via SHAP, thereby enhancing clinical decision-making transparency.

M5B-SPOB-3 IDENTIFYING INTIMATE PARTNER VIOLENCE THROUGH OBSTETRIC AND GYNAECOLOGIC IMAGING: A RETROSPECTIVE CASE-CONTROL STUDY

Saurabh Pallod, MD,DMRD (*Presenter*)
Bharti Khurana, MD, MBA (*Abstract Co-Author*)

PURPOSE

To investigate whether distinct patterns of obstetric and gynecologic (OB/GYN) findings on imaging are associated with a history of intimate partner violence (IPV), and to explore how these patterns can inform early identification, clinical decision-making, and referral pathways.

METHODS AND MATERIALS

This retrospective case-control study included 341 patients (cases) reporting IPV and 921 control patients who never reported IPV, with 9,091 OB/GYN imaging reports analyzed over 29,828 person-years. Demographics, imaging frequency, and complication rates were compared using linear regression and overall chi-square test adjusted for age and race. OB/GYN imaging utilization and findings were compared.

RESULTS

Cases underwent significantly more OB/GYN imaging (median 7 vs. 3 studies; $p<0.0001$), with markedly higher ultrasound utilization (445.3 vs. 247.8 studies per 1,000 person-years; IRR 1.72, 95% CI 1.64-1.80, $p<0.0001$). Cases also showed significantly higher obstetric complications, including subchorionic hematoma (IRR 3.57, 95% CI 2.32-5.52, $p <0.0001$), oligohydramnios (IRR 3.33, 95% CI 1.98-5.61, $p <0.0001$), intrauterine growth restriction (IUGR) (IRR 2.66, 95% CI 1.61-4.38, $p =0.0001$), retained products of conception (IRR 2.11, 95% CI 1.13-3.95, $p =0.02$), and failed pregnancies (IRR 1.54, 95% CI 1.03-2.31, $p =0.035$). Among gynecologic conditions, ectopic pregnancy was more frequent in the cases (IRR 1.80, 95% CI 0.76-4.24, $p =0.18$), while tubo-ovarian abscess (TOA) showed a higher but borderline-significant increase (IRR 3.13, 95% CI 0.81-12.08, $p =0.1$), though nothing came close to significant. No significant differences were observed in major gynecologic trauma such as pelvic fractures or vaginal injuries.

CONCLUSION

Women with a history of IPV demonstrate a significantly increased incidence of obstetric complications on imaging, especially subchorionic hematoma, oligohydramnios, IUGR, and retained products of conception. In the absence of other clear etiologies, these imaging patterns may serve as early radiologic indicators of IPV.

CLINICAL RELEVANCE/APPLICATION

Radiologists should recognize that certain Obstetric imaging findings occur more frequently in patients with a history of IPV. Integrating this awareness into radiological interpretation may support early IPV detection and facilitate timely intervention.

M5B-SPOB-4 BETTER ALGORITHM IN THE DIFFERENTIAL DIAGNOSIS OF ATYPICAL UTERINE LEIOMYOMA VS LEIOMYOSARCOMA: AN ADDED VALUE FOR RADIOLOGISTS WITH DIFFERENT EXPERIENCE?

Sara Vigano, MD (*Presenter*)
Gregorio Chierchia, MD (*Abstract Co-Author*)
Constanze Husen, MD (*Abstract Co-Author*)
Pietro A. Bonaffini, MD (*Abstract Co-Author*)
Paolo Marra, MD (*Abstract Co-Author*)
Sandro Sironi, MD (*Abstract Co-Author*)

PURPOSE

To evaluate whether the BETTER algorithm proposed by J. Smith et al. can help relatively inexperienced radiologists in the differential diagnosis between atypical uterine leiomyomas and uterine leiomyosarcomas at preoperative MRI investigation.

METHODS AND MATERIALS

Patients who underwent preoperative 1.5T or 3T pelvic MRI due to ultrasound suspicion of atypical uterine leiomyoma vs leiomyosarcoma were retrospectively included. MRI images were independently evaluated by three observers: (1) a radiologist specialized in gynecologic imaging with three years of experience; (2) a radiology resident with two years of experience in pelvic MRI; and (3) a radiology resident at the initial stage of training in pelvic MRI. Each observer independently assessed the images following the checklist of the BETTER algorithm: B (irregular Border), E (heterogeneous Enhancement), T1 (presence of hemorrhage on T1-WI), T2 (areas of hypointensity on T2-WI), E (Endometrial involvement), and R (Restricted diffusion on DWI/ADC). The presence of two or more criteria was considered indicative of suspicion for uterine sarcoma. Interobserver agreement regarding the diagnostic suspicion of sarcoma vs. atypical leiomyoma, and the evaluation of each BETTER parameter was assessed using Cohen's Kappa.

RESULTS

Eleven patients (mean age: 50 years) were included. Histopathological analysis following hysterectomy, considered the gold standard, revealed uterine leiomyosarcoma in 2/11 patients, smooth muscle tumor of uncertain malignant potential (STUMP) in 1/11 patient, and benign leiomyoma in 8/11 patients. Interobserver agreement in suspecting atypical leiomyoma vs leiomyosarcoma was moderate between Observer 1 and Observer 2, and fair between Observer 1 and Observer 3. The imaging parameters most frequently misinterpreted as suspicious by Observer 3, in comparison to Observers 1 and 2, were: T2, due to signal inhomogeneity on T2-weighted images; and R, related to the evaluation of restricted diffusion on DWI and corresponding hypointense areas on ADC maps.

CONCLUSION

Application of the BETTER algorithm in the evaluation of MRI images may allow identification of suspicious criteria for leiomyosarcoma vs atypical leiomyoma particularly for less experienced radiologists. However, specific parameters remain challenging to interpret for less experienced readers, underscoring the need for targeted training in these areas.

CLINICAL RELEVANCE/APPLICATION

The BETTER algorithm provides a structured approach for differentiating atypical uterine leiomyomas from leiomyosarcomas on preoperative MRI, though certain parameters remain challenging to interpret reliably, particularly to radiologists with limited experience in pelvic imaging.

M5B-SPPD-4 INCREASED RISK OF NEURODEVELOPMENTAL IMPAIRMENT ASSOCIATED WITH REDUCED BRAIN VOLUME AT TERM-EQUIVALENT AGE IN PRETERM INFANTS WITH GERMINAL MATRIX HEMORRHAGE

Chanyoung Rhee, MD (*Presenter*)
Jae-Yeon Hwang, MD (*Abstract Co-Author*)
Young Hun Choi, MD, PhD (*Abstract Co-Author*)
Sun Won Park, MD, PhD (*Abstract Co-Author*)

PURPOSE

Germinal matrix hemorrhage (GMH) is common in preterm infants and affects neurodevelopment, especially in high-grade intraventricular hemorrhage (IVH). However, the effects of low-grade GM-IVH on brain volume and neurodevelopment remain unclear. This study aimed to investigate the effect of low-grade GM-IVH on supratentorial and white matter volumes at term-equivalent age and their association with neurodevelopmental impairment (NDI) in preterm infants.

METHODS AND MATERIALS

This retrospective study included preterm infants (gestational age < 37 weeks) who underwent three-dimensional T1-weighted brain magnetic resonance imaging at 34-50 weeks' postmenstrual age from December 2020 to August 2024. The preterm infants were categorized into the control, GMH (Papile grades 1-2), punctate white matter lesion (PWML), or other severe condition (Papile grades 3-4 or other major anomalies) groups. A U-Net-based algorithm was used to automatically segment supratentorial and white matter volumes. NDI was defined as a motor score = 85 or cognitive and language scores both = 85 on the Bayley-III. Standardized residuals were calculated to assess volume deviation from the reference (control group) and compared according to low-grade GM-IVH and NDI status. Two-way ANOVA with Tukey's post hoc test was used to compare standardized residuals across the subgroups.

RESULTS

We included 203 infants (102 girls; gestational age: 28.46 ± 2.90 weeks, postmenstrual age: 38.22 ± 2.84 weeks), with 120 in the control, 42 in the GMH, and 11 in the PWML group. The other infants had severe conditions. Supratentorial volume growth was lower in the GMH ($P = 0.02$) and PWML ($P = 0.07$) groups than in the control group. Standardized residuals of supratentorial and white matter volumes showed that low-grade GM-IVH with volume reduction was associated with a higher risk of NDI. In the GMH group, significant differences were observed between the NDI and non-NDI subgroups for supratentorial volume (NDI, -1.12 ± 0.58; non-NDI, 0.35 ± 0.69; $P < 0.001$) and white matter volume (NDI, -0.95 ± 0.68; non-NDI, 0.29 ± 0.92; $P < 0.001$). In contrast, no significant differences were found in the control group for supratentorial volume (NDI, 0.14 ± 1.21; non-NDI, 0.11 ± 0.95; $P = 0.95$) or white matter volume (NDI, 0.49 ± 1.31, non-NDI, 0.17 ± 0.94; $P = 0.57$).

CONCLUSION

Low-grade GM-IVH with reduced supratentorial or white matter volume is associated with an increased risk of NDI in preterm infants.

CLINICAL RELEVANCE/APPLICATION

Deep learning-based volumetric analysis can identify preterm infants with low-grade GM-IVH at risk of NDI, enabling closer monitoring and early intervention.

M5B-SPPH-3 AI-DRIVEN AUTOMATED QUANTIFICATION OF BONE LESION BURDEN IN SYSTEMIC CANCER: A MULTI-PARAMETRIC WB-MRI TOOL FOR FAST AND REPRODUCIBLE TDV AND ADC MEASUREMENTS USING DIXON AND DWI SEQUENCES

Antonio Candito, PhD, MSc (*Presenter*)
Matthew Blackledge, MSc, PhD (*Abstract Co-Author*)
Richard P. Holbrey, PhD (*Abstract Co-Author*)
Alina D. Dragan, MRCS,FRCR (*Abstract Co-Author*)
Christina Messiou, MD, BMBS (*Abstract Co-Author*)
Nina Tunariu, MD (*Abstract Co-Author*)
Dow-Mu Koh, FRCR (*Abstract Co-Author*)

PURPOSE

WB-MRI demonstrates high sensitivity in detecting malignant bone lesions, which show low relative fat fraction (rFF) on T1w Dixon and high signal on high b-value (b=900 s/mm 2 , b900) DWI. DWI can also be used to quantify two response biomarkers: (i) Apparent Diffusion Coefficient (ADC), which inversely correlates with tumour cellularity, and (ii) Total Diffusion Volume (TDV, in millilitres). We developed an AI-driven algorithm to delineate suspected bone lesions and quantify ADC and TDV from WB-MRI scans within 90 sec using T1w Dixon and DWI images as inputs.

METHODS AND MATERIALS

A previously developed weakly supervised Residual U-Net (ResU-Net) model generates a skeleton probability map and spinal cord mask from calculated b0 and ADC images to (i) isolate bone from image background and (ii) compute a signal-normalised b900 image to reduce inter-patient signal variability. Skeleton map, signal-normalised b900, and calculated ADC and rFF maps are input to a multi-channel ResU-Net with multi-head dilated encoders. This architecture helps mitigate false positives from T2 shine-through and Dixon-DWI lesions misalignment due to EPI-induced geometric distortion. The resulting lesion mask is applied to the ADC map to extract ADC statistics and TDV. The model was developed using an IRB-approved retrospective dataset of patients with Advanced Prostate Cancer (APC, 110/13 training/testing) and Multiple Myeloma (MM, 90/12 training/testing). Ground-truth manual lesion delineations were performed by experienced radiologists.

RESULTS

The multi-channel model showed good agreement with expert manual delineations of malignant bone lesions across test cases. Dice score, precision, and recall averaged 0.65/0.66/0.71, respectively, with a mean surface distance below 5mm. Relative differences in median ADC and log-transformed TDV were below 3% and 6%, respectively. Delineation accuracy improved in patients with extensive disease burden. Compared to a DWI-only model, our approach improved dice score by 25% and reduced TDV error by 33% relative to expert annotations.

CONCLUSION

This pilot study demonstrates the performance of a new AI-driven algorithm combining Dixon and DWI sequences to automatically delineate suspected bone lesions and quantify ADC and TDV, showing good concordance with radiologists. This solution could support a shift toward a quantitative paradigm for staging and treatment response assessment, potentially improving clinical decision-making for APC and MM patients.

CLINICAL RELEVANCE/APPLICATION

Our AI-driven algorithm automatically processes WB-MRI to provide fast, reproducible ADC and TDV measurements from delineated bone lesion masks, potentially supporting clinical decision-making in patients with systemic cancer.

M5B-SPPH-4 MOBILE HEADCT NOISE REDUCTION USING IMPLICIT IMAGE-TO-IMAGE SCHRöDINGER BRIDGE

Ling Chen (*Presenter*)
Rehab N. Khalid, MBBS (*Abstract Co-Author*)
Sukanya Iyer (*Abstract Co-Author*)
Jun Young Park (*Abstract Co-Author*)
Yuechen Qian, PhD (*Abstract Co-Author*)
Yuang Wang (*Abstract Co-Author*)
Zhennong Chen, PhD (*Abstract Co-Author*)
Rajiv Gupta, PhD, MD (*Abstract Co-Author*)
Dufan Wu, PhD (*Abstract Co-Author*)

PURPOSE

Mobile head computed tomography (CT) needs to tackle high noise levels due to hardware constraints including limited radiation and motions. To address this, we proposed a generative AI model for noise reduction based on Implicit Image-to-Image Schrodinger Bridge (I3SB).

METHODS AND MATERIALS

I3SB is the state-of-the-art diffusion model for image restoration, which builds an accelerated Schrodinger Bridge between the noisy and clean images. Physics-based simulated noise was added 92 brain CT volumes acquired with fixed CT scanners and a 2D I3SB model was trained to map noisy images to clean ones. In evaluation, the trained model was first evaluated on 20 brain CT volumes with simulated noise and then applied to 19 brain CTs acquired with a mobile CT scanner. One radiologist and two image specialists independently assessed each volume before and after noise reduction and scored the image quality regarding six different brain structures on a scale from -2 to +2.

RESULTS

I3SB took 8 seconds per slice for inference on an A100 and demonstrated significant noise reduction. In the evaluation of 20 CT scans with simulated noise, the model improved RMSE from 8.34±1.38 HU to 3.59±1.11 HU and SSIM from 0.88±0.04 to 0.92±0.02. In the evaluation of mobile CT scans, the denoised images achieved equal or better scores than the original CT images across all 19 cases and all six evaluation criteria, based on the average scores of three readers. For Reader 1, the average scores for the six criteria—cerebrum, cerebellum, gray/white matter separation, ventricles, CSF, and overall quality—were +1.47, +1.05, +1.26, +1.21, +1.26, and +1.26, respectively. Reader 2 reported average scores of +1.42, +1.21, +1.05, +1.05, +1.32, and +1.21. Reader 3 reported average scores of +0.89, +0.89, +1.00, +0.89, +1.00, and +0.79. Importantly, gray/white matter differentiation, a common limitation in mobile CT due to reduced dose, was consistently improved across all readers.

CONCLUSION

The I³SB framework demonstrates substantial noise suppression and consistent reader score improvement for mobile brain CT imaging.

CLINICAL RELEVANCE/APPLICATION

High levels of image noise remain a major challenge in portable brain CT imaging due to low-dose acquisition and hardware limitations. Our proposed approach significantly reduces noise, thereby improving image clarity and enhancing the diagnostic utility of portable brain CT.

M5B-SPPH-5 PATIENT-SPECIFIC POST TRIGGER TIMING PROTOCOL FOR IMPROVED CONTRAST ENHANCEMENT IN CT PULMONARY ANGIOGRAPHY

Kyrillos Grace (*Presenter*)
Alireza Shojazadeh, MD (*Abstract Co-Author*)
Neda Ziaei (*Abstract Co-Author*)
Lynn Duong (*Abstract Co-Author*)
Justin Truong (*Abstract Co-Author*)
Dale Black, BS (*Abstract Co-Author*)
Katherine Hyde, BS (*Abstract Co-Author*)
Liqiang Ren, PhD (*Abstract Co-Author*)
Cecelia Brewington, MD (*Abstract Co-Author*)
Sabee Y. Molloi, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate a patient-specific post-trigger delay (PTD) protocol estimating peak contrast enhancement timing in the main pulmonary artery (MPA) and all lobar branches during CT pulmonary angiography (CTPA).

METHODS AND MATERIALS

Thirty-nine patients with suspected lung lesions underwent CT perfusion imaging every 2 seconds for 28 seconds after receiving 40-50 mL of Isovue 370 and 20 mL saline chaser at 5 mL/s. Contrast enhancement curves (CEC) were generated using a gamma variate function to measure peak contrast enhancement (CE), contrast-to-noise ratio (CNR), and time to peak enhancement for the MPA and all lobar branches. CECs were then used to simulate peak CE and CNR for the patient-specific (PS) and fixed-delay protocols (4-7 seconds). We used the hypothesis that the PTD timing correlates directly with contrast injection duration, with the MPA peak CE occurring at half the injection time plus a 1-second dispersion constant. Statistical significance between protocols was tested using Friedman's test with post-hoc Wilcoxon signed-rank comparisons.

RESULTS

The patient-specific PTD demonstrated the smallest difference from the reference for both CE and CNR for all the measurements. For the MPA the CE differences (reference - PS) were -10.55, -63.43, -13.61, -36.69, and -113.85 and corresponding CNR differences were -0.19, -1.14, -0.24, -0.68, and -2.11 (PS, 4s, 5s, 6s, and 7s), respectively. For the left lower lobe, the CE differences were -14.68, -78.17, -17.45, -32.03, and -109.72 and CNR differences were -0.27, -1.41, -0.32, -0.61, and -1.98. For the left upper lobe, the CE differences were -14.09, - 80.52, -16.6, -30.65, and -101.78 and CNR errors were -0.25, -1.48, -0.29, -0.50, and -1.81. The right lower lobe had CE differences of -17.22, -90.21, -19.82, -28.57, and -101.74 and CNR errors of -0.31, -1.66, -0.35, -0.53, and -1.92. The right middle lobe CE differences were -14.35, -90.29, -17.09, -22.03, and -91.14 and CNR differences were -0.26, -1.72, -0.31, -0.39, and -1.68. The right upper lobe CE differences were -9.91, -87.34, -12.26, -18.29, and -86.56 and CNR differences were -0.18, -1.62, -0.22, -0.33, and -1.56. Statistically significant differences were observed between the PS and 4,6, and 7 second fixed-delay protocols ($p < 0.05$), with no significant differences observed between the PS and 5s protocol.

CONCLUSION

This study demonstrates that a patient-specific PTD protocol accurately captures peak contrast enhancement and improves visualization of pulmonary arteries at peak contrast, with potential clinical benefit through enhanced CNR.

CLINICAL RELEVANCE/APPLICATION

The proposed protocol overcomes limitations of test bolus and bolus tracking by using patient-specific timing, improving CTPA consistency and diagnostic accuracy.

M5B-SPPH-6 GLOBAL TUBE CURRENT MODULATION CONFIGURATIONS: A COMPARATIVE STUDY BETWEEN PHOTON-COUNTING AND ENERGY-INTEGRATING CT IN ONCOLOGICAL CLINICAL SETTING

Benjamin Lopez, PHD (*Presenter*)
Ke Li, PhD (*Abstract Co-Author*)
Frank Dong, PhD (*Abstract Co-Author*)
Corey T. Jensen, MD (*Abstract Co-Author*)
Xiujiang J. Rong, PhD (*Abstract Co-Author*)
Megan C. Jacobsen, PhD (*Abstract Co-Author*)
Xinming Liu, PhD (*Abstract Co-Author*)

PURPOSE

Siemens CT tube current modulation (CAREDose4D) global implementation can be specified at 5 possible levels for different patient sizes and anatomical regions. The purpose of this study is to compare the x-ray output (CTDI vol) and reconstructed image noise power spectrum (NPS) in a diameter-varying phantom imaged with a Siemens photon-counting detector (PCD) CT and energy-integrating detector (EID) CT.

METHODS AND MATERIALS

A Sun Nuclear Mercury 4.0 phantom was first imaged using a customized abdomen protocol on a NAEOTOM Alpha PCD-CT. Data was acquired in helical mode from largest to smallest diameter regions [water-equivalent diameters (WED): 15, 20, 25, 30, and 35 cm] and repeated twice per CAREDose4D level (Very Weak, Weak, Average, Strong, Very Strong). Virtual monoenergetic 67 keV images were acquired/reconstructed using 140 kVp, 0.8 pitch, 3.0 mm slices, 2.5 mm slice interval, Br40f kernel, and no iterative reconstruction. Acquisitions at each CAREDose4D level were then made on a SOMATOM Force EID-CT using a comparable routine abdomen protocol (120 kVp and Br40d kernel instead), after matching CTDI vol of the Average CAREDose4D setting across both systems. Mean CTDI vol values (mGy) and 2D NPS curves (HU 2 mm 2) per CAREDose4D level were calculated within 3 homogeneous slices per WED region. To facilitate comparisons, NPS curves were normalized by multiplying by their corresponding WED CTDI vol .

RESULTS

With Average CAREDose4D, reported overall CTDI vol was 9.0 mGy for both PCD and EID CTs and increased with WED from 4.2 to 16.2 mGy (PCD-CT) and from 2.3 to 19.7 mGy (EID-CT). CTDI vol for all CAREDose4D settings and both systems converged at approximately 32 cm WED, with Very Strong CAREDose4D resulting in the highest output >32 cm but lowest output <32 cm. Beyond that similarity, the relationship between tube output and WED differed between systems and was notably higher in the EID at the 35 cm WED (>3 mGy differences). After normalization, NPS curves for a given WED and CT model were effectively equivalent across all CAREDose4D levels. Overall, PCD-CT images had higher noise but comparable noise texture than counterpart EID-CT images.

CONCLUSION

This initial comparison of global tube current modulation settings of abdomen protocols in Siemens NAEOTOM Alpha and SOMATOM Force systems has highlighted possible dose-sparing by using PCD-CT in larger patients and also noise differences in PCD-CT images that warrant further evaluation.

CLINICAL RELEVANCE/APPLICATION

Differences in tube output, noise characteristics, and other image quality metrics in PCD and EID CT systems necessitate separately optimizing acquisition and reconstruction protocols for oncological disease staging, diagnosis, and management.

M5B-SPPH-7 EFFECTS OF DTI DEEP LEARNING RECONSTRUCTION ON CLINICAL TRACTOGRAPHY IN PATIENTS WITH BRAIN TUMORS

Brian A. Taylor, PhD (*Presenter*)
Jun Hong (*Abstract Co-Author*)
Vinodh A. Kumar, MD (*Abstract Co-Author*)
Ping Hou, PhD (*Abstract Co-Author*)
Alexander M. Khalaf, MD (*Abstract Co-Author*)
Max Wintermark, MD (*Abstract Co-Author*)
Ho-Ling Anthony Liu, PhD (*Abstract Co-Author*)

PURPOSE

Preoperative MRI with diffusion tensor imaging (DTI) tractography is routinely used for brain tumor surgical planning. DTI fiber tracking relies on voxel-level diffusion estimates, making the technique sensitive to image noise and artifacts. Deep learning-based reconstruction (DL Recon) has demonstrated improved SNR and reduced artifacts. This study evaluates its impact on clinical DTI tractography in a single institution.

METHODS AND MATERIALS

Preoperative DTI from 8 brain tumor patients was acquired on a 3T GE Premier XT scanner (48-channel head coil, EPI, 64 directions, b=1000 s/mm², 2-mm isotropic voxels) with and without DL Recon ('high' setting). Two datasets per patient (with/without DL Recon) were analyzed. Tractography was manually performed using DynaSuite software by three experienced MRI physicists, generating 27 tracts (2-5 per patient). The corticospinal tract (CST) and arcuate fasciculus (AF) were constructed for all subjects. Additionally, inferior fronto-occipital fasciculus, optic radiation, frontal aslant, inferior longitudinal fasciculus, and uncinate fasciculus tracts were obtained in selected cases based on tumor location. Two independent, experienced radiologists, blinded to randomly ordered images and each other's assessments, qualitatively compared the tracts, which were post-hoc labeled using a 3-point Likert scale (1 = preference for DL Recon, 0 = no preference, -1 = preference for non-DL Recon). Quantitative metrics included tract volume, fractional anisotropy (FA), apparent diffusion coefficient (ADC) and SNR.

RESULTS

DL Recon significantly increased SNRs ($p < .01$) in uniform regions in deep white matter (100-200 cm²): median values at b = 0 were 64.7 (IQR: 63.1-73.7) with DL Recon and 44.9 (IQR: 37.9-45.7) without; median values at b = 1000 s/mm² were 6.5 (IQR: 3.8-8.1) vs. 3.0 (IQR: 2.3-3.2) without. Visual assessment showed moderate inter-rater agreement (44% concordance), with no strong consensus favoring one reconstruction method ($p=0.01$). Median volume differences (DL Recon - no DL Recon) for all tracts is 15.6% (IQR: -10.9% to 12.7%), CST -1.8% (IQR: -4.7% to 2.8%), AF -2.5% (IQR: -12.7% to 9.5%), none statistically significant. Similarly, average FA and ADC values show no significant differences across all tracts.

CONCLUSION

DL Recon improves image SNR but did not significantly impact clinical tractography qualitatively or quantitatively with the DTI protocol used in this study.

CLINICAL RELEVANCE/APPLICATION

DTI tractography is vital for neurosurgical planning. Though DL Recon enhances SNR, it does not meaningfully alter tractography under standard protocols. Its impact may be greater with lower-quality DTI (e.g., low SNR, fewer directions) or more advanced tractography methods.

M5B-SPPH-8 QUANTITATIVE COMPARISON OF CT METAL ARTIFACT REDUCTION (MAR) ALGORITHMS AMONG RADIATION ONCOLOGY

James J. Sohn, PhD (*Presenter*)
Beechui Koo (*Abstract Co-Author*)
Hyunuk Jung, PHD (*Abstract Co-Author*)
Indra Das, PhD (*Abstract Co-Author*)
Siyong Kim, PhD (*Abstract Co-Author*)

PURPOSE

Metal artifacts in computed tomography (CT) significantly compromise image quality and dose calculation accuracy in radiation oncology. This study provides a quantitative comparison of four commercial metal artifact reduction (MAR) algorithms using standardized metrics and a novel analytical framework, offering radiation oncology physicists transparent, vendor-neutral performance data.

METHODS AND MATERIALS

A custom 3D-printed solid water phantom with interchangeable inserts (solid water, aluminum, titanium, and stainless steel) was scanned using four CT systems: Canon, GE, Philips, and Siemens. Each system's proprietary MAR algorithm was evaluated using acquisition parameters matched as closely as possible across scanners. Quantitative analysis employed multiple complementary methods: (1) Circular profile analysis measuring mean HU deviations from solid water reference at concentric distances from metal inserts; (2) geometric accuracy assessment of metal objects; and (3) volumetric artifact characterization using bad voxel analysis and a composite M Error index that integrates both artifact extent and intensity. ?HU color maps and accumulated histograms were used to characterize artifact patterns and MAR performance.

RESULTS

Significant performance differences were observed across the MAR algorithms. All four methods yielded consistently low |?HU| values at mid (2.80 cm) and far (3.80 cm) radial distances. Meanwhile, at the nearest distance (1.27 cm), |?HU| increased significantly for all MAR techniques. Smart-MAR exhibited the highest |?HU| for aluminum (16.83 HU), while O-MAR showed the greatest deviations for titanium and stainless steel (42.40 HU and 42.60 HU, respectively). SEMAR and i-MAR maintained high geometric accuracy across all materials, with percent diameter errors below 5%. In contrast, O-MAR produced a 9.17±0.29% error for aluminum, and Smart-MAR showed substantial deviations for titanium (20.39±0.84%) and stainless steel (19.03±0.63%). M Error values were lowest for SEMAR, Smart-MAR, and i-MAR (range: 0.00-0.83), while O-MAR displayed significantly elevated values (2.66-3.64), reflecting more severe residual artifacts.

CONCLUSION

This study provides a quantitative, slice-level evaluation of four commercial MAR techniques using a uniform phantom, offering insights to guide clinical decision-making and future system benchmarking in radiation oncology.

CLINICAL RELEVANCE/APPLICATION

By providing a standardized, quantitative comparison of four widely used commercial MAR techniques, this study enables clinicians and medical physicists to make informed decisions when selecting imaging protocols or systems for patients with metal implants.

M5B-SPPH-9 CONJUGATE GRADIENT AND DEEP LEARNING RECONSTRUCTIONS: SCAN TIME REDUCTION WITHOUT AFFECTING THE IMAGE QUALITY AND NODULE DETECTION CAPABILITY ON LUNG MRI WITH ULTRASHORT TE

Yoshiharu Ohno, MD, PhD (*Presenter*)
Takeshi Yoshikawa, MD (*Abstract Co-Author*)
Yoshiyuki Ozawa, MD, PhD (*Abstract Co-Author*)
Takahiro Ueda, MD, PhD (*Abstract Co-Author*)
Masahiko Nomura, MD, PhD (*Abstract Co-Author*)
Natsuka Yazawa (*Abstract Co-Author*)
Maiko Shinohara (*Abstract Co-Author*)
Kaori Yamamoto (*Abstract Co-Author*)
Yuichiro Sano, RT (*Abstract Co-Author*)
Masato Ikedo (*Abstract Co-Author*)
Masanori Ozaki (*Abstract Co-Author*)
Masao Yui (*Abstract Co-Author*)
Daisuke Takenaka, MD (*Abstract Co-Author*)

PURPOSE

Conjugate gradient reconstruction (CG Recon) and deep learning reconstruction (DLR) for magnetic resonance imaging (MRI) with ultra-short echo time (UTE-MRI) have been developed or clinically set to shorten scan time without image quality reduction instead of grid reconstruction (Grid Recon). The purpose of this study was to determine the utility of CG Recon and DLR to reduce scan time while maintaining the image quality and nodule detection capability on lung UTE-MRI obtained using 1.5- and 3-T MR systems.

METHODS AND MATERIALS

In the in vitro and in vivo studies, the NEMA phantom and 35 patients with pulmonary nodules were scanned by UTE-MRI with original (TE original), 1/2 (UTE 1/2), and 1/4 (UTE 1/4) spoke numbers obtained by both methods and reconstructed with and without DLR. The signal-to-noise ratios (SNR) of the phantom, lung (SNR Lung), and lesion (SNR Lesion) on UTE-MRI were assessed. In in vivo study, the overall image quality, artifact, lesion conspicuity, and nodule detection capability were assessed using five-point systems on UTE-MRI. Quantitative and qualitative indices were then compared between the standard MR protocol and others using Dunnett's post-hoc test or Wilcoxon’s signed-rank test. Finally, a receiver operating characteristic (ROC) analysis was performed to compare the standard MR protocol and other protocols.

RESULTS

In in vitro and in vivo studies, all SNRs were significantly different between the standard MR protocol and each UTE-MRI with CG Recon and DLR ($p<0.05$). Each qualitative index of the standard MR protocol differed significantly from those of all UTE 1/2 s and UTE 1/4 s, except for UTE 1/4 reconstructed with CG Recon and DLR ($p<0.05$). The area under the curve (AUC) of each UTE Original obtained by CG Recon was significantly larger than that of the standard MR protocol ($p<0.05$).

CONCLUSION

CG Recon and DLR can reduce scan time while maintaining image quality and nodule detection capability on lung UTE-MRI obtained using 1.5- and 3-T MR systems in patients with pulmonary nodules.

CLINICAL RELEVANCE/APPLICATION

CG Recon and DLR can reduce scan time while maintaining the image quality and nodule detection capability on lung UTE-MRI obtained using 1.5- and 3-T MR systems in patients with pulmonary nodules.

M5B-SPPH-10 NOISE REDUCTION PERFORMANCE OF NEWLY DEVELOPED DEEP LEARNING IMAGE RECONSTRUCTION FOR HIGH RESOLUTION KERNELS: A PHANTOM STUDY SIMULATING CHEST CT

Kazuma Fujimoto, MS (*Presenter*)
Hiroki Kawashima, PhD (*Abstract Co-Author*)
Katsuhiro Ichikawa, PhD (*Abstract Co-Author*)

PURPOSE

A deep learning CT image reconstruction (DLR) applicable for high-resolution kernels has been newly developed and clinically available. We aimed to characterize the noise reduction performance of the developed DLR technique in a chest phantom experiment, comparing filtered back projection (FBP) and iterative reconstruction (IR).

METHODS AND MATERIALS

An anthropomorphic chest phantom was used as a base phantom. After removing the default bronchial parts of the phantom, we packed cotton balls that simulated the density of ground-glass opacity into the right lung of the phantom to make a non-uniform region. The left lung remained the uniform air region. The axial scanning was repeated 30 times at CTDI of 2.9 mGy. CT images were reconstructed with a field of view of 200 mm in each lung. Three types of kernels (Standard, Lung, and Bone plus) and three types of reconstruction techniques [FBP, True Fidelity Deep Learning (DLR) with low, medium, and high settings, and ASiR-V (IR) with 50% and 100% blending levels] were evaluated. The region of interest with 128×128 pixels was placed at the uniform air region. The standard deviation (SD) of the CT number in the ROI was measured as an index of noise magnitude. The noise power spectrum (NPS) was also measured using the same ROI. For the non-uniform region, the noise magnitude map was generated by calculating the pixel-wise inter-image SD across the 30 images at the same table position.

RESULTS

The SD values of FBP, IR50%, IR100%, DLR-low, DLR-medium, and DLR-high were 17, 13, 9, 8, 6 and 5 HU for Standard kernel, respectively; 66, 46, 25, 30, 21 and 13 HU for Lung kernel; 82, 70, 59, 49, 38 and 25 HU for Bone plus kernel. Unlike IR, the NPS values of DLR decreased from the low spatial frequency. For the noise magnitude map of high-resolution kernels (Lung and Bone Plus), IR showed little difference between uniform and non-uniform regions; however, DLR showed lower noise reduction magnitude at the non-uniform regions, suggesting quasi-intelligent behavior to efficiently improve visibility of the region.

CONCLUSION

Noise reduction performance depends on the combination of filter kernels and reconstruction techniques. When using the high-resolution kernels, DLR demonstrated adaptive noise reduction while preserving the details of low-contrast signals.

CLINICAL RELEVANCE/APPLICATION

The newly developed DLR for high-resolution kernels has higher noise reduction performance than IR and the potential to improve the image quality of high-resolution chest CT. The noise map we used efficiently presented the DLR's performance that is clinically relevant.

M5B-SPPH-11 FEASIBILITY OF BIOLOGY-GUIDED RADIOTHERAPY BASED ON GALLIUM 68-LABELED FIBROBLAST ACTIVATION PROTEIN INHIBITOR PET IMAGING

Chunhui Han, PhD (*Presenter*)
Grant Gibbard (*Abstract Co-Author*)
Heather McGee (*Abstract Co-Author*)
Yi-Chun Wang (*Abstract Co-Author*)
Terence M. Williams, MD, PhD (*Abstract Co-Author*)
An Liu, PhD (*Abstract Co-Author*)

PURPOSE

A medical linac (X1, RefleXion Medical Systems, Hayward, CA) uses real-time PET signals from the tumor to guide beam delivery in biology-guided radiotherapy (BgRT). This study aims to evaluate the feasibility of using the Gallium 68-labeld fibroblast activation protein inhibitor (FAPI) radiotracer as a bio-guide for BgRT to treat tumors in different anatomical sites.

METHODS AND MATERIALS

Sequential patients who received diagnostic FAPI PET/CT scans at a single institution were reviewed. Fifty patients with malignancies in the head and neck, lung, liver, pancreas, and cervix sites were selected with ten patients for each disease site. The gross tumor volume (GTV) was drawn based on a standard uptake value (SUV) threshold of 40% of the maximum SUV for the lesion. The planning target volume (PTV) was created by adding a site-specific margin to the GTV. A biology tracking zone (BTZ) was created by adding a margin to the PTV to encompass the range of tumor motion. Each case was first screened for BgRT eligibility based on GTV size and FAPI uptake in the surrounding tissue. For candidate BgRT cases, the diagnostic PET images were first converted to simulated PET images on the X1 machine. The BgRT plans used a jaw width of 2 cm and a prescription dose of 9 to 10 Gy per fraction for 3 to 5 fractions. The activity concentration (AC) and normalized target signal (NTS) were calculated to evaluate BgRT feasibility on the X1.

RESULTS

Patients received an average FAPI injection dose of 3.19±0.76 mCi (range: 1.97 - 5.18 mCi) prior to FAPI PET/CT scans. Thirty cases were excluded in pre-plan screening due to GTV length and/or high FAPI uptake surrounding the tumor. Clinically acceptable BgRT plans were generated for thirteen cases while planning failed for seven cases due to inadequate FAPI PET characteristics in the tumor. In the BgRT plans, the average AC and NTS were 10.1± 3.8 kBq/ml (range: 6.0 - 19.3 kBq/ml) and 12.3±4.0 (range: 5.2 - 20.7), respectively. The average PTV dose coverage, conformity index, and homogeneity index were 94.4±1.6%, 1.33±0.23, and 1.28±0.11, respectively. With an average PTV volume of 53.4±30.0 cm 3 (range: 22.4 - 120.0 cm 3), the average treatment beam-on time was 1985±566 sec (range: 1,200 - 2,956 sec).

CONCLUSION

With proper patient selection based on tumor size and uptake characteristics, the Gallium 68-labeled FAPI radiotracer could be potentially used as a bio-guide for BgRT on the X1 for various disease sites. Suitable thresholds for AC and NTS to ensure delivery accuracy have not yet been established for this bio-guide.

CLINICAL RELEVANCE/APPLICATION

As FAPI tracers offer high sensitivity and specificity for certain tumor types, the use of FAPI tracers may allow more precise targeting in BgRT treatments compared to other tracers.

M5B-SPRO-1 HYBRID INTELLIGENCE IN ONCOLOGY: COMPARING HUMAN EXPERTS AND LARGE LANGUAGE MODELS IN INTERPRETING COMPLEX CANCER TREATMENT GUIDELINES

Gorkem Durak, MD (*Presenter*)
Berna Yildirim (*Abstract Co-Author*)
Baver Bunyamin Tutun (*Abstract Co-Author*)
Emre Batuhan Yildirim (*Abstract Co-Author*)
Emre Uysal (*Abstract Co-Author*)
Sukru Mehmet Erturk, MD (*Abstract Co-Author*)
Ulas Bagci, MSc, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate and compare the accuracy and convergence of medical specialists and large language models (LLMs) in interpreting the complex recommendation details within ASTRO and ASCO-SNO-ASTRO (ASCO) guidelines for brain metastases management.

METHODS AND MATERIALS

In this study, we assessed the performance of neurosurgeons, radiation oncologists, and four state-of-the-art LLMs (ChatGPT-4o, Gemini 2.0, Microsoft Bing Pro, and Deepseek R1) in interpreting guideline recommendations. Accuracy, near-answer rates, and Cohen's weighted kappa coefficients were calculated to evaluate convergence on the strength of recommendation (SoR) and quality of evidence (QoE). Statistical analysis was performed using Microsoft Excel 2024 and SPSS v26.

RESULTS

For the ASTRO guideline SoR evaluation: Medical experts achieved accuracy of 35.29-58.82%, near-answer rates of 58.82-94.11%, with poor to moderate convergence (? = 0.504). LLMs demonstrated superior performance with 94.11-100% accuracy and near-answer rates, showing near-perfect to perfect convergence (? = 0.881-1.000). For the ASTRO guideline QoE evaluation: Medical experts showed accuracy of 29.41-58.82%, near-answer rates of 47.05-94.11% with poor to moderate convergence (? = 0.406). LLMs achieved accuracy of 29.41-70.58%, near-answer rates of 88.23-94.11%, and fair to moderate convergence (? = 0.227-0.595). For the ASCO guideline SoR evaluation: Medical experts demonstrated accuracy of 15.38-53.84%, near-answer rates of 38.46-92.30%, with poor to moderate convergence (? = 0.428). LLMs showed accuracy of 7.69-61.53%, near-answer rates of 76.92-100%, and poor to moderate convergence (? = 0.428). For the ASCO guideline QoE evaluation: Medical experts achieved accuracy of 15.38-69.23%, near-answer rates of 46.15-100%, with poor to substantial convergence (? = 0.644). LLMs demonstrated accuracy of 7.69-46.15%, near-answer rates of 69.23-84.61%, and poor to fair convergence (? = 0.286). Among the LLMs, Gemini 2.0 and Deepseek R1 consistently demonstrated the highest performance in evaluating guideline details.

CONCLUSION

This pioneering study comprehensively analyzes the interpretation of complex oncology guidelines by both multidisciplinary medical experts and various LLMs. While both groups faced challenges with the complex details of recommendations, LLMs exhibited higher overall accuracy and convergence than medical experts, particularly for strength of recommendation assessments.

CLINICAL RELEVANCE/APPLICATION

Ambiguity in clinical guidelines can disrupt interdisciplinary coordination and affect patient management. LLMs integrated into clinical workflows may promote consistent guideline interpretation, thereby improving clinical outcomes.

M5B-SPVA-3 CLINICAL APPROACH TO CATEGORIZING THE HELICAL MORPHOLOGY OF TYPE B AORTIC DISSECTIONS USING CT

Fikunwa Kolawole, PhD (*Presenter*)
Christopher Cheng (*Abstract Co-Author*)

PURPOSE

Characterizing Type B aortic dissection (TBAD) helicity can aid in diagnosis and treatment planning. Surface-based algorithms for quantifying TBAD helicity are time-intensive, limiting clinical utility. Thus, we developed a streamlined centerline-based method and compared TBAD helicity categorization with a validated surface-based approach.

METHODS AND MATERIALS

The 3D surface-based approach for quantifying the helical morphology of TBAD utilized 3D segmentation of the aorta, true lumen, left common carotid artery (LCCA), and celiac artery (CA) using SimVascular (SV) {1}. The centerline-based approach used semi-automatically extracted centerlines of these same structures in TeraRecon (TR). Orthogonal planes along the aorta centerline were constructed, and the LCCA ostium was projected onto these planes to define the LCCA's circumferential position along the length of the aorta. On each normal plane, the angular position of the true lumen was computed relative to the LCCA position. The true lumen helical angle (HA) was defined as the change in angular position of the true lumen from the intimal tear to the CA. Both surface- and centerline-based methods categorized TBADs into right-hand (<-90° HA), left-hand chiral (>90° HA), non-helical (-90° to 90° HA & <22.5°/cm peak twist), and mixed-helical (-90° to 90° HA & >22.5°/cm peak twist in one direction, with a reversal of twist direction) groups.

RESULTS

The centerline-based approach correctly classified 92% of subjects in this study (79 out of 86), demonstrating excellent agreement with the surface-based method (Cohen's kappa = 0.88, $p < 0.001$). The few discrepancies (7 out of 86) involved adjacent categories: one left-hand chiral misclassified as non-helical, one left-hand chiral as mixed-helical, one non-helical as left-hand chiral, two non-helical as mixed-helical, one mixed-helical as non-helical, and one mixed-helical as right-hand chiral. Right-hand chiral classifications had no errors.

CONCLUSION

The centerline-based approach we developed shows favorable correspondence in categorizing TBAD helicity compared to a more onerous surface-based approach.

CLINICAL RELEVANCE/APPLICATION

This characterization of aortic dissection helicity, using a simple method integrated into clinical workflows, offers the potential for improved patient-specific diagnostics, treatment planning, surveillance, and large population studies to investigate the helical pathology and progression of TBAD. In addition, widespread helical characterization of TBAD can spur the development of asymmetric aortic endografts to treat asymmetric dissections. Reference : {1} doi:10.1152/ajpheart.00778.2020

R2-SPBR-1 EXTERNAL VALIDATION OF BREAST CANCER RISK ASSESSMENT MODEL MIRAI ON DIVERSE SCREENING COHORT

Hari Santhanam (*Presenter*)
Walter Mankowski (*Abstract Co-Author*)
Despina Kontos, PhD (*Abstract Co-Author*)
Sachin Jambawalikar, PhD (*Abstract Co-Author*)
Katherine Crew, MD (*Abstract Co-Author*)
Julia McGuinness (*Abstract Co-Author*)

PURPOSE

The purpose of this study is to evaluate the performance of MIRAI, a deep learning model for breast cancer risk prediction, using screening mammograms collected from a racially and ethnically diverse population at our institution. Assessing MIRAI's performance on an external cohort is critical to understanding its generalizability and potential for real-world clinical deployment.

METHODS AND MATERIALS

We retrospectively analyzed mammogram data from 1,024 unique women (race: 9% non-Hispanic Black, 23% non-Hispanic White, 43% Hispanic, 5% Asian and Pacific Islander, 20% other), of which 34 were diagnosed with breast cancer. We externally validated this cohort on MIRAI, a deep learning architecture that takes the four standard mammographic views as input for each patient. MIRAI integrates a convolutional neural network, a transformer, and a risk factor predictor to estimate breast cancer risk over one- to five-year horizons. The model outputs a probability risk score between 0 and 1 for each time point, representing the likelihood of cancer. We assessed validation performance using standard machine learning metrics, such as the area under the receiver operating characteristic curve (AUC).

RESULTS

We achieved AUCs of 0.731, 0.731, 0.597, and 0.605 for the two-year, three-year, four-year, and five-year time horizons, respectively. As an AUC of 1.0 indicates perfect discrimination, these results demonstrate moderate to strong validation performance, particularly at shorter time horizons.

CONCLUSION

We performed an external validation of MIRAI on a racially and ethnically diverse cohort, demonstrating its effectiveness in predicting breast cancer risk across multiple time horizons using standard machine learning metrics.

CLINICAL RELEVANCE/APPLICATION

These results support MIRAI's potential in accurate breast cancer risk estimation and contribute to the growing body of work highlighting MIRAI's robust performance across heterogeneous populations.

R2-SPBR-2 DUAL-ENERGY CONTRAST-ENHANCED SPECTRAL MAMMOGRAPHY IMPROVES DIAGNOSTIC ACCURACY FOR BI-RADS 4 MICROCALCIFICATIONS: A SURGICAL PATHOLOGY-VALIDATED STUDY

Jie Liu (*Presenter*)
Fan Yang, MD (*Abstract Co-Author*)
Juan Tao (*Abstract Co-Author*)
Shuyi Peng (*Abstract Co-Author*)
Peng Sun, MD,MD (*Abstract Co-Author*)

PURPOSE

To evaluate whether dual-energy contrast-enhanced spectral mammography (CESM) enhances diagnostic accuracy for BI-RADS 4 microcalcifications by providing functional vascular information in calcified regions.

METHODS AND MATERIALS

From June 2022 to October 2023, all patients who were diagnosed with suspicious malignant calcification (BI-RADS 4) on full-field digital mammography(FFDM) were included in this study. All diagnoses were subsequently confirmed via surgical pathology. Two experienced radiologists independently evaluated both FFDM images and the CEM silhouette images. The FFDM images characterized calcifications by their morphology and distribution type, categorizing them into low-risk (BI-RADS 4). The CEM silhouette images documented whether or not the calcified area exhibited enhancement. The sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) of diagnosing malignant calcification based on FFDM images alone or in combination with CEM images were compared between groups. The additional diagnostic performance of CEM images for BI-RADS 4 calcifications was also evaluated.

RESULTS

Of the 67 pathologically confirmed lesions, 32 were malignant and 35 were benign. Using histopathology as the gold standard, the sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and accuracy of diagnosing malignant calcifications based solely on FFDM images were 68.7% (22/32), 88.5% (31/35), 53.6% (22/41), 86.1% (31/36), and 79.1% (53/67), respectively. The sensitivity, specificity, PPV, NPV, and accuracy of diagnosing malignant calcifications using a combination of CEM silhouette images were 90.6% (29/32), 97.1% (34/35), 82.8% (29/35), 97.1% (34/35), and 94.0% (63/67), respectively. The sensitivity, PPV, and accuracy of DE-CESM in diagnosing malignant calcifications were significantly higher than those of FFDM images alone ($P<0.05$).

CONCLUSION

CEM can enhance the diagnostic efficiency of BI-RADS 4 calcifications, particularly for calcifications with low-risk morphology or distribution. CEM can also accurately locate calcification points and areas of enhancement, providing reliable clinical value for preoperative stereotactic localization of suspicious calcifications.

CLINICAL RELEVANCE/APPLICATION

CEM can furnish information regarding the blood supply to breast tissue in calcified regions and enhance the diagnostic efficiency of calcifications with low-risk morphology or distribution(BI-RADS 4). Enhancement of calcified areas suggested a high likelihood of malignancy lesion.

R2-SPBR-3 PREDICTING NEOADJUVANT RESPONSE IN HER2+ BREAST CANCER: A RADIOMIC-PATHOLOGY FEATURE SELECTION APPROACH

Alae Eddine Mrani (*Presenter*)
Veronique Debien (*Abstract Co-Author*)
Alexandre De Wind (*Abstract Co-Author*)
Rabie Najem (*Abstract Co-Author*)
Paulus Kristanto (*Abstract Co-Author*)
Stylianos Drisis, MD (*Abstract Co-Author*)

PURPOSE

Neoadjuvant therapy (NAT) is increasingly used in early-stage breast cancer (BC), though some patients may experience toxicity or limited benefit. While radiomics may predict response, the biological basis of these features remains unclear. This study aims to refine the selection process by prioritizing only radiomic features significantly associated with pathology/molecular markers to enhance biological explainability.

METHODS AND MATERIALS

Patients with early HER2+ BC treated with NAT (2015-2020) were retrospectively included based on: age =18, early-stage HER2+ BC, baseline H&E WSI and MRI. Immune microenvironment was assessed by an expert breast pathologist. Associations with response (RCB 0-1 vs. 2-3) were assessed using ?²/Fisher's and U/t-tests. Tumor and peritumoral segmentation and feature extraction used MMRadiomics (SyngoVia). Feature selection involved U test, Pearson correlation and LASSO in 5-fold CV; stability was defined as frequency across folds. Radiomic-pathology correlations were assessed via Spearman's/U tests. Only significantly correlated features ($p<0.05$) trained a Random Forest (RF) classifier.

RESULTS

Among 43 patients, median age was 56yo (IQR 17.9), median tumor size was 31.5 mm (IQR 26.3), 76% were HR+ (n=31); 55.8% had LN+ on MRI (n=24). RCB 0-1 response rate was 55.8% (24/43). HER2 3+ (p= 0.001), intratumoral Tumor Infiltrating Lymphocytes (TIL) (p = 0.03) and inflammatory pattern (IP) (p=0.03) were significantly higher in responders.Feature selection identified 14 radiomic features linked to response and pathology, the 4 most stable were selected for modeling. Among them, features from subtraction images were texture-based (GLSZM) and correlated more with molecular markers—HER2 (ES = -0,51), ER (ES = -0,32), and Ki-67 (ES = -0,4). In contrast, T1W features included one texture (GLDM) and one first-order feature, both correlated with immune infiltration: GLDM feature was associated with intra-tumoral TILs (ES= -0.33), tertiary lymphoid structures (TLS) (ES= -0.33), and IP (ES= -0.4), while first-order median was associated with total TILs (ES=-0.31), intra-tumoral TILs (ES=-0.35), TLS (ES=-0.33), and IP (ES= -0.35).An RF model using the 4 features achieved AUC 0.78 (TPR 0.68, TNR 0.69).

CONCLUSION

Linking feature selection to biology improves radiomic model explainability, enabling tumor microenvironment characterization from a glance at their macroscopic imaging.

CLINICAL RELEVANCE/APPLICATION

Incorporating biological explainability into radiomic models supports clinical integration and facilitates customized treatment. Emphasizing explainability—whether in traditional ML or DL—is key to building trustworthy AI tools.

R2-SPBR-4 ALGORITHM TO ENABLE MORE ACCURATE BREAST CANCER DETECTION RATE ESTIMATION WHEN REGISTRY OUTCOMES ARE NOT AVAILABLE

Elizabeth S. Burnside, MD, MPH (*Presenter*)
Hong Li (*Abstract Co-Author*)
Brian L. Sprague, PhD (*Abstract Co-Author*)
Janie M. Lee, MD, MSc (*Abstract Co-Author*)
Michael Lasarev (*Abstract Co-Author*)
Diana Miglioretti, PhD (*Abstract Co-Author*)
Robert A. Smith, PhD (*Abstract Co-Author*)

PURPOSE

Cancer detection rate (CDR), an important screening mammography audit metric ensuring adequate sensitivity, is typically determined using facility records of biopsy results (CDR-biopsy). Though resource-intensive, practices can also link with cancer registries (CDR-registry), a method used for establishing benchmarks. Using CDR-biopsy as a reference standard, which often has incomplete outcomes capture, can artificially lower CDR measurements, increasing the chance that facilities fall below the ACR benchmark of 2.5 cancers per 1000 screening mammograms. We developed an algorithm to estimate CDR-registry when registry linkage is not available.

METHODS AND MATERIALS

Using Breast Cancer Surveillance Consortium (BCSC) data, we calculated facility-specific ascertainment rate (AR) by dividing biopsies with available (ascertained) pathology arising from screen-detected findings by all biopsies recommended from screening (with or without available pathology). BCSC data enabled analysis of both facility level CDR-biopsy and CDR-registry; determination of the number of facilities erroneously below the benchmark of 2.5/1000 using CDR-biopsy; and development of an algorithm to compensate for non-ascertained biopsies to estimate CDR-registry using facility level data other than registry-linkage. To measure algorithm performance, we used discrepancy thresholds of 0.5/1000 and 1/1000 and concordance correlation coefficient between the algorithmically estimated CDR vs. CDR-registry.

RESULTS

Across 105 BCSC facilities, AR ranged from 17.1—100% (median [IQR] of 84.9 [70.8—89.8]%). Using CDR-registry, all facilities exceeded the ACR CDR benchmark. Using CDR-biopsy, 11 facilities (10.5%) fell below 2.5/1000. 66 facilities (62.9%) were within 0.5/1000 and 88 facilities (83.8%) were within 1.0/1000 of their CDR-registry measurement. Using our algorithm, 94 facilities (89.5%) were within 0.5/1000 and 102 facilities (97.1%) were within 1.0/1000 of their CDR-registry measurement. Our algorithm corrected the 11 facilities with CDR-biopsy below the benchmark, to accurately meet the 2.5/1000 threshold. The concordance correlation coefficient between algorithmically estimated CDR vs. CDR-registry was 0.923.

CONCLUSION

One tenth of BCSC facilities erroneously fell below ACR CDR benchmarks when following the common clinical practice of using CDR-biopsy as a reference standard. Our algorithm successfully corrected this phenomenon.

CLINICAL RELEVANCE/APPLICATION

Our algorithm identified and corrected all facilities that inaccurately missed CDR benchmarks, demonstrating the potential to improve mammography audits at facilities that do not link to cancer registries.

R2-SPBR-5 SELF-REQUESTED MAMMOGRAPHY: UTILIZATION TRENDS AT AN ACADEMIC INSTITUTION

Julia Liu (*Presenter*)
Katherine H. Cavallo Hom, MD (*Abstract Co-Author*)

PURPOSE

Self-requested mammograms allow eligible patients to undergo screening without requiring an order from a referring provider. This study investigates utilization of self-requested screening and subsequent true positive rates within provider-referred and self-requested patients.

METHODS AND MATERIALS

This retrospective review analyzed screening mammograms performed at our academic institution between 2020 and 2023 (N=33,500). True positive (TP) results, defined as a diagnosis of breast malignancy within 365 days of screening, were calculated. These cases were then categorized as provider-referred or self-requested. Local availability of self-requested screening mammography was assessed (N= 5).

RESULTS

Of 33,500 total screening mammograms, 18,947 (56.6%) were self-requested. The total number of screening mammograms steadily increased from 6,151 to 10,358 per year throughout the study period, while the percentage of self-requested mammograms also notably increased from 53.1% in 2020 to 59.4% in 2023. There were 236 TP screening mammograms, of which 117 (49.6%) were provider-referred and 119 (50.4%) were self-requested. Locally, 40% of institutions offer self-requested screening mammography for patients meeting ACR screening guidelines, without requiring additional criteria.

CONCLUSION

The raw number and percentage of self-requested screening mammograms demonstrate a consistent upward trend. Approximately half of all screening-detected breast malignancies originated from a self-requested mammogram by the patient. This pathway for patient access to screening mammograms is critical for early detection of breast cancer.

CLINICAL RELEVANCE/APPLICATION

Self-requested screening mammography usage continues to rise, which improves access to preventive screening by reducing scheduling barriers. 50.4% of all cancers found during the study period originated from self-requested screening mammography. This pathway model highlights an opportunity to improve access to patient care, as only 40% of local institutions currently offer this option without additional criteria.

R2-SPBR-6 MRI-GUIDED BIOPSY AFTER CONTRAST-ENHANCED MAMMOGRAPHY FOR OCCULT LESIONS

Maya Grisaru Kacen, MD, MBA (*Presenter*)
Alexander Tsibulski, MD (*Abstract Co-Author*)
Kristopher McKenzie, MD (*Abstract Co-Author*)
Anat Kornecki, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the feasibility of MRI-guided biopsy (MRB) directly following the detection of mammographically and sonographically occult lesions using contrast-enhanced mammography (CEM).

METHODS AND MATERIALS

We retrospectively reviewed the records of 2,599 patients who underwent CEM at our institution between October 2017 and December 2020. Patients with suspicious lesions (BI-RADS category 4 or 5) detected by CEM, which were otherwise occult and required MRB, were eligible for the trial. The patients were divided into two cohorts: 1. those who had MRB directly after CEM and 2. those who had MRI prior to MRB. Data collection included histopathology, MRB cancellation rates, and time-to-diagnosis. Statistical analysis was performed using Microsoft Excel.

RESULTS

A total of 55 patients with 61 lesions detected by CEM were eligible for the study. Of these, 44 patients with 47 lesions proceeded directly to MRB, while 11 patients with 14 lesions underwent MRI prior to MRB. Of the 47 lesions that underwent MRB directly following CEM, biopsy was canceled for 4 patients due to non-visualization of the lesion at the time of MRB. Of the remaining 43 lesions, 13 (30.2%) were malignant, including 11 invasive cancers and 2 cases of high-grade ductal carcinoma in situ (DCIS). Of the 14 lesions detected by both CEM and MRI that underwent MRB, 3 (21.4%) were invasive cancers. For patients who had an MRI following CEM, the average time to diagnosis was extended by 8 days.

CONCLUSION

Direct MRB following CEM demonstrated a 91.5% biopsy success rate (43 out of 47) with 30.2% malignancy yield, comparable to MRI-detected lesion biopsy performance. CEM alone can sufficiently localize lesions for MRB without the need for a prerequisite MRI, thereby avoiding diagnostic delays.

CLINICAL RELEVANCE/APPLICATION

Omitting pre-MRB MRI for CEM-detected lesions streamlines workflow, reduces delays by 8 days, and maintains diagnostic accuracy. This approach optimizes resource utilization while ensuring timely cancer diagnosis.

R2-SPCA-1 NECESSITY AND OPTIMAL TIMING OF DELAYED IMAGING IN PULMONARY VEIN CTA FOR LEFT ATRIAL APPENDAGE THROMBUS EVALUATION PRIOR TO ATRIAL FIBRILLATION ABLATION

Tuo He (*Presenter*)
Xiaohui Li (*Abstract Co-Author*)
Wei Huang (*Abstract Co-Author*)
Yue Yao (*Abstract Co-Author*)
Baobin Guo (*Abstract Co-Author*)

PURPOSE

To evaluate the necessity and optimal timing of delayed-phase imaging in pulmonary vein CT angiography (PVCT) for accurate assessment of left atrial appendage (LAA) thrombus prior to atrial fibrillation (AF) radiofrequency ablation.

METHODS AND MATERIALS

In this prospective and IRB-approved study, 93 patients scheduled for AF ablation underwent multiphase PVCT and transesophageal echocardiography (TEE). TEE served as the reference standard for detecting LAA thrombus and assessing emptying velocity; CHA2DS2-VASc scores were retrieved from clinical documentation. All patients received a low-dose helical PVCT scan, followed by low-dose ECG-triggered axial LAA scans at 10s, 20s, and 35s delays on a 256 CT scanner. Four imaging groups were generated for each patient for analysis: single-phase, +10s, +20s, and +35s delay. CT attenuation values of the left atrium (LA), LAA, and ascending aorta were measured. Image interpretation was performed independently by three radiologists, classifying LAA findings as negative or indeterminate for thrombus.

RESULTS

Delayed-phase imaging significantly improved diagnostic performance, with the +10s delay achieving the highest specificity (97.7%) and accuracy (97.8%), and 100% sensitivity and negative predictive value (NPV). The LAA/LA attenuation ratio moderately correlated with LAA emptying velocity ($r=0.420$, $p<0.05$), and when =1.14, indicated significantly reduced flow. Linear regression analysis revealed a stronger correlation ($R = 0.502$) when combining LAA/LA ratio from the +10s group with CHA2DS2-VASc scores in predicting LAA flow velocity. ROC analysis confirmed optimal diagnostic value at a cutoff of 1.14 for the +10s group. Multivariate logistic regression incorporating the +10s LAA/LA ratio and CHA2DS2-VASc score showed the strongest predictive power for thrombus ($R^2 = 0.319$). Diagnostic consistency improved with delayed imaging, with the +10s group yielding the highest interobserver agreement (? = 0.982).

CONCLUSION

A 10-second delayed-phase PVCT markedly improves specificity and accuracy while preserving 100% sensitivity for LAA thrombus exclusion, and offers a valuable, noninvasive alternative to TEE in pre-ablation thrombus screening. Lower LAA/LA ratios indicate higher thrombus risk, especially when combined with CHA2DS2-VASc scores.

CLINICAL RELEVANCE/APPLICATION

Implementing 10-second delayed PVCT in routine pre-ablation assessment may reduce reliance on invasive TEE, streamline clinical workflows, and improve patient comfort—while maintaining high diagnostic confidence in LAA thrombus exclusion and risk stratification.

R2-SPCA-2 MBSS-T1: AN AI-BASED MOTION CORRECTION TECHNIQUE FOR ROBUST CARDIAC T1 MAPPING IN BREATH-HOLD AND FREE-BREATHING CONDITIONS - TEST-RETEST REPEATABILITY ASSESSMENT

Ilya Volovik, MD (*Presenter*)
Adi Zehavi-Lenz (*Abstract Co-Author*)
Eyal Hanania (*Abstract Co-Author*)
Moti Freiman, PhD (*Abstract Co-Author*)

PURPOSE

Cardiac T1 mapping is essential for assessing myocardial tissue characteristics and detecting conditions such as fibrosis and edema, critical for diagnosing and managing heart diseases. However, motion artifacts, especially in free-breathing, can impact the accuracy and reproducibility of myocardial T1 mapping. This study evaluates the test-retest repeatability of MBSS-T1, an AI-based motion correction technique, for myocardial T1 mapping using the MOLLI protocol in both breath-hold and free-breathing conditions, compared to scanner-based standard motion correction and uncorrected data.

METHODS AND MATERIALS

Twelve healthy male volunteers (aged 20-36) underwent myocardial T1 mapping on a 3T MRI using the 5(3)3 MOLLI protocol. Breath-hold and free-breathing datasets were acquired before and after a 20-minute rest. T1 maps were reconstructed using MBSS-T1, scanner-based motion correction, and uncorrected data. Test-retest repeatability was assessed with intraclass correlation coefficients (ICC), Bland-Altman analysis, within-subject coefficient of variation (CV w), and repeatability coefficients (RC).

RESULTS

MBSS-T1 had mean±std T1 values of 1127.72±99.33 (BH) and 1049.60±92.41 (FB). The scanner-based method yielded 1230.69±78.71 (BH) and 1131.60±88.78 (FB), while uncorrected data showed 1195.44±71.56 (BH) and 1099.92±101.87 (FB). MBSS-T1 showed superior repeatability compared to scanner-based motion correction and uncorrected data. Under breath-hold, MBSS-T1 had an ICC of 0.953 (excellent), vs. 0.829 (good) for scanner-based and 0.804 (good) for uncorrected data. In free-breathing, MBSS-T1 outperformed with an ICC of 0.636 (moderate), compared to 0.531 (moderate) for scanner-based and 0.240 (poor) for uncorrected data. MBSS-T1 also had the lowest CVw and RC: 3.6% and 14.2% (breath-hold), and 5.1% and 19.9% (free-breathing). Bland-Altman analysis showed narrower limits of agreement for MBSS-T1.

CONCLUSION

MBSS-T1 improves myocardial T1 mapping reproducibility compared to standard motion correction and uncorrected data. It shows significant improvements under breath-hold conditions and enhances repeatability in free-breathing acquisitions. These results suggest MBSS-T1 could improve cardiac MRI reliability, especially for patients unable to perform breath-holds.

CLINICAL RELEVANCE/APPLICATION

MBSS-T1 provides an AI-based solution for more accurate and reproducible myocardial T1 mapping. Its performance under both breath-hold and free-breathing conditions makes it suitable for patients with respiratory limitations, enabling more precise cardiac assessments and benefiting the diagnosis and monitoring of cardiac conditions.

R2-SPCA-4 MYOCARDIAL STRAIN ASSESSMENT IN CINE SEQUENCES ACQUIRED USING ARTIFICIAL INTELLIGENCE TECHNIQUES

Giuseppe Muscogiuri, MD (*Presenter*)
Daniele Sferratore, MD (*Abstract Co-Author*)
Jessica Usai, MD (*Abstract Co-Author*)
Gregorio Chierchia, MD (*Abstract Co-Author*)
Paolo Marra, MD (*Abstract Co-Author*)
Sandro Sironi, MD (*Abstract Co-Author*)

PURPOSE

Cardiac Magnetic Resonance (CMR) with cine imaging is the gold standard for evaluating ventricular function and myocardial structure. Recent advancements in deep learning (DL) have enabled accelerated acquisition protocols, potentially reducing scan time without compromising diagnostic accuracy. This study aimed to evaluate the diagnostic performance and efficiency of different DL-accelerated cine acquisition schemes compared to the standard protocol.

METHODS AND MATERIALS

Between September 2024 and January 2025, twenty adult patients referred for CMR were prospectively enrolled. All underwent cine imaging on a 1.5T scanner (Signa Voyager, GE HealthCare) using both standard (5 cardiac cycles, DL factor 6) and three DL-accelerated protocols: 2/12 (2 cycles, DL factor 12), 4/6 (4 cycles, DL factor 6), and 8/3 (8 cycles, DL factor 3). Quantitative analysis included left ventricular (LV) volumes, mass, ejection fraction (EF), and global strain parameters (GLS, GCS, GRS). Image quality was rated using a 5-point Likert scale. Acquisition times were recorded. Statistical comparisons were performed using paired tests and Bland-Altman analysis.

RESULTS

Compared to the standard 5 RR acquisition, GLS was significantly overestimated in the 2/12 configuration ($p = 0.0096$, mean bias = -1.69%). EF was significantly overestimated in the 8/3 configuration ($p = 0.021$). No significant differences were found for EDV, ESV, SV, LV mass, GCS, or GRS across protocols. The 4/6 configuration demonstrated optimal agreement with the standard protocol across all parameters. Acquisition time was reduced by 25% with 2/12 and 12.5% with 4/6, whereas 8/3 resulted in a 133% increase. Image quality was rated highest in 8/3 (mean score 4.5), comparable in 4/6 and 5 RR (score 4), and slightly lower in 2/12 (score 3.5).

CONCLUSION

DL-accelerated cine CMR can significantly reduce acquisition time while maintaining diagnostic accuracy. However, the choice of acquisition scheme impacts specific functional parameters. GLS and EF showed significant variability with certain protocols, highlighting the importance of protocol selection in clinical and research settings. The 4/6 configuration offers the best balance between scan time, image quality, and parameter reliability.

CLINICAL RELEVANCE/APPLICATION

The application of artificial intelligence is rapidly changing the diagnostic and prognostic pathway in radiology. Optimal compromise between image quality and diagnostic reliability will be crucial. In this abstract we identify the best combination of DL accelerated cine images in order to reduce time of acquisition and preserve reliable images.

R2-SPCA-5 DUAL ORGAN IMAGING BIOMARKERS: HEPATIC STEATOSIS AND BREAST ARTERIAL CALCIFICATION INDEPENDENTLY PREDICT INCIDENT HEART FAILURE AND ENHANCE RISK STRATIFICATION

Theodorus Dapamede, MD, PhD (*Presenter*)
Seyed Mohammadreza Chavoshi, MD (*Abstract Co-Author*)
Aawez Mansuri, BS, MS (*Abstract Co-Author*)
Chad Robichaux (*Abstract Co-Author*)
Frank Li, PhD (*Abstract Co-Author*)
Bardia Khosravi, MD, MPH (*Abstract Co-Author*)
Rohan Satya Isaac (*Abstract Co-Author*)
Beatrice Brown-Mulry (*Abstract Co-Author*)
Janice M. Newsome, MD (*Abstract Co-Author*)
William C. O'Neill, MD (*Abstract Co-Author*)
Imon Banerjee, PhD (*Abstract Co-Author*)
Hari Trivedi, MD (*Abstract Co-Author*)
Judy W. Gichoya, MBChB, MS (*Abstract Co-Author*)

PURPOSE

Early identification of women at risk for heart failure (HF) is crucial. This study assessed if MRI-derived hepatic fat fraction (HFF) and mammographic breast arterial calcification (BAC), two potentially opportunistic imaging findings, are independent predictors of incident HF and improve risk stratification beyond traditional cardiovascular risk factors.

METHODS AND MATERIALS

This retrospective study included 653 women (mean age 59.0 ± 9.9 years) with screening mammograms and abdominal MRI between 2012 and 2020. HFF was quantified from MRI (in-phase/out-of-phase sequences) on liver volumes segmented using TotalSegmentatorMR. Hepatic steatosis was defined as >5%. BAC was automatically quantified from mammograms using a validated in-house AI model. Incident HF was identified via EHR ICD codes post-imaging studies. Univariate associations were initially explored with Kaplan-Meier analysis. Multivariable Cox models were employed to determine the independent predictive strength of HFF and BAC, after adjusting for age, diabetes, smoking, hypertension, and hyperlipidemia. The incremental value of these imaging biomarkers was further evaluated by comparing C-indices of models with and without their inclusion.

RESULTS

Over a median follow-up of 7.5 years, 33 (5.0%) women developed incident HF. Steatosis and BAC were each present in 25.7% (168/653) of participants. Kaplan-Meier analysis demonstrated that women with hepatic steatosis ($p=0.026$) or with BAC ($p=0.016$) had a significantly higher incidence of HF. Importantly, after adjusting for traditional risk factors, multivariable Cox models confirmed both steatosis (Adjusted Hazard Ratio [aHR]: 2.56; 95%CI: 1.23-5.30; $p=0.01$) and the presence of BAC (aHR: 2.52; 95%CI: 1.21-5.25; $p=0.01$) as robust independent predictors of incident HF. Adding HFF and BAC to a model with traditional risk factors significantly improved risk discrimination, increasing the C-index from 0.66 (traditional factors alone) to 0.71.

CONCLUSION

MRI-identified hepatic steatosis and BAC quantified on mammography are significant independent predictors of incident heart failure in women. These biomarkers offer incremental prognostic information, substantially enhancing risk prediction beyond traditional cardiovascular risk factors.

CLINICAL RELEVANCE/APPLICATION

Opportunistic assessment of hepatic fat on abdominal MRI and BAC on routine mammography can identify women at elevated risk for future heart failure, facilitating targeted preventative strategies and enhanced cardiovascular risk stratification.

R2-SPCA-6 ARTIFICIAL INTELLIGENCE DENOISING ENHANCES ULTRA-HIGH-RESOLUTION PHOTON-COUNTING-DETECTOR CCTA IMAGE QUALITY BEYOND QUANTUM ITERATIVE RECONSTRUCTION

Anton Kilburg, MD (*Presenter*)
Moritz Halfmann, MD (*Abstract Co-Author*)
Philipp Locherer (*Abstract Co-Author*)
Tilman S. Emrich, MD (*Abstract Co-Author*)

PURPOSE

Ultra-high-resolution (UHR) coronary CT angiography (CCTA) with photon-counting detector CT (PCD-CT) provides exceptional detail but is associated with increased image noise. Quantum iterative reconstruction (QIR), a denoising algorithm specifically developed for PCD-CT, can improve image quality without compromising sharpness. However, even with the highest QIR strength setting, UHR CCTA images still exhibit substantial noise. This study aims to evaluate whether an artificial intelligence (AI)-based denoising algorithm can further enhance UHR CCTA image quality

METHODS AND MATERIALS

We retrospectively analyzed CCTA scans from 25 patients with coronary artery disease, all of whom underwent PCD-CT with an in-plane resolution of 0.11 mm. Image sets were reconstructed with 0.2 mm slice thickness, both without QIR and with all QIR strength levels (1-4). Subsequently, each image set was processed using a CE-marked AI-based denoising tool (ClariACE, ClariPi). Two radiologists, trained in assessing CCTA images, evaluated overall image quality, sharpness, noise, and vessel wall contour delineation using a 5-point Likert scale. Differences between image sets were analyzed using Wilcoxon signed-rank tests.

RESULTS

Both radiologists rated AI-denoised images significantly higher ($P < 0.001$) across all parameters compared to those without denoising. For overall image quality, AI-denoised images at all QIR levels scored better (2 [IQR, 2-3] vs. 4 [IQR, 3-5], $P < 0.001$). The best results were observed for AI-denoised images at the highest QIR strength (level 4), with vessel wall contour delineation showing a notable improvement (AI-denoised QIR 4: 5 [IQR, 4-5] vs. QIR 4: 4 [IQR, 3-4]). Inter-reader agreement was good.

CONCLUSION

AI-denoising significantly improves the quality of UHR CCTA images compared to QIR alone, enhancing image sharpness and reducing noise. The most prominent benefits were observed in AI-denoised images at the highest QIR strength level, suggesting that AI-based denoising could be a valuable tool in optimizing CCTA image quality.

CLINICAL RELEVANCE/APPLICATION

Existing AI-based tools for improved image quality to be used on increased spatial resolution PCD-CCTA

R2-SPCA-10 COMPARISON OF NON-GATED AND TRADITIONAL GATED TECHNIQUES IN AUTOMATED CORONARY ARTERY CALCIUM SCORING

Tao Zhou (*Presenter*)
Zhang Min (*Abstract Co-Author*)
Zhuangfei Ma (*Abstract Co-Author*)
Bingsheng Li (*Abstract Co-Author*)
Zhiwei Zhang (*Abstract Co-Author*)
Yunxiang Chang (*Abstract Co-Author*)
Luqiang Jiang (*Abstract Co-Author*)

PURPOSE

To investigate the differences between traditional electrocardiogram (ECG)-gated calcium scoring and non-ECG-gated calcium scoring using lung/mediastinum window parameters.

METHODS AND MATERIALS

This prospective study enrolled subjects who underwent both coronary artery calcium (CAC) scoring scans and non-contrast chest CT scans at our institution between January 2025 and March 2025.Inclusion criteria: (1)Interval between non-contrast chest CT and ECG-gated CAC scans =3 months; (2)Age =18 years; (3)No history of cardiac surgery.Exclusion criteria: Severe artifacts or poor image quality. (1)Imaging was performed using a Canon Aquilion ONE Genesis Edition 320-detector row CT scanner.ECG-gated scans (Group A): Non-gated scans (Group B).All datasets were reconstructed using Adaptive Iterative Dose Reduction 3D (AIDR 3D) with 3-mm slice thickness and interval. CAC scores were measured using the Neusoft Coronary Artery Calcium Automated Analysis System (Neusoft CCSpro). CAC scores were categorized into five risk levels: very low (0), low (1-10), moderate (11-100), high (101-400), and very high (>400).Objective Metrics: CT attenuation values of the aortic root and left ventricular myocardium; Standard deviation (SD) of regions of interest (ROI) to quantify noise; Signal-to-noise ratio (SNR = CT attenuation/SD).

RESULTS

Among 27 initially enrolled patients, 3 were excluded due to severe coronary calcification artifacts, leaving 24 patients (mean age 66.9 ± 6.9 years; male-to-female ratio 1.7:1).Image Quality ComparisonAortic root: Group A: CT attenuation = 48.41 ± 1.86, SD = 11.30 ± 1.27, SNR = 4.33 ± 0.44Group B: CT attenuation = 43.99 ± 1.10, SD = 17.10 ± 1.11, SNR = 2.59 ± 0.22 (all $p < 0.05$).Agatston Score ComparisonGroup A (491.46 ± 890.02) showed higher Agatston scores than Group B (481.67 ± 837.64, $p = 0.025$).Subgroup AnalysisNo significant differences were observed between Group A and Group B in very low-, low-, and moderate-risk CAC categories ($p = 0.254$). However, significant differences were found in high- and very high-risk categories ($p = 0.023$).

CONCLUSION

Non-gated coronary artery calcium (CAC) scoring using lung/mediastinum window parameters demonstrates significant correlation with traditional ECG-gated CAC scoring. However, the agreement between the two methods is stronger in low- to moderate-risk populations, suggesting that non-gated CAC scoring can serve as a preliminary screening tool for these groups.

CLINICAL RELEVANCE/APPLICATION

The non-gated CAC scoring technique, when applied to low- to moderate-risk populations, helps avoid unnecessary additional ECG-gated CAC examinations, thereby reducing radiation exposure while maintaining diagnostic utility.

R2-SPCA-12 FEASIBILITY OF ULTRA-LOW FLOW CORONARY CT ANGIOGRAPHY USING PHOTON-COUNTING CT: A PROSPECTIVE TRIAL

Shuangxiang Lin, MSc (*Presenter*)
Xinhong Wang (*Abstract Co-Author*)
Jiaxing Wu (*Abstract Co-Author*)
Jianzhong Sun, MMed (*Abstract Co-Author*)

PURPOSE

This study evaluates the feasibility of coronary CT angiography (CCTA) using photon-counting detector CT (PCD-CT) at ultra-low flow contrast rates, while maintaining diagnostic image quality.

METHODS AND MATERIALS

In this prospective trial, 292 patients underwent CCTA using one of three protocols: ultra-low flow rate (1.5-1.8 mL/s) with PCD-CT, routine flow rate (4.0-5.0 mL/s) with PCD-CT and energy-integrating detector CT (EID-CT). All scans employed ECG-gated high-pitch acquisition (pitch 3.2) with heart rate-based phase selection. PCD-CT images were reconstructed with 45 keV virtual monoenergetic algorithms. A total of 4,672 segments were analyzed. Objective image quality was measured by CT attenuation values, contrast-to-noise ratio (CNR), and signal-to-noise ratio (SNR). Subjective image quality was assessed by a 4-point Likert scale.

RESULTS

Objective analysis showed comparable attenuation, CNR (24.1-26.8), and SNR (18.3-19.4) across all groups (P >0.05). Subjectively, ultra-low flow PCD-CT showed more Score-3 ratings (55.2% in posterior descending right coronary artery (RCA), 77.1% in distal LCX), while routine flow PCD-CT and EID-CT had more Score-4 ratings (70.7% and 72.2%, P <0.05). Significant differences were noted in the posterior descending, distal LCX, and obtuse marginal branches.

CONCLUSION

Ultra-low contrast flow rates in PCD-CT maintain objective image quality comparable to standard protocols. Despite minor reductions in subjective quality, diagnostic performance remains acceptable, offering a viable option for patients with limited venous access.

CLINICAL RELEVANCE/APPLICATION

PCD-CT provides comparable objective image quality at reduced contrast flow rates, with clinically acceptable diagnostic performance. This supports its use in patients with renal impairment or fragile veins, where low contrast loads are preferred.

R2-SPCA-13 THE VALUE OF WIDE DETECTOR CT ANGIOGRAPHY IN EVALUATING LEFT VENTRICULAR FUNCTION AND STRAIN IN PATIENTS WITH AORTIC STENOSIS

Wendi Zhang (*Presenter*)
Wanlin Peng, MS (*Abstract Co-Author*)
Xinyang Lv (*Abstract Co-Author*)
Ke Shi (*Abstract Co-Author*)
Chunchao Xia (*Abstract Co-Author*)
Zhenlin Li, MD (*Abstract Co-Author*)

PURPOSE

This study aimed to evaluate the clinical value of wide-detector cardiac computed tomography angiography (CTA) in assessing left ventricular (LV) function and strain changes in patients with aortic stenosis (AS), using cardiac magnetic resonance (CMR) as the reference standard.

METHODS AND MATERIALS

A total of 42 AS patients who underwent both wide-detector cardiac CTA and CMR from January 2020 to October 2024 were retrospectively enrolled. Structural parameters, functional parameters and strain parameters derived from CTA and CMR were measured and compared. LV morphology was classified based on LV mass (LVM) index and mass-to-volume ratio from both modalities.

RESULTS

For structural parameters, four-chamber LV end-diastolic diameter (LVEDD), LV end-systolic diameter (LVESD) and short-axis LVEDD from CTA showed no significant differences with CMR (all P>0.05). Correlation analysis showed that structural parameters obtained by CTA were all strongly positively correlated with the corresponding CMR parameters (r=0.907, r=0.951, r=0.949, r=0.970, all P<0.001). In terms of function, LV stroke volume (LVSV) and LV ejection fraction (LVEF) from CTA had no significant differences with CMR (all P>0.05). Correlation analysis showed that the LV end-diastolic volume (LVEDV), LV end-systolic volume (LVESV), LVSV, LVEF, and LVM obtained by CTA were all strongly positively correlated with the corresponding CMR parameters (r = 0.998, r = 0.997, r = 0.974, r = 0.995, r = 0.998, all P<0.001). CTA showed excellent intra-observer consistency in the measurement of all LV structural and functional parameters (all ICC>0.9). When measuring LV strain, correlation analysis showed that 2D GRPS, 2D GCPS, and 2D GLPS obtained by CTA were strongly positively correlated with the corresponding CMR parameters (r = 0.792, r = 0.774, r = 0.713, all P<0.001). In addition, CTA and CMR had a high degree of consistency in the classification of LV hypertrophy in AS patients (Kappa = 0.892, P<0.001).

CONCLUSION

Wide-detector CTA demonstrates good consistency with CMR in evaluating LV structure, function, and 2D global strain in AS patients. It can accurately classify LV hypertrophy and serve as an alternative to CMR, especially for patients ineligible for CMR.

CLINICAL RELEVANCE/APPLICATION

This study's results have important clinical value. Wide - detector cardiac CTA, highly consistent with CMR in assessing LV function and structure, provides a viable alternative. For patients unsuitable for CMR due to metallic implants, claustrophobia, etc., CTA can offer reliable data for diagnosis and treatment planning, guiding surgical and long - term management decisions to enhance patient care.

R2-SPCA-14 NOVEL PHOTON COUNTING CT SPECIFIC AI DENOISING SIGNIFICANTLY IMPROVES IMAGE QUALITY IN CARDIAC CT

Nour Maalouf, MD (*Presenter*)
Andreas Brendlin, MD, PhD (*Abstract Co-Author*)
Ulrich Schmid (*Abstract Co-Author*)
Saif Afat, MD (*Abstract Co-Author*)

PURPOSE

Photon Counting CT (PCCT) has substantially enhanced coronary artery calcium (CAC) scoring and coronary computed tomography angiography (CCTA). However, the influence of modern AI-based denoising (AID) algorithms on image quality and their clinical interchangeability with quantum iterative reconstruction (QIR) has not been established. This study evaluated the impact of an AID algorithm on subjective and objective image quality and clinical interchangeability compared to QIR in cardiac PCCT.

METHODS AND MATERIALS

We retrospectively analyzed 100 patients (57±12 y, 26 female) who underwent CAC and CCTA scans using the same PCCT scanner. Scans were reconstructed with both QIR and AID, resulting in 400 datasets. Three radiologists independently assessed all dataset combinations for subjective image quality (-1 = inferior, 0 = equal, 1 = superior). Scores were averaged to obtain semiquantitative evaluations, with intra-rater reliability and inter-rater agreement assessed using Spearman's correlation coefficients. Objective image quality metrics included CT attenuation stability, noise (via Noise Power Spectrum, NPS), and edge-rise distance measurements at

cartilage-muscle interfaces (CAC) and contrast-enhanced chamber-muscle borders (CCTA). Clinical interchangeability was evaluated by comparing Agatston scores, coronary age assessments, manual correction times (CAC), and left ventricular end-diastolic volume (LVED) and muscle mass (CCTA) between QIR and AID datasets. Mixed-effects modeling, adjusted for relevant factors, analyzed pooled subjective and objective image quality results.

RESULTS

AID significantly improved subjective image quality compared to QIR ($p<0.001$), with very strong reliability/agreement ($r=0.76$). Objective analyses showed significantly reduced edge-rise distances and lower average NPS with AID compared to QIR for both CAC and CCTA (each $p<0.001$), while maximum and minimum CT attenuation values remained unchanged ($p=0.901$). Clinical interchangeability analyses revealed no significant differences between QIR and AID regarding Agatston scores, coronary age, manual correction times (each $p=0.532$), LVED volume ($p=0.153$), or muscle mass ($p=0.632$).

CONCLUSION

The AID algorithm is clinically interchangeable with QIR for cardiac PCCT applications while providing significantly enhanced subjective and objective image quality, particularly regarding noise reduction and improved sharpness.

CLINICAL RELEVANCE/APPLICATION

AID enhance PCCT by improving image sharpness and reducing noise. Clinicians can safely replace QIR with AID without compromising clinical usability. High consistency and reliability of image quality assessments across radiologists support widespread adoption.

R2-SPCH-1 SHARPER THAN EVER: OPTIMIZING KERNEL SELECTION FOR ULTRA-HIGH RESOLUTION PHOTON-COUNTING DETECTOR CT PULMONARY ANGIOGRAPHY

Pauline Pannenbecker, MD, BA (*Presenter*)
Philipp Gruschwitz, MD (*Abstract Co-Author*)
Jan P. Grunz, MD (*Abstract Co-Author*)
Thorsten A. Bley, MD (*Abstract Co-Author*)
Henner Huflage, MD (*Abstract Co-Author*)

PURPOSE

To identify the convolution kernel offering the best trade-off between image noise and vessel sharpness in ultra-high resolution CT pulmonary angiography (CTPA) with Photon-Counting Detector (PCD) at two dose levels.

METHODS AND MATERIALS

In this IRB-approved study, 152 CTPAs between April and October 2024 acquired on a dual-source PCD-scanner at two dose levels were retrospectively analyzed (76 PCD-CT at IQ level 50 with a CTDIvol of 6.7 mGy, 76 at IQ level 25 with a CTDIvol of 3.0 mGy). Scans were performed using flash mode (pitch 3.0, 140 kV tube voltage) and reconstructed at 55 keV in three vascular kernels (Bv48, Bv56, Bv64) and three quantitative kernels (Qr48, Qr56, Qr64). For each kernel, objective image quality parameters (vessel attenuation, signal-to-noise and contrast-to-noise (SNR, CNR)) were assessed using standardized ROIs. Subjective image quality was assessed using a browser-based, pairwise comparison tool with 8 radiologists performing 18,240 comparisons (9,120 per dose level), resulting in a preference-based ranking.

RESULTS

Attenuation in the main pulmonary artery peaked with intermediate sharpness kernels (Bv56 and Qr56) at both dose levels (e.g., Bv56: 640.5 HU at IQ25; 598.4 HU at IQ50; both $p < 0.001$), followed by Bv64/ Qr64 and Bv48/Qr48. Both, SNR and CNR decreased with increasing kernel levels, as is exemplified with a median CNR within the pulmonary trunk of 13.4 in Bv48 vs. 10.5 in Bv56 vs. 6.7 in Bv64 at IQ50 (all $p<0.001$). In subjective image ratings, Bv56 kernel was ranked highest, followed by Bv64, Bv48, Qr64, Qr56 and Qr48 respectively across both dose levels. Interreader reliability was substantial, indicated by a Kendall's W of 0.67.

CONCLUSION

Among all tested convolution kernels, Bv56 achieved the most favorable balance of vessel sharpness and image noise in ultra-high resolution CTPA using PCD-CT. This finding was consistent across both objective metrics and reader preference, independent of dose level.

CLINICAL RELEVANCE/APPLICATION

Selecting the appropriate reconstruction kernel for UHR CTPAs with PCD can have a relevant impact on both, subjective and objective image quality. Using Bv56 allows for excellent vascular visualization in the diagnosis of pulmonary embolism even at lower radiation dose levels.

R2-SPCH-2 EVALUATION OF THE LABORATORY D-DIMER TEST IN DETECTION OF PULMONARY EMBOLISM IN POST-OPERATIVE AND FRACTURE PATIENTS

Hannah Johnson, BS (*Presenter*)
Christian J. Konopka, MD, PhD (*Abstract Co-Author*)
Scott D. Long, MD (*Abstract Co-Author*)
Teresa Wilson (*Abstract Co-Author*)
Kristin Delfino (*Abstract Co-Author*)

PURPOSE

Recent surgery and lower limb fractures are risk factors for pulmonary embolism (PE). The risk of developing a PE post-operatively is 5 to 20-fold. Incidence among those with lower limb fracture is 0.35% to 24%. The consensus of the utility of the laboratory D-dimer test prior to a diagnostic computed tomography pulmonary angiogram (CTPA) varies. Currently, there are no D-dimer guidelines for ordering a CTPA at HSHS St. John's Hospital, a regional medical center in the rural Midwest. The aim of this study was to evaluate D-dimer levels and presence of PE in patients with recent surgery and lower limb fracture.

METHODS AND MATERIALS

This retrospective chart review included patients that presented to HSHS St. John's Hospital in Springfield, IL and underwent CTPA for suspected PE between January 1, 2022 and December 31, 2022. Data included clinical factors, D-dimer levels, and CTPA results. Continuous variables were compared using the T-test or Mann Whitney U test. Associations with categorical variables were analyzed with Fischer's Exact test. P-values < 0.05 were considered statistically significant.

RESULTS

A total of 660 patients were included in this study, with 8% positive for PE. Among these patients, 55 had either underwent surgery with general anesthesia or had a lower limb fracture within a month of presentation. Compared to those without recent surgery or fracture, this subgroup had a significantly higher incidence of PE (22% vs. 7%, $p < 0.001$). D-dimer levels were higher (elevated > 500 ng/mL) in the surgical-fracture cohort (1363 ng/mL [533-11781]) compared to the non-surgical cohort (911 ng/mL [81-19518]), but not statistically significant ($p = 0.0682$). Within the surgical-fracture cohort, patients with PE had a significantly lower oxygen saturation on presentation (96% [84-98]) compared to those without PE (98% [73-100], $p = 0.034$), and a significantly higher Wells Scores (6 [3-10.5]) compared to those without PE (4.5 [0-9], $p = 0.011$).

CONCLUSION

Significant association was found between history of recent surgery or lower limb fracture and presence of PE. The Wells Score was significantly greater among the surgical-fracture cohort patients with PE. Furthermore, the oxygen saturations among the surgical-fracture cohort were significantly lower in those with PE. Thus, the Wells Score and oxygen saturation may help facilitate clinical suspicion and detection of PE in patients with recent surgery or lower limb fracture. Future work will investigate potential differences in pulmonary involvement between the surgical-fracture and non-surgical-fracture PE cohorts utilizing CTPA scan results

CLINICAL RELEVANCE/APPLICATION

This study analyzes the D-dimer and other clinical factors in formulating clinical suspicion for PE prior to diagnostic CTPA.

R2-SPCH-4 THE CHARACTERISTICS OF PULMONARY ARTERY INVOLVEMENT IN TAKAYASU ARTERITIS BASED ON CTPA

Ran Xiao (*Presenter*)
Ruijie Zhao (*Abstract Co-Author*)
Rui Zhao (*Abstract Co-Author*)
Jiaru Wang (*Abstract Co-Author*)
Sirong Piao (*Abstract Co-Author*)
Zicheng Liao (*Abstract Co-Author*)
Ying Ming (*Abstract Co-Author*)
Wei Song, MD (*Abstract Co-Author*)
Longfei Zhao (*Abstract Co-Author*)
Bing Li (*Abstract Co-Author*)
Lin Li (*Abstract Co-Author*)

PURPOSE

Takayasu arteritis (TA) with pulmonary artery involvement (PAI) often leads to pulmonary hypertension (PH) and poor outcomes, but diagnosis remains challenging due to nonspecific symptoms. This study aimed to characterize TA-PAI using computed tomography pulmonary angiography (CTPA)-based quantitative analysis of pulmonary arterial volume (PAV) and compare imaging features between TA-PAI patients and controls, as well as between TA-PAI subgroups with and without PH.

METHODS AND MATERIALS

This retrospective study included 90 TA-PAI patients and 47 controls who underwent CTPA. PAV was automatically segmented and categorized by arterial diameter (=0.8, 0.8-1.6, 1.6-2.4, 2.4-3.2, 3.2-4.0, >4.0 mm). Imaging findings (stenosis, occlusion, dilation, aneurysm, wall thickening, thrombosis) and main pulmonary artery diameter were assessed. PH was defined echocardiographically. Clinical and laboratory data were collected.

RESULTS

TA-PAI patients showed significant PAV reductions in arteries =2.4-4.0 mm compared to controls ($p<0.001$), with the most pronounced loss in 1.6-3.2 mm vessels ($p=0.001$). The PH subgroup (n=17) had larger main pulmonary artery diameters ($p<0.001$) and higher frequencies of stenosis ($p=0.045$), dilation ($p=0.001$), and aneurysms ($p=0.007$) than the non-PH subgroup. No significant PAV differences were observed between PH and non-PH groups.

CONCLUSION

TA-PAI is characterized by significant volume loss in intermediate-sized pulmonary arteries (1.6-3.2 mm), detectable via CTPA. PH-associated TA-PAI exhibits more severe structural changes (stenosis, dilation, aneurysms), but PAV alone did not differentiate PH status, possibly due to sample size limitations.

CLINICAL RELEVANCE/APPLICATION

Quantitative CTPA analysis of PAV, particularly in 1.6-3.2 mm arteries, may aid early TA-PAI diagnosis and monitoring. The association of PH with arterial dilation/aneurysms underscores the need for vigilant hemodynamic assessment in TA-PAI. Further studies should validate PAV thresholds for disease stratification and explore longitudinal changes.

R2-SPCH-5 MULTICENTER EXTERNAL VALIDATION OF CT-BASED AI TOOL FOR ESTIMATING BONE MINERAL DENSITY

PURPOSE

To perform an external validation study of an AI tool for opportunistic osteoporosis detection on non-contrast chest CT in a real-world, multinational, multicenter setting, using spine DEXA as the reference standard.

METHODS AND MATERIALS

With IRB approval, 556 consecutive, non-contrast chest CT exams (mean age 65 ± 12 years; M:F 91:464) from 16 sites in Brazil and US were retrospectively identified either through manual review or an Epic-based clinical data warehouse. Adult patients (>/=21 years) with CT chest and spine DEXA performed within 12 months were included. Multivendor thin-section CT images (1-1.25 mm) were deidentified and processed with an AI tool (Claripi.Inc) for volumetric BMD estimation. Ground truth T-scores, Z-scores, and BMD values were extracted from corresponding DEXA reports. Statistical analysis included Kruskal-Wallis and median tests to assess non-normal BMD distributions across diagnostic categories.

RESULTS

DEXA-BMD values differed significantly across all three BMD categories (Normal BMD, Osteopenia, Osteoporosis) based on Kruskal-Wallis and median tests ($p < 0.001$). Post-hoc comparisons confirmed significant differences between all diagnostic groups ($p < 0.001$). AI-predicted BMD values also showed significant variation across categories, with higher medians in normal BMD subjects. AI-predicted BMD values significantly differentiated normal BMD from both osteopenia ($p < 0.001$) and osteoporosis ($p < 0.001$), however it failed to distinguish between osteopenia and osteoporosis ($p = 1.00$). Distribution analysis revealed greater variability in AI-

predicted CT-BMD values (mean = 88.5 mg/cc, SD = 41.9) compared to DEXA-BMD value (mean = 0.93 g/cm2, SD = 0.17), suggesting calibration or scaling limitations.

CONCLUSION

AI-based opportunistic assessment of bone mineral density from non-contrast chest CT demonstrates statistically significant differentiation between normal and osteoporosis groups. However, the AI model shows limited ability to distinguish between osteopenia and osteoporosis group and exhibits a higher variability in BMD estimations as compared to DEXA.

CLINICAL RELEVANCE/APPLICATION

CT-BMD estimation with non-contrast chest CT AI can provide an accessible, cost-effective screening tool for detecting low bone mineral density in a real-world, multi-institutional setting. Integration of such tools into clinical workflows could enable earlier identification and management of osteoporosis, especially in patients who may not otherwise undergo dedicated DEXA screening.

R2-SPCH-7 QUANTITATIVE EVALUATION OF PULMONARY PERFUSION AND VENTILATION IN PULMONARY HYPERTENSION PATIENTS USING PHASE-RESOLVED FUNCTIONAL LUNG MRI

Anqi Liu, MD (*Presenter*)
Linfeng Xi (*Abstract Co-Author*)
Min Liu (*Abstract Co-Author*)

PURPOSE

Recent advances have established phase-resolved functional lung MRI (PREFUL MRI) as a novel, noninvasive imaging technique for assessing regional pulmonary ventilation and perfusion. This study aimed to evaluate the value of quantitative PREFUL MRI parameters in distinguishing Group 1 pulmonary arterial hypertension (PAH) from Group 4 chronic thromboembolic pulmonary hypertension (CTEPH), with a particular focus on the correlation between pulmonary perfusion/ventilation parameters and hemodynamic indices, as well as their diagnostic performance.

METHODS AND MATERIALS

This prospective cohort study recruited patients with suspected pulmonary hypertension who underwent right heart catheterization and PREFUL MRI between January 2024 and January 2025. Pulmonary perfusion and ventilation parameters were obtained using PREFUL MRI. The K-W test was used to compare perfusion and ventilation parameters among different PH subgroups. Spearman correlation was applied to assess the relationships between PREFUL MRI parameters and hemodynamic measurements.

RESULTS

52 patients were included: 21 with Group 1 PAH, 22 with Group 4 CTEPH, and 9 with normal pulmonary arterial pressure (non-PH controls). The total ventilation defect percentage (VDPtotal) did not significantly differ among the three groups ($P > 0.05$). In contrast, the total perfusion defect percentage (QDPtotal) was significantly higher in PH patients (combining PAH and CTEPH) compared to non-PH controls (42.90% [23.90%-61.10%] vs. 10.20% [4.40%-20.10%], $P < 0.001$). QDPtotal was also significantly higher in the CTEPH group than in the PAH group (58.40% [39.52%-66.62%] vs. 31.00% [23.10%-47.00%], $P = 0.019$). QDPtotal was positively correlated with mean pulmonary arterial pressure (? = 0.544, $P < 0.001$), mean right ventricular pressure (? = 0.482, $P < 0.001$), and pulmonary vascular resistance (? = 0.505, $P < 0.001$). The area under the ROC curve (AUC) of QDPtotal for differentiating PAH from CTEPH was 0.709 ($P < 0.05$).

CONCLUSION

QDPtotal derived from PREFUL MRI effectively reflects the degree of pulmonary vascular pathology in PH patients, with more pronounced perfusion defects in CTEPH than in PAH. It correlates with hemodynamic parameters and shows moderate value for distinguishing PAH from CTEPH (AUC = 0.709), suggesting its potential as a noninvasive imaging biomarker for pulmonary hypertension.

CLINICAL RELEVANCE/APPLICATION

PREFUL MRI offers a noninvasive way to assess lung perfusion and ventilation, aiding in the diagnosis and classification of pulmonary hypertension. Its correlation with hemodynamics suggests potential for clinical monitoring and treatment guidance.

R2-SPCH-8 EMPHYSEMA ON BASELINE LOW-DOSE CT STRONGLY PREDICTS DEATH DUE TO CHRONIC PULMONARY OBSTRUCTIVE DISEASE AND CARDIOVASCULAR DISEASE UP TO 25 YEARS OF FOLLOW-UP OF ASYMPTOMATIC PARTICIPANTS IN PROGRAMS OF CT SCREENING FOR LUNG CANCER

Rowena Yip, PhD, MPH (*Presenter*)
Jessica Gonzalez (*Abstract Co-Author*)
Javier J. Zulueta, MD (*Abstract Co-Author*)
Samuel M. Aguayo (*Abstract Co-Author*)
Daniel M. Libby (*Abstract Co-Author*)
Mark Pasmantier, MD (*Abstract Co-Author*)
David F. Yankelevitz, MD (*Abstract Co-Author*)
Claudia I. Henschke, PhD, MD (*Abstract Co-Author*)

PURPOSE

The usefulness of assessing baseline visual emphysema in lung cancer screening (LCS) cohorts is unknown. Our study aims to determine whether assessment of emphysema on low-dose chest CT (LDCT) is a predictor of death up to 25 years later from all-causes, chronic obstructive pulmonary disease (COPD), and cardiovascular (CVD).

METHODS AND MATERIALS

Prospective cohort of smokers aged 40-85 years underwent baseline LDCT screening for LC between June 2000 and December 2008 and were followed until December 31, 2024.Visual emphysema was classified as none(0), mild(1), moderate(2), or severe(3). Self-reported smoking history and comorbidities were documented at baseline. Date and cause of death (ICD-10) were obtained from the National Death Index, physicians, and family. Adjusted Cox proportional hazards regression models and Fine-Gray subdistribution hazard model analyzed emphysema and mortality outcomes.

RESULTS

Among 9047 participants (51.2% women, 48.8% men; median age: 65 years [IQR:61-69]; median pack-years: 43[IQR:28-64]), 2637(29.1%) had emphysema. It was mild(1908;21.1%), moderate(512; 5.7%), and severe(217; 2.4%). After adjusting for sex, age, pack-years, and years since quitting, emphysema remained a significant predictor of all-cause mortality (HR: 1.29; 95%CI: 1.21-1.38), COPD mortality (HR: 3.28; 95%CI: 2.58-4.17), and CVD mortality(HR:1.14; 95%CI: 1.01-1.30). A dose-response relationship was observed between emphysema severity and both all-cause and COPD mortality, but not CVD mortality, with greater emphysema severity associated with higher risk. Adjusted Fine-Gray subdistribution hazard model, which accounts for competing risks, the association between emphysema and COPD mortality remained significant but was attenuated(HR: 3.01; 95%CI: 2.36-3.84), while the association with CVD mortality was no longer significant (HR: 1.02; 95%CI: 0.89-1.16).

CONCLUSION

Baseline emphysema on LDCT in asymptomatic participants of a LCS cohort predicts all-cause, COPD, and CVD mortality up to 25 years later, underscoring the importance of emphysema diagnosis in comprehensive LCS programs.

CLINICAL RELEVANCE/APPLICATION

Visual emphysema on baseline LDCT is a strong predictor of long-term mortality, particularly from COPD and cardiovascular disease. Incorporating emphysema assessment into lung cancer screening may improve risk stratification and guide preventive interventions beyond cancer detection.

R2-SPCH-9 PERFORMANCE OF ENSEMBLE DEEP LEARNING FOR DETECTION OF SURGICALLY-CONFIRMED CTEPH ON CT ANGIOGRAPHY

Yasmine Kasiri (*Presenter*)
Karen Pu (*Abstract Co-Author*)
Ye Ra Choi, MD (*Abstract Co-Author*)
Jihang Kim, MD (*Abstract Co-Author*)
Jenny Yang (*Abstract Co-Author*)
Nick H. Kim, MD (*Abstract Co-Author*)
Seth J. Kligerman, MD, MS (*Abstract Co-Author*)
Albert Hsiao, MD, PhD (*Abstract Co-Author*)

PURPOSE

Chronic thromboembolic pulmonary hypertension (CTEPH) is a surgically-treatable form of pulmonary hypertension associated with prior pulmonary embolism. Computed tomography angiography (CTA) is an essential diagnostic tool which can be used to confirm CTEPH diagnosis and disease extent. However, the features of CTEPH on CTA can be subtle and are often overlooked and misdiagnosed. Deep learning algorithms have potential to support diagnosis of rare and treatable diseases such as CTEPH. We therefore sought to evaluate a newly-developed algorithm to identify patients with surgically-confirmed CTEPH, and compare this performance against subspecialty radiologists.

METHODS AND MATERIALS

With IRB-approval and HIPAA-compliance, we evaluated the deep learning algorithm-an ensemble of eight convolutional neural networks (CNN)-to detect CTEPH in a composite population of 356 patients who underwent CTA. This included 211 patients who underwent CTA who had no clinical or radiologic evidence of CTEPH, and 145 patients who underwent pulmonary thromboendarterectomy (PTE). Three subspecialty radiologists with cardiovascular or thoracic subspecialty training each independently reviewed at least 100 CTAs for findings of CTEPH, including pulmonary arterial and right ventricular morphologic characteristics, blinded to clinical data, and overlap of at least 27 patients. Statistical analyses included Cohen's Kappa, area under the receiver operating characteristic curve (AUROC), sensitivity, and specificity for detection of disease.

RESULTS

In the 145 patients who underwent PTE surgery, the most proximal level of disease found surgically was 33%, 42%, 21%, and 4% for levels 1-4, respectively. Overall, there was strong agreement between the algorithm and readers (?=0.73-0.82) and between readers (?=0.73-0.83). The algorithm showed similar performance for detection of CTEPH (AUROC 0.96) to subspecialty radiologists (AUROC 0.91-0.98). At the Youden index, the algorithm had 90% sensitivity and 95% specificity for detecting CTEPH. Radiologists varied from 82-93% sensitivity and 95-98% specificity. For each disease level 1-4, the algorithm had 92-100% sensitivity and 91-99% specificity. In aggregate, radiologists showed 83-96% sensitivity and 95-98% specificity with slightly greater performance on proximal disease.

CONCLUSION

An ensemble convolutional neural network is capable of detecting surgically-confirmed CTEPH on CTA with performance comparable to subspecialty radiologists.

CLINICAL RELEVANCE/APPLICATION

A specialized deep learning algorithm may aid radiologists in identifying patients with CTEPH to facilitate medical or surgical management.

R2-SPCH-11 HEPATOPULMONARY SYNDROME - CHEST CT FINDINGS IN A LARGE COHORT

Matthew T. Stib, MD (*Presenter*)
Jeremiah Sanders, PhD (*Abstract Co-Author*)
Michael B. Gotway, MD (*Abstract Co-Author*)
Carlos Andres Rojas, MD (*Abstract Co-Author*)
Prasad M. Panse, MD (*Abstract Co-Author*)

PURPOSE

Hepatopulmonary syndrome (HPS) is a complication of liver disease characterized by pulmonary vascular dilations and impaired oxygenation. On computed tomography (CT), parenchymal changes seen in HPS can overlap with features of pulmonary fibrosis, raising the risk of misdiagnosis and potentially excluding patients from liver transplantation, the only definitive treatment for HPS. We evaluated CT findings in a large cohort of HPS patients before and after liver transplantation.

METHODS AND MATERIALS

The retrospective study included consecutive patients from a multi-center academic institution with clinically confirmed HPS and chest CT. 99mTc-MAA lung perfusion scintigraphy and pulmonary function testing was recorded when available. A subset of patients had a post-operative chest CT scan (>6 months after transplantation). CTs were reviewed for subpleural reticulation and peripheral ground-glass (features hypothesized to relate to HPS) and for findings of fibrosis, including traction bronchiectasis and honeycombing (unrelated to HPS). Measurements were recorded of the pulmonary vasculature.

RESULTS

A total of 246 patients met inclusion criteria. The mean age was 58 years, and 29% were female. Mean PaO2 was 54.7 mmHg and mean MAA lung scintigraphy shunt fraction was 25.2%. PFTs demonstrated abnormal diffusion capacity (mean DLCO was 50.6%). The mean main pulmonary artery diameter was normal (26.5 mm). Subsegmental pulmonary veins were enlarged (mean 7.1 mm), compared to arteries (5.7 mm) and bronchi (5.0 mm), resulting in an elevated vein-to-bronchus ratio of 1.4. Subpleural reticulation and peripheral ground-glass were present in 70% and 21%, respectively. Findings consistent with fibrosis, including moderate/severe traction bronchiectasis and honeycombing, were observed in 4% and 1%, respectively. Following transplantation, subsegmental pulmonary veins and arteries decreased in diameter by 1.3 mm ($p < 0.001$) and 0.3 mm ($p < 0.001$), respectively. Subpleural reticulation also decreased ($p = 0.04$).

CONCLUSION

Subpleural reticulation and ground-glass opacities, often present in HPS, can mimic pulmonary fibrosis, and that an increased subsegmental vein-to-bronchus ratio serves as a useful distinguishing feature. Post-transplant CT showed improvement in vascular abnormalities and a reduction in subpleural reticulation.

CLINICAL RELEVANCE/APPLICATION

CT findings in HPS may be misinterpreted as pulmonary fibrosis, potentially leading to inappropriate exclusion of patients from transplantation. Our results demonstrate that many of these imaging abnormalities improve following transplantation, suggesting that recognition of these distinct features could expand transplant eligibility.

R2-SPCH-12 HOW CONCURRENT BOUNDING-BOX DISPLAY AFFECTS VISUAL SEARCH IN CHEST X-RAY READING: AN EYE-TRACKING PILOT STUDY

Tomohiro Kikuchi, MD, PhD (*Presenter*)
Yusuke Takagi (*Abstract Co-Author*)
Daiju Ueda, MD, PhD (*Abstract Co-Author*)
Ryoma Kobayashi, MD (*Abstract Co-Author*)

soichiro kojima, MD (*Abstract Co-Author*)
Daisuke Matsumoto, MD (*Abstract Co-Author*)
Ryo Sato (*Abstract Co-Author*)
Sho Kawabe, MBA (*Abstract Co-Author*)
Harushi Mori, MD, PhD (*Abstract Co-Author*)

PURPOSE

To quantify how concurrent-reader-style bounding-box (BB) highlighting affects radiologist behavior during chest-radiograph interpretation and to obtain preliminary insights that may guide its clinical use.

METHODS AND MATERIALS

A total of 180 chest radiographs were extracted from the VinDR-CXR data set: 120 contained a single solitary pulmonary nodule or mass and 60 contained neither. BBs were manually placed to achieve overall display sensitivity and specificity of 80%. Correct BBs were applied to 96 of the 120 lesion-positive images, defining the true-positive (TP) group.Three radiologists (11-, 5- and 1-years' experience) interpreted every case twice. Images were first shown with BBs (simulated concurrent-read AI support) and, after a wash-out interval of =10 days, were reread without BBs. Readers assessed only the lung fields. To emulate routine AI use, they were falsely informed that the boxes came from an algorithm reporting 80% sensitivity and specificity. They were told that eye-tracking would be performed, but its purpose was not disclosed.Gaze data were recorded with an EyeTech VT3 Mini. Analysis focused on the TP group. Outcomes were the percentage change between readings with and without BBs in (i) interpretation time, (ii) time to first fixation on the lesion, (iii) dwell time on the lesion, (iv) gaze-path length and (v) lung-field coverage, defined as the percentage of 50-pixel lung-field grid cells crossed by the gaze path. Each outcome was modelled with a generalized linear mixed model (GLMM) that treated reading condition as a fixed effect and both case and tester as random intercepts to test for significant changes.

RESULTS

Without BBs, the lowest-highest per-reader means were 6.1-12.0 s for interpretation time, 2.2-2.6 s for time to first fixation on the lesion, 0.8-3.9 s for dwell time on the lesion, 2.8-7.0 × 10 3 pixels for gaze-path length, and 45-69 % for lung-field coverage.GLMM estimates (BB-assisted ÷ unassisted) were: interpretation time = 1.45× (95 % CI 1.32-1.60; $p < 0.001$); time to first fixation on the lesion = 0.70× (0.53-0.93; $p = 0.014$); dwell time on the lesion = 4.31× (2.94-6.32; $p < 0.001$); gaze-path length = 1.42× (1.30-1.54; $p < 0.001$); and lung-field coverage = 1.21× (1.18-1.25; $p < 0.001$).

CONCLUSION

Within the TP group, concurrent lesion highlighting accelerates initial localization yet prolongs overall reading by encouraging additional verification, producing a "find fast, verify thoroughly" workflow.

CLINICAL RELEVANCE/APPLICATION

Because concurrent BB prompts can simultaneously hasten detection and extend verification, recognizing their net impact on individual reading styles is essential for radiologists aiming to integrate AI tools judiciously into clinical practice.

R2-SPCH-13 DIFFERENCES IN PULMONARY ARTERIAL AND VENOUS VOLUMES BETWEEN SUPINE AND UPRIGHT CT SCANS

Orito Ikeda (*Presenter*)
Yoshitake Yamada, MD, PhD (*Abstract Co-Author*)
Minoru Yamada, RT (*Abstract Co-Author*)
Yoichi Yokoyama, MD (*Abstract Co-Author*)
Masahiro Jinzaki, MD, PhD (*Abstract Co-Author*)

PURPOSE

Postural changes affect pulmonary blood flow and vascular volume; however, no prior study has quantitatively assessed these effects by separately evaluating pulmonary arteries and veins. The recently developed upright 320-detector-row CT and advances in 3D imaging have made such evaluation feasible. This study aimed to quantify changes in pulmonary vascular volume (PVV), arterial volume (PAV), and venous volume (PVnV) from the supine to standing position across the whole lung, individual lobes, and the upper, middle, and lower regions, to characterize gravity-dependent vascular distribution.

METHODS AND MATERIALS

This prospective study was approved by the IRB. CT scans performed between January and December 2018 were included. Sixty-two healthy adults underwent both supine and upright CT within 2 h. Twelve participants were excluded owing to peripheral abnormalities (e.g., nodules and atelectasis) or technical issues (e.g., motion or poor inspiration), leaving 50 participants for analysis. Arteries and veins were semi-automatically segmented using Synapse Vincent (Fujifilm). PVV, PAV, and PVnV were measured for the whole lung, each lung, and regions defined as upper (above the carina), middle (below the carina), and lower (below left B8/B9+10). Vascular density was calculated as vessel volume divided by lung volume. Paired t-tests were used for comparisons.

RESULTS

From supine to standing, PVV decreased by 18.8±8.5%, PAV by 11.1±6.8%, and PVnV by 25.4±7.4% (all $p < 0.001$), with venous reductions exceeding arterial ones. By region, PVV decreased by 25.2±8.1% in the upper lung, 20.9±6.7% in the middle, and 12.0±9.6% in the lower. PAV decreased by 20.1±9.2%, 10.3±7.2%, and 6.0±10.9%, while PVnV decreased by 30.0±11.2%, 32.6±8.5%, and 16.7±11.3%, respectively (all $p < 0.001$). Vascular density showed a similar pattern, with greater reductions in the upper and middle lungs.

CONCLUSION

Transitioning from supine to standing significantly reduced both PAV and PVnV, with a more pronounced decrease in PVnV. Reductions in PAV and PVnV were greater in the upper and middle lung regions, with the smallest decreases observed in the lower regions.

CLINICAL RELEVANCE/APPLICATION

This study provides the first quantitative assessment of postural changes in pulmonary arterial and venous volumes in healthy individuals, demonstrating vascular redistribution in the upright position. These findings establish a physiological baseline that may inform future investigations into pathologic vascular alterations, such as those in pulmonary hypertension or heart failure.

R2-SPER-1 ACTIVE BLEEDING ON ADMISSION CT CORRELATES WITH BLOOD TRANSFUSION NEEDS IN THE SETTING OF MULTI-SYSTEM TRAUMA

Abigail Abernathy, MD (*Presenter*)
Greg Gaski, MD (*Abstract Co-Author*)
Todd McKinley, MD (*Abstract Co-Author*)
Katherine Frey (*Abstract Co-Author*)
Scott D. Steenburg, MD (*Abstract Co-Author*)

PURPOSE

To evaluate if trauma patients with active bleeding detected on CT scan had different transfusion needs than trauma patients without active bleeding.

METHODS AND MATERIALS

Data were extracted from the database from large, prospective multi-center trial comprised of trauma centers participating in the Major Extremity Trauma and Rehabilitation Consortium (METRC). Active bleeding was identified on deidentified whole body computed tomography scans by a trauma radiologist. The patient cohort was divided into two groups: patients with and those without active bleeding detected on admission CT. Clinical data from each patient was collected including number of transfusions and transfusion volume. Shock index (SI) was calculated for each patient using admission heart rate (HR) and systolic blood pressure (SBR, SI=HR/SBP). Data were analyzed using unpaired T-tests, with a P value of < 0.05 considered to be statistically significant. P values of < 0.05 was considered to be statistically significant.

RESULTS

The study cohort consisted of 321 patients, of which 37 (11.5%) were found to have active bleeding on admission CT. Patients with active bleeding on initial CT were found to have significantly higher mean number of transfusions (4.46 vs 1.81, $p<0.0001$), mean transfusion volume (2.57L vs 1.05L, $p=0.0008$), and mean shock index scores (1.00 vs 0.888, $p=0.0329$) compared to patients without active bleeding detected on admission CT. The active bleeding rate for patients who received blood transfusions was higher than those who did not receive a blood transfusion, though the difference was not statistically significant (4.72 mL/min vs 1.56 mL/min $p=0.1869$).

CONCLUSION

Trauma patients with active bleeding identified on admission CT had greater transfusion needs than patients without active bleeding, requiring a higher mean number of transfusions and transfusion volume. Additional larger studies are needed to confirm the findings of this pilot study and further investigate the role of using admission CT as a tool to potentially prospectively predict trauma patient transfusion needs.

CLINICAL RELEVANCE/APPLICATION

Early detection of active bleeding on CT in the patient evaluation process may prospectively identify patients who require blood transfusions.

R2-SPER-2 ARTIFICIAL INTELLIGENCE-BASED SOFTWARE DETECTION OF MISSED HEMORRHAGES ON BRAIN CTS IN THE EMERGENCY DEPARTMENT

Dongyeong Kim, MD (*Presenter*)
Narae Yang (*Abstract Co-Author*)
Sujeong Kwon, BA (*Abstract Co-Author*)
Eunjee Youk (*Abstract Co-Author*)
Jihwan Kim, BSc, MSc (*Abstract Co-Author*)
Taehyun Kim (*Abstract Co-Author*)
Gil-Sun Hong, MD, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate the sensitivity of artificial intelligence (AI)-based software in detecting missed intracranial hemorrhages (ICH) on non-enhanced head CTs (NECT) in the emergency department (ED), and to assess the potential impact on patients' clinical outcomes.

METHODS AND MATERIALS

In this retrospective study, we identified 240 patients who underwent NECT for traumatic or non-traumatic headaches in the ED of a single urban tertiary academic center between January 2010 and February 2024. All patients were initially discharged with a diagnosis of "no ICH," but were later confirmed with ICH based on final radiology reports. After excluding 47 patients who either lacked follow-up or had follow-up shorter than a week, 193 patients were included in the final analysis. We applied a commercial AI software to detect missed ICH in this cohort and evaluated its per-patient sensitivity using two modes: standard (A mode) and high-sensitivity (B mode), as provided by commercial AI software. We also examined patients' adverse clinical outcomes, including hospitalization, delayed surgery, and in-hospital mortality.

RESULTS

Overall, the per-patient sensitivity for detecting missed ICH was 74.6% (144 of 193) in A mode and 82.4% (159 of 193) in B mode. Among the 193 patients included in the final cohort, 75.6% (146 of 193) had a history of trauma, while 24.4% (47 of 193) had no history of trauma. In trauma-related cases, the AI detected 76.7% (112 of 146) of missed ICH in A mode and 85.6% (125 of 146) in B mode. In non-trauma cases, the detection rates were 68.1% (32 of 47) in A mode and 72.3% (34 of 47) in B mode. There were two adverse events in the cohort: one hospitalization for a traumatic ICH and one delayed surgical intervention for a non-traumatic ruptured aneurysm. The AI software detected only the traumatic ICH in A mode, but detected both events in B mode. Accordingly, the number of potentially preventable adverse events was one with A mode and two with B mode.

CONCLUSION

Depending on the operational mode and trauma status, the AI software demonstrated moderate-to-high sensitivity in detecting missed ICH on NECTs performed in the ED. The high-sensitivity mode improved detection performance and successfully identified all ICH associated with adverse clinical outcomes in this cohort.

CLINICAL RELEVANCE/APPLICATION

Integration of AI into the ED workflow may help reduce missed ICH diagnoses and potentially prevent adverse events. However, the trade-off between sensitivity and specificity in high-sensitivity modes necessitates careful implementation to avoid overdiagnosis and alarm fatigue.

R2-SPGI-2 DEVELOPMENT OF A CT RADIOMICS MODEL TO PREDICT LOCALLY ADVANCED DISEASE IN GASTRIC ADENOCARCINOMA

Sk Rahatul Jannat, PhD, MS (*Presenter*)
Kyle Klingbeil, MD,PhD,BS (*Abstract Co-Author*)
Dighvijay Giri (*Abstract Co-Author*)
Ketki Kinkar (*Abstract Co-Author*)
Steven Cen, PhD (*Abstract Co-Author*)
Anokh Pahwa, MD (*Abstract Co-Author*)
Maitraya K. Patel, MD (*Abstract Co-Author*)
Karoly Viragh, MD (*Abstract Co-Author*)
Mariam Thomas, MD (*Abstract Co-Author*)
Brian Kadera (*Abstract Co-Author*)
Bino A. Varghese, PhD (*Abstract Co-Author*)

PURPOSE

Gastric adenocarcinoma often requires computed tomography (CT), endoscopic ultrasound (EUS) and diagnostic laparoscopy (DL) to define clinical TNM staging. Patients with locally advanced disease (T2+ or N1+) benefit from neoadjuvant chemotherapy prior to gastrectomy. Development of a CT radiomics model that accurately predicts clinical TNM staging may reduce the reliance on invasive diagnostic procedures, thereby streamlining diagnosis and optimizing treatment decisions.

METHODS AND MATERIALS

A retrospective cohort of patients diagnosed with gastric cancer from a single hospital system who underwent CT imaging at time of diagnosis were included for analysis. Clinical TNM staging was defined by EUS and DL, serving as the gold standard. Automated stomach segmentation was performed using 3DSlicer (v4.11.0) software with the Total Segmentator extension and validated by an expert radiologist. A total of 120 radiomic features were extracted using PyRadiomics software. Random Forest was used to predict TNM staging with a 10-fold cross validation. Performance was reported as area under the ROC curve (AUC). SAS 9.4 was used for all statistical analyses.

RESULTS

Ninety-nine patients were included, with distributions of T1 (n=19), T2 (n=24), T3 (n=46), N0 (n=52), N1 (n=18), N2 (n=19), M0 (n=89) and M1 (n=10) disease. The cohort comprised 58 males and 41 females, with a mean age of 68 ± 15.85 years. Tumors were predominantly located in the distal stomach (n=71, 71.7%). Histologically, 38 tumors were diffuse subtype, and 42 were intestinal subtype. Automated segmentation of the stomach accurately outlined the stomach. Performance by 10-fold cross validation showed AUCs of 0.88 (95% CI: 0.81-0.95) for T1 vs T2/T3; 0.99 (95% CI: 0.97-1.00) for N0 vs N1/ N2; and 0.84 (95% CI: 0.76-0.93) for M0 vs M1, indicating very good to excellent discrimination ability. The clinical relevance of radiomic features was assessed through univariate analysis, revealing differing proportions of metrics with statistically significant associations across various clinical stage comparisons: 28% for T1 vs (T2, T3), 42% for (T1, T2) vs T3, 24% for T2 vs (T3, T1), 47% for N0 vs (N1, N2), 42% for (N0, N1) vs N2, and 13% for M0 vs M1.

CONCLUSION

We developed a CT radiomics model capable of accurately predicting clinical TNM staging in patients with gastric adenocarcinoma. The model demonstrated excellent performance, particularly in identifying locally advanced disease.

CLINICAL RELEVANCE/APPLICATION

The use of radiomic models to predict clinical TNM staging in gastric adenocarcinoma may reduce the reliance on invasive procedures, which are not universally available, thereby streamlining and expanding access to cancer care.

R2-SPGI-4 PREDICTING NEUROENDOCRINE TUMOR SSTR POSITIVITY AND GRADE USING RADIOMICS AND PHOTON-COUNTING DETECTOR CT

Jacob Lam, MD (*Presenter*)
Natally AlArab, MD, MSc (*Abstract Co-Author*)
Nikahat Yasmine, MBBS, MD (*Abstract Co-Author*)
Ryan Staudte, MD (*Abstract Co-Author*)
Ramandeep Singh, MD, MBBS (*Abstract Co-Author*)

PURPOSE

To predict somatostatin receptor (SSTR) positivity and grade of neuroendocrine tumors using radiomic features on photon-counting detector CT (PCD-CT) images of neuroendocrine tumor (NET) metastatic focal liver lesions.

METHODS AND MATERIALS

Retrospectively, 82 liver lesions (29 M; 53 F; mean age 67 ± 9 years) from metastatic pancreatic (n=25), small bowel (n = 31), and lung NETs (n = 26) with dual phase protocol on PCD-CT were assessed. SSTR positivity was recorded from pathology reports, with 66 positive cases and 16 negative cases. Grades (G) were assigned using Ki-67 index, with 14 G1, 44 G2, and 26 G3 cases. Axial single photon processing (SPP) arterial and venous phase images were exported and processed on a standalone prototype (Radiomics V1.5.0, Siemens Healthineers, Forchheim, Germany) which allowed automatic generation of features for virtual monoenergetic (VM), iodine maps (I) and virtual non-contrast (VNC) images of each phase within the prototype. 854 radiomic features (110 original and 744 wavelet) were extracted. Multivariate logistic regression and receiver operating characteristics were performed.

RESULTS

When comparing SSTR positive and negative arterial images, virtual non-contrast and iodine images had the greatest AUC of 0.87. Combining the best features from multiple series resulted in an AUC of 0.93. For venous images, SPP images had the greatest AUC of 0.94 followed by VM 60 keV and iodine images (both AUC 0.93). The combination of best features resulted in an AUC of 0.95. When comparing the grades of tumors, the greatest AUC for arterial images series were iodine (0.86), virtual non-contrast (0.85), and VM 40 keV (0.85). For venous images, the greatest AUCs were also found in iodine (0.92) and VM 40 keV (0.91). Combining the best features from multiple series resulted in AUCs of 0.90 and 0.93 for arterial and venous images, respectively.

CONCLUSION

Radiomic features of liver lesions on photon counting detector CT (PCCT) virtual non-contrast, virtual monoenergetic and iodine images can potentially differentiate SSTR positivity and grade of lesions in the liver.

CLINICAL RELEVANCE/APPLICATION

Radiomics holds promise as a non-invasive tool for stratifying metastatic neuroendocrine tumors. As SSTR serves as a drug target and SSTR positivity is correlated to increased survival in NET patients, determining a patient's SSTR status has great prognostic value. Additionally, neuroendocrine tumor grade impacts the accuracy of diagnostic PET scans and also has prognostic value. Incorporating radiomic analysis into clinical practice may enhance treatment decision-making and monitoring in patients with neuroendocrine tumor metastases, optimizing therapeutic strategies and patient care.

R2-SPGI-5 DYNAMICS OF INTRAHEPATIC FAT AND IRON FOLLOWING SVR IN PATIENTS WITH CHRONIC HEPATITIS C: ANALYSIS USING MULTI-ECHO CHEMICAL-SHIFT-ENCODED MR IMAGING

Hiromitsu Onishi, MD, PhD (*Presenter*)
Atsushi Nakamoto, MD, PhD (*Abstract Co-Author*)
Takashi Ota, MD, PhD (*Abstract Co-Author*)
Hideyuki Fukui, MD, PhD (*Abstract Co-Author*)
Masatoshi Hori, MD, PhD (*Abstract Co-Author*)
Noriyuki Tomiyama, MD, PhD (*Abstract Co-Author*)
Takahiro Tsuboyama, MD (*Abstract Co-Author*)
Kengo Kiso (*Abstract Co-Author*)
Toru Honda, MD (*Abstract Co-Author*)

PURPOSE

The purpose of this study was to evaluate the transition of liver fat and liver iron concentration (LIC) using the R2* value of MR imaging to investigate the influence of intrahepatic fat and iron on carcinogenesis after sustained virological response (SVR) in patients with chronic hepatitis C.

METHODS AND MATERIALS

This retrospective study included 21 patients (9 men and 12 women) who underwent MR imaging for evaluation of hepatocellular carcinoma before and after SVR of hepatitis C virus. Of the 21 patients, 15 had chronic hepatitis C and six had cirrhosis caused by hepatitis C virus. The examinations were performed with a 3.0-T MR system, and proton density fat fraction (PDFF) maps and R2* maps were obtained using confounding factor-corrected multi-echo chemical-shift-encoded MR imaging (IDEAL-IQ; TR: 6.7 ms, TE: 1.0, 1.8, 2.6, 3.4, 4.2, 5.0 ms, FA: 3°) together with other images. Approximately 1.5-cm 2 regions of interest were placed in eight segments of the liver, from S1 to S8, avoiding blood vessels, bile ducts, and focal lesions. The PDFF and R2* values of the liver parenchyma were respectively measured on the maps, and the LIC was calculated from the R2* values using the method of d'Assingnies et al. The PDFF and LIC before and after SVR were compared using paired t -tests. P values less than 0.05 were considered significant.

RESULTS

The period between SVR and subsequent MR imaging ranged from 1.3 to 9.6 years (mean, 5 years). The PDFF before SVR ranged from 0.54% to 9.36% (mean, 2.82%) and the PDFF after SVR ranged from 0.64% to 4.93% (mean, 2.32%; P = .32). Of the 21 patients, seven had an increase in PDFF of 10% or more and nine had a decrease of 10% or more after SVR. The LIC before SVR ranged from 538 μg/g to 1047 μg/g (mean, 779 μg/g) and the LIC after SVR ranged from 489 μg/g to 1321 μg/g (mean, 731 μg/g; P = .84). Of the 21 patients, six had an increase in LIC of 10% or more and seven had a decrease of 10% or more after SVR.

CONCLUSION

Intrahepatic fat and iron fluctuated in individual patients after SVR in hepatitis C virus, although no significant changes were observed on average.

CLINICAL RELEVANCE/APPLICATION

Given the finding that intrahepatic fat and iron levels change after sustained virological response in patients with chronic hepatitis C, further investigation of the impact of these dynamics on the development of hepatocellular carcinoma is imperative.

R2-SPGI-6 FEASIBILITY OF HIGH-RESOLUTION 3D MRI OF THE MESOESOPHAGUS IN HEALTHY VOLUNTEERS - FIRST IN VIVO QUANTIFICATION

Sebastian Kubasch (*Presenter*)
Marc-David Kunnemann (*Abstract Co-Author*)
Emily Hoffmann (*Abstract Co-Author*)
Jens Peter Holzen (*Abstract Co-Author*)
Mazen Juratli (*Abstract Co-Author*)
Jan Philipp Masthoff (*Abstract Co-Author*)
Tobias Krahling (*Abstract Co-Author*)
Gesa Helen Pohler (*Abstract Co-Author*)

PURPOSE

To proof the feasibility of establishing normative volume values for the esophagus and mesoesophagus using 3T MRI in healthy volunteers and to explore the correlation between the esophagus volume and the mesoesophagus volume.

METHODS AND MATERIALS

In a single-center study, 25 healthy volunteers were examined using a 3T MRI scanner. The esophagus and extra-esophageal mesoesophagus volumes were semiautomatically segmented using Slicer 3D software. The volumes were extracted in both voxel count and cubic millimeters. Spearman's rank correlation was applied to assess the relationship between the esophagus and mesoesophagus volumes. Subgroups of male and female healthy volunteers have been created and the Spearman's rank correlation was applied again.

RESULTS

In all healthy volunteers (100%), the aortopleural ligamant and the ductus thoracicus were detected and used to accurately define the dorsal mesoesophagus. The median volume of the infracarinal esophagus was 6739.03 mm^3 (25th percentile: 5768.29 mm^3; 75th percentile: 8946.31 mm^3), and for the mesoesophagus 5866.9 mm^3 (25th percentile: 3610.74 mm^3; 75th percentile: 7763.04 mm^3). The study revealed a correlation between the esophagus and mesoesophagus volumes, with a Spearman rank correlation coefficient of 0.758 (p = 1.12 × 10?5). In male volunteers, the Spearman rank correlation was significant in male participants with 0.770 (p = 0.009) and in female participantswith 0.593 (p = 0.020). There was no significant correlation to Age, BMI and pack years (p>0.05).

CONCLUSION

This is the first in vivo study to visualize and quantify the mesoesophagus using high-resolution 3T MRI. The technique proves feasible and reveals a strong volumetric relationship with the esophagus. These normative data provide a foundation for future studies and may support individualized staging and treatment monitoring in esophageal cancer.

CLINICAL RELEVANCE/APPLICATION

Establishing normative volume data for the esophagus and mesoesophagus using 3T MRI enables more precise anatomical assessment, which may enhance staging accuracy and preoperative planning in esophageal cancer.

R2-SPGI-7 PREOPERATIVE PREDICTION OF TUMOR BUDDING GRADE IN RECTAL CANCER BY MULTI-FREQUENCY MAGNETIC RESONANCE ELASTOGRAPHY AND TIME-DEPENDENT DIFFUSION MRI:A PRELIMINARY STUDY

Aerzuguli Abudulimu (*Presenter*)
Yijing Luo (*Abstract Co-Author*)
Mengsi Li (*Abstract Co-Author*)
Yigang Pei, MD (*Abstract Co-Author*)
Wenguang Liu (*Abstract Co-Author*)
Yuting Shi (*Abstract Co-Author*)
Huiting Zhang (*Abstract Co-Author*)
Lan Zhou (*Abstract Co-Author*)
Wenzheng Li, MD,PhD (*Abstract Co-Author*)

PURPOSE

To investigate whether multi-frequency magnetic resonance elastography and time-dependent diffusion magnetic resonance imaging techniques can be used to predict tumor budding grade in rectal cancer preoperatively.

METHODS AND MATERIALS

This prospective study enrolled 107 patients with pathologically confirmed rectal cancer between April 2023 and December 2024. Preoperative conventional MRI, multi-frequency MRE and t d -dMRI were performed in all patients who underwent tumor resection surgery. The clinical data ,imaging features of conventional MRI, mechanical parameters c,f) of mMRE and the quantitative parameters of t d -dMRI (diameter , f in , D ex , cellularity , D 50Hz , D 25Hz , D 0Hz) of the patients were collected. The patients were categorized into the low-intermediate grade tumor budding group (BD 1+2) and the high grade tumor budding group (BD 3) according to the postoperative HE staining results. Three models were constructed respectively based on mMRE parameter (Model1), t d -dMRI parameter (Model2) and combination of mMRE and t d -dMRI parameters (Model3).

RESULTS

(1)Analysis of clinical data.The mMRE mechanical parameters (c and f), and t d -d MRI quantitative parameters (f in and cellularity) in the high grade tumor budding group of rectal cancer were significantly higher than those in the low-intermediate grade tumor budding group (P = 0.006, <0.001, <0.001, 0.001, <0.001, respectively)(Table1 ,Table2). The t d -dMRI quantitative parameter (D 0Hz) in the high grade tumor budding group of rectal cancer was significantly lower than that in the low-intermediate grade tumor budding group (P = 0.002)(Table 2).(2) Predicting tumor budding grade in rectal cancer based on mMRE parameter, t d -dMRI parameter and a combination of mMRE and t d -dMRI parameter.Three separate multivariate logistic regression were performed to construct three models. The nomogram based on Model 1 was constructed using cN staging and tumor shear wave speed (c)(Table 3, Figure1) .The nomogram based on Model2 was constructed using cN stage and cellularity (Table 4, Figure 2) .The nomogram based on Model 3was constructed using tumor shear wave speed (c) and cellularity (Table 5, Figure 3) .

CONCLUSION

The model based on the combination of mMRE and t d -dMRI parameter showed higher diagnostic and clinical decision-making value compared to the single quantitative models for preoperative prediction of tumor budding grade in rectal cancer.

CLINICAL RELEVANCE/APPLICATION

The model based on the multi-frequency magnetic resonance elastography and time-dependent diffusion MRI is a potential tool for noninvasively evaluating tumor budding grade in rectal cancer ,which may contribute to personalized treatment strategies for patients withrectal cancer.

R2-SPGI-8 IMAGING CHARACTERISTICS OF PORTOSINUSOIDAL VASCULAR DISEASE: A RETROSPECTIVE COHORT FROM A TERTIARY CENTER IN MEXICO CITY WITH IMPLICATIONS FOR DIAGNOSTIC ACCURACY AND QUALITY OF CARE

Tania D. Grimaldo Galeana, MD (*Presenter*)
Elisa De Jesus Ramos, MD (*Abstract Co-Author*)
Eunice L. Urbina Marure, MD (*Abstract Co-Author*)

PURPOSE

Portosinusoidal vascular disease (PSVD) is a rare and underrecognized liver disorder characterized by portal hypertension without cirrhosis and with preserved liver function. Misdiagnosis can lead to inappropriate management. Despite increasing use of cross-sectional imaging in liver disease, the radiologic features of PSVD are poorly defined. This study aimed to describe the imaging characteristics of PSVD on contrast-enhanced CT and Doppler ultrasound to improve diagnostic accuracy and support clinical decision-making.

METHODS AND MATERIALS

We performed a retrospective study of patients evaluated for abnormal liver tests or signs of portal hypertension who underwent liver biopsy at the Instituto Nacional de Ciencias Médicas y Nutrición "Salvador Zubirán" (2010-2024). PSVD diagnosis was based on high-quality biopsy excluding cirrhosis and meeting at least one of the following: (1) specific portal hypertension signs (varices, bleeding, collaterals), (2) PSVD-specific histology (obliterative portal venopathy, nodular regenerative hyperplasia), or (3) non-specific signs of PH (ascites, thrombocytopenia, splenomegaly) plus non-specific histological lesions. Patients without multiphasic CT within three months of diagnosis or with incomplete data were excluded. We analyzed clinical, histologic, and imaging features including portal vein thrombosis, collateral vessels, ascites, hepatic nodules, spleen volume, and portal vein flow velocity. Overall survival was calculated from the date of portal hypertension or abnormal tests to last follow-up.

RESULTS

Fifty-six patients were included (57.1% female; median age 42.6 years). Most presented with portal hypertension complications (62%), primarily hemorrhagic (54.2%). Comorbidities were identified in 51.8%, predominantly immune-mediated diseases (48.2%).CT revealed splanchnic vein thrombosis in 35.7%, portosystemic collaterals in 53.6%, ascites in 30.4%, and hepatic nodules in only 7.1%. Mean splenic volume was 766.4 cc and splenic length 16.6 cm.On Doppler, mean portal vein velocity was 13.5 cm/s. Splenomegaly was observed in 46.4%.Mean overall survival was 7.6 years, with 92.9% of patients alive at last follow-up.

CONCLUSION

PSVD imaging overlaps with cirrhosis but shows key distinctions: relatively preserved portal flow, fewer hepatic nodules, and frequent vascular abnormalities (thrombosis, collaterals). Recognizing these patterns is essential since PSVD does not require HCC surveillance and often follows a benign course. Incorporating imaging findings may improve diagnostic algorithms and patient care.

CLINICAL RELEVANCE/APPLICATION

Identifying imaging predictors of progression may enable earlier intervention and reduce morbidity in PSVD patients.

R2-SPGI-10 PREOPERATIVE PREDICTION OF PERINEURAL INVASION IN PANCREATIC DUCTAL ADENOCARCINOMA USING DUAL-LAYER SPECTRAL DETECTOR CT

Jiawei Liu (*Presenter*)
Luyong Wei (*Abstract Co-Author*)
Liqin Wang (*Abstract Co-Author*)
Jinhui Yu (*Abstract Co-Author*)
Shi-Ting Feng (*Abstract Co-Author*)
Mingjie Chen (*Abstract Co-Author*)
Siya Shi (*Abstract Co-Author*)
Yanji Luo (*Abstract Co-Author*)

PURPOSE

This study aimed to evaluate the value of dual-layer spectral CT (DLCT) parameters in perineural invasion (PNI) in pancreatic ductal adenocarcinoma (PDAC).

METHODS AND MATERIALS

This study included patients with pathologically confirmed PDAC who underwent DLCT between August 2019 and March 2024. Risk factors were identified using univariate and multivariate logistic regression analyses. Receiver operating characteristic and precision-recall curves accessed diagnostic performance.

RESULTS

We included 100 patients (mean age: 60.88 ± 11.39 years old, 59 males). There were 71 patients with PNI and 29 without PNI. Relevant factors for PNI included tumour diameter, normalised CT attenuation during the pancreatic parenchymal phase in conventional CT (nCTa), normalised CT attenuation during the pancreatic parenchymal phase in DLCT at 40 keV, and normalised iodine concentration during the pancreatic parenchymal phase (nDIa) (odds ratio [OR], 1.34; 95% confidence interval [CI]: 1.19, 1.51; $p < 0.001$). Of these, nDIa was the only independent predictor ($p < 0.001$; adjusted OR, 1.41; 95% CI: 1.19, 1.68) and demonstrated superior diagnostic performance compared to nCTa, with a cutoff value of 0.16, a higher area under the curve (0.93 vs 0.84, $p < 0.001$), higher accuracy (77% vs 52%, $p = 0.048$), an F 1 score of 0.90, higher sensitivity (72% vs 37%, $p = 0.03$), and the same specificity of 90% ($p = 0.13$).

CONCLUSION

The DLCT parameter nDIa allows for non-invasive prediction of PNI in PDAC with superior diagnostic efficacy compared to conventional CT parameters.

CLINICAL RELEVANCE/APPLICATION

The DLCT parameter may serve as an effective and convenient tool for the preoperative prediction of PNI in PDAC.

R2-SPGI-14 PHOTON-COUNTING DETECTOR CT WITH IODINE QUANTIFICATION: IMPROVED DISTINCTION BETWEEN BLAND AND NEOPLASTIC PORTAL VEIN THROMBOSIS

Lukas Mueller, MD, PhD (*Presenter*)
Tobias Jorg, MD (*Abstract Co-Author*)
Jan P. Grunz, MD (*Abstract Co-Author*)
Dirk Graafen, MD, PhD (*Abstract Co-Author*)
Aline Maehringer-Kunz, MD (*Abstract Co-Author*)
Friedrich Foerster, MD (*Abstract Co-Author*)
Henner Huflage, MD (*Abstract Co-Author*)
Daniel Pinto dos Santos, MD (*Abstract Co-Author*)
Tobias Baeuerle, MD (*Abstract Co-Author*)
Roman Kloeckner, MD (*Abstract Co-Author*)
Tilman S. Emrich, MD (*Abstract Co-Author*)

PURPOSE

Neoplastic portal vein thrombosis (PVT) has significant prognostic implications in patients with hepatocellular carcinoma (HCC) yet distinguishing it from bland PVT remains challenging. Photon-counting detector CT (PCD-CT) enables iodine density (ID) quantification with every scan. This study evaluated the diagnostic value of ID in differentiating bland from neoplastic PVT.

METHODS AND MATERIALS

This retrospective study included 104 patients with suspected PVT who underwent PCD-CT between 09/2022 and 08/2024. Patients were classified into four groups: (1) HCC with neoplastic or (2) bland PVT, (3) non-malignant bland PVT, or (4) neoplastic PVT in malignancies other than HCC. ID was measured in the late arterial phase (LAP) and portal venous phase (PVP) by two raters and compared to an established CT feature-based diagnostic score (including direct infiltration, vessel extension, and arterial hyperenhancement).

RESULTS

ID measurements showed excellent inter- and intra-rater agreement (ICC=0.99). ID was significantly higher in neoplastic PVT in both phases, achieving 100% and 93.1% sensitivity and 95.9% and 100% specificity in LAP and PVP, respectively. The CT score reached 89.7%/86.2% sensitivity and 81.6%/95.5% specificity for thresholds of =1/=2 features. In non-HCC malignancies, ID in LAP had a sensitivity of 69.2% and a specificity of 95.9 %, while ID in PVP achieved 92.3% sensitivity and 100% specificity, supporting its diagnostic utility.

CONCLUSION

This study highlights ID as a valuable imaging biomarker for differentiating bland from malignant PVT in HCC, supporting its role in complementing established CT features. Regarding contrast phases, ID achieved high accuracy in both late arterial and portal venous phases for HCC. Looking into PVT in patients with non-HCC malignancy ID was an effective discriminator in the portal venous phase.

CLINICAL RELEVANCE/APPLICATION

Iodine density quantification with photon-counting detector CT enables highly accurate differentiation between bland and neoplastic portal vein thrombosis in hepatocellular carcinoma and other malignancies, complementing established CT features and supporting improved diagnostic confidence and treatment planning.

R2-SPGI-16 PROGNOSTIC VALUE OF MUSCLE-FAT RATIO QUANTIFIED BY PHOTON-COUNTING CT IN DIABETIC GASTRIC CANCER PATIENTS

Shuangxiang Lin, MSc (*Presenter*)
Jianzhong Sun, MMed (*Abstract Co-Author*)
Xinhong Wang (*Abstract Co-Author*)
Jiaxing Wu (*Abstract Co-Author*)

PURPOSE

This study aimed to access the prognostic value of muscle-to-fat ratio (MFR), measured by photon-counting CT (PCD-CT), in patients with diabetic gastric cancer, with a specific focus on predicting major postoperative complications and improving risk stratification. We hypothesized that abnormal muscle-to-fat ratio is significantly associated with adverse clinical outcomes in this population.

METHODS AND MATERIALS

We retrospectively analyzed 134 type 2 diabetic gastric cancer patients who underwent preoperative PCCT. Body composition parameters, including skeletal muscle and fat areas, were quantified. Logistic regression identified predictors of poor prognosis, defined as major postoperative complications. We developed predictive models based on clinical variables alone and models integrating clinical variables with MFR. Model performance was evaluated using ROC curves, area under the curve (AUC), integrated discrimination improvement (IDI), and net reclassification improvement (NRI).

RESULTS

Patients with poor prognosis (n = 35) had significantly lower skeletal muscle and higher fat accumulation. An abnormal MFR (0.34 - 0.57) was strongly associated with poor outcomes (OR = 1.94, 95% CI: 1.17-2.58, $p < 0.01$). The combined model including clinical variables and MFR showed superior predictive accuracy (AUC = 0.75, sensitivity = 0.74, specificity = 0.71) compared to models using clinical variables alone. Predictive improvements were significant, with NRI of 0.52 ($p < 0.01$) and an IDI of 0.09 ($p < 0.01$).

CONCLUSION

Muscle-to-fat ratio quantified by PCD-CT, is a robust and non-invasive predictor of poor prognosis in diabetic gastric cancer patients. Incorporating this metric into clinical evaluation improves risk stratification and supports individualized postoperative management.

CLINICAL RELEVANCE/APPLICATION

An abnormal MFR, derived from PCD-CT, is significantly associated with adverse outcomes such as infections and delayed wound healing. PCCT-based body composition analysis provides a non-invasive tool to identify high-risk patients early, aiding surgical planning and postoperative care. The integration of this imaging biomarker into routine preoperative assessment may improve patient outcomes.

R2-SPGU-1 DIAGNOSIS OF FIBROSIS WITH MAGNETIZATION-PREPARED GOLDEN-ANGLE RADIAL SPARSE PARALLEL (MP-GRASP) T1 MAPPING IN RENAL ALLOGRAFTS

Mickael Tordjman, MD, MS (*Presenter*)
Octavia Bane, PhD, MS (*Abstract Co-Author*)
Li Feng, PhD (*Abstract Co-Author*)
Ding Xia (*Abstract Co-Author*)
Mira M. Liu, PhD (*Abstract Co-Author*)
Thangamani Muthukumar (*Abstract Co-Author*)
Jonathan P. Dyke,, PhD (*Abstract Co-Author*)
Madhav Menon (*Abstract Co-Author*)
Samira Farouk (*Abstract Co-Author*)
Bachir Taouli, MD (*Abstract Co-Author*)
Sara Lewis, MD (*Abstract Co-Author*)

PURPOSE

To compare T 1 mapping values and diagnostic performance for identification of renal transplant fibrosis of novel inversion-recovery with stack-of-stars readout [Golden-angle RAdial Sparse Parallel T 1 mapping (GraspT1)] acquisitions against variable flip angles (VFA) acquisitions.

METHODS AND MATERIALS

In our IRB-approved, prospective ongoing study, 61 patients [37 M, age 50±12y] with renal transplant had multiparametric MRI at 3T (Skyra, Siemens). Patients were scanned in controlled hydration conditions with 2 matched, B1-corrected VFA (20 3-mm slices, FOV=380x380, matrix=192x154, TE=1.13, FA=2,10,TR=4.29, AT=12s and FA=2,5,9,TR=3.45, AT=16s), 2D single-slice GraspT1 and 3D GraspT1 (20 3-mm slices, FOV=360x360, matrix=256x256, TR/TE/FA=2.75/1.35/5, 60 TI's:11xTR-11xTR+59x24xTR, 25 trajectories/TI, AT=4min:21s) T1 mapping coronal acquisitions, centered on the renal allograft hilum. An abdominal radiologist selected 6 circular ROIs in the renal allograft cortex and medulla (2 each in the upper, mid- and lower pole) at the allograft hilum. Mean and standard deviation T 1 and cortico-medullary difference [?T 1 =100x (T 1 Cortex-T 1 Medulla)/T 1 Cortex] were reported. Serum eGFR was collected and interstitial fibrosis/tubular atrophy (IFTA score) was evaluated on biopsy using Banff 2017 criteria.

RESULTS

57 of 61 patients had indication biopsy 6±15 days from MRI, with no (IFTA 0; n=15), mild-to-moderate (IFTA 2; n=16), moderate (IFTA 4; n=11) and severe fibrosis (IFTA 6; n=15). There were slight discrepancies between the GraspT1 and the VFA measurements, with significantly higher cortical and medullary 2FA and 3FA VFA T 1 than 3DGraspT1 (Figure 1a). ?T1 measured with the 3D GraspT1 sequence identified dysfunctional allografts (eGFR<45ml/min/1.73m 2) with AUC(CI)=0.67(0.52-0.81) (Figure 1b). ?T1 with the 2FA VFA sequence (Figure 1c) identified allografts with severe fibrosis, [IFTA=6; AUC(CI)= 0.72 (0.57-0.88), and any fibrosis [IFTA>0; AUC(CI)=0.68 (0.53-0.85)], with good and fair diagnostic performance, respectively. Medulla T 1 measured with 2D GraspT1 [AUC(CI)=0.81(0.64-0.99)] and Stdev of medulla T 1 measured with 3 FA VFA sequence [AUC(CI)=0.77(0.59-0.95)] identified functional allografts (eGFR=45ml/min/1.73m 2) with fibrosis with very good diagnostic performance.

CONCLUSION

Native T1 values showed sensitivity to the presence of fibrosis, prior to eGFR decline, and can be easily measured clinically with one breath-hold pulse sequences.

CLINICAL RELEVANCE/APPLICATION

Renal T1 showed diagnostic sensitivity to the presence of renal allograft fibrosis, even in patients with preserved renal function, and thus can potentially be useful to select patients for biopsy or other interventions before serum eGFR decline.

R2-SPGU-2 INTEROBSERVER AGREEMENT AND DIAGNOSTIC SENSITIVITY OF DOPPLER AND CONTRAST-ENHANCED ULTRASOUND IN CHARACTERIZING INDETERMINATE RENAL LESIONS

Madeleine Sertic, MBBCh (*Presenter*)
Elizabeth Asch, MD (*Abstract Co-Author*)
Sai Dhanush Reddy Jeggari, MBBS (*Abstract Co-Author*)
Theodore T. Pierce, MD, MPH (*Abstract Co-Author*)

PURPOSE

To estimate inter-reader agreement for assessment of color Doppler vascularity and ultrasound contrast enhancement of indeterminate renal lesions and to compare their sensitivity for detecting renal neoplasm.

METHODS AND MATERIALS

Retrospective search of the electronic medical record of two tertiary care hospitals was performed from 1/1/2019 to 3/15/2025 to identify patients with contrast enhanced ultrasound (CEUS) of indeterminate renal lesions. Vascularity was assessed on color Doppler images and enhancement by CEUS following intravenous injection of sulfur hexafluoride microbubble contrast by 2 board certified subspecialty trained radiologists blinded to the final diagnosis. Cohen's kappa assessed inter-reader agreement of vascularity and enhancement. Discordant cases between readers were considered negative. Frequency of features were compared by McNemar's test. Pathology results were documented, if available, as the reference for diagnosing neoplasm. Sensitivity and 95% confidence intervals were reported.

RESULTS

45 renal lesions (12 solid, 33 cystic) in 38 patients (mean age 66.7 years; 21 male) were identified. There was strong inter-reader agreement for assessment of vascularity (Kappa 0.738) and presence and type of enhancement (Kappa 0.814). Lesions were more likely to enhance (n=34,76%) than show vascularity (n=13, 29%), p<0.001. Only 6 (18%) enhancing lesions showed vascularity. 9 lesions assessed by biopsy were neoplasms (8 renal cell carcinoma, 1 oncocytoma); all 9 demonstrated enhancement (100% sensitivity; 95% CI: 66-100%), but only 5 demonstrated vascularity (56% sensitivity; 95% CI: 21-86%).

CONCLUSION

Enhancement on CEUS is more sensitive than color Doppler vascularity in detecting renal neoplasms, allowing for the small sample size of this study. Most enhancing lesions do not demonstrate Doppler vascularity.

CLINICAL RELEVANCE/APPLICATION

In the evaluation of renal masses, CEUS demonstrates superior sensitivity to Doppler ultrasound for detecting neoplasms. All biopsy-proven cancers enhanced, despite nearly half demonstrating no flow with color Doppler. These results highlight the limitations of color Doppler US to assess for solid components and support integrating CEUS into routine imaging protocols for characterization of indeterminate renal lesions.

R2-SPGU-3 NOMOGRAM COMBINING CONTRAST-ENHANCED CT-DERIVED EXTRACELLULAR VOLUME FRACTION AND CLINICAL PROGNOSTIC FACTORS TO PREDICT DISEASE-FREE SURVIVAL IN PATIENTS WITH CLEAR CELL RENAL CELL CARCINOMA POSTOPERATIVELY

Wangyang Sun (*Presenter*)

PURPOSE

This study aims to develop a nomogram incorporating the extracellular volume (ECV) fraction, the Mayo Clinic stage, size, grade, and necrosis score(SSIGN score), along with various clinical prognostic factors(CPFs), for predicting disease-free survival (DFS) in patients with clear cell renal cell carcinoma (ccRCC) after the operation.

METHODS AND MATERIALS

This retrospective study was conducted involving 195 patients with ccRCC from February 2019 to December 2021. The ECV fraction was measured using preoperative contrast-enhanced CT equilibrium images. Clinical data, including age, gender, surgical approach, systemic immune-inflammation index (SII), prognostic nutritional index (PNI), the SSIGN score, and the Mayo Adhesive Probability score (MAP score), were collected. Tumor size, grading, and staging were derived from postoperative pathological findings. Independent prognostic factors affecting DFS were identified using univariate and multivariate Cox regression analysis. Kaplan-Meier curves and log-rank tests were used to draw survival curves. The performance of the nomogram was assessed using calibration curves, receiver operating characteristic (ROC) curves, concordance index (C-index), and decision curve analysis (DCA).

RESULTS

Multivariate Cox regression analysis revealed that the ECV fraction [hazard ratio (HR): 6.685, P <0.001], SII [HR: 2.916, P =0.027], WHO/ISUP grade [HR: 2.835, P =0.034], tumor stage (P <0.05), and SSIGN score (P <0.05) were independent factors influencing DFS in patients with ccRCC. The nomogram based on ECV fraction combined with SSIGN score and CPFs demonstrated high predictive accuracy (C-index = 0.835), with area under the curve (AUC) values for predicting 2-year and 3-year DFS of 0.914 and 0.892, respectively. DCA indicated that the nomogram provided good clinical benefit. Calibration curves showed that the predicted DFS closely aligned with the actual DFS outcomes.

CONCLUSION

The nomogram based on ECV fraction, the SSIGN score, and CPFs effectively predicts DFS in patients with ccRCC postoperatively, providing a valuable reference for individualized treatment strategies.

CLINICAL RELEVANCE/APPLICATION

In conclusion, our study indicated that the ECV fraction, SSIGN score, SII, WHO/ISUP grade, and TNM staging were independent prognostic factors for patients with ccRCC. Moreover, we have constructed a prognostic nomogram that integrating these factors alongside CPFs, demonstrating its efficacy in predicting DFS following surgical intervention. This nomogram facilitated the adoption of personalized follow-up and therapeutic strategies, ultimately improving the prognostic outcomes for individuals with ccRCC.

R2-SPGU-4 RADIATION DOSE REDUCTION USING PHOTON-COUNTING DETECTOR CT IN POST-ABLATION FOLLOW-UP OF RENAL TUMORS: A COMPARATIVE STUDY WITH ENERGY-INTEGRATING DETECTOR CT

Yusuke Matsui, MD, PhD (*Presenter*)
Fumiyo Higaki (*Abstract Co-Author*)
Takahiro Kitayama, MD, PhD (*Abstract Co-Author*)
Kazuaki Munetomo (*Abstract Co-Author*)
Koji Tomita (*Abstract Co-Author*)
Noriyuki Umakoshi, MD (*Abstract Co-Author*)
Soichiro Okamoto, MD (*Abstract Co-Author*)
Takao Hiraki, MD, PhD (*Abstract Co-Author*)

PURPOSE

To compare radiation dose and image quality of follow-up imaging after renal tumor ablation between photon-counting detector (PCD) computed tomography (CT) and conventional energy-integrating detector (EID) CT.

METHODS AND MATERIALS

This retrospective study included 60 patients (median age, 69 years; 47 males, 13 females) who underwent CT-guided cryoablation for renal cell carcinoma and were followed up with periodic contrast-enhanced CT. The radiation dose and image quality of follow-up CT examinations using PCD- and EID-CT scanners were compared in the same patients. The CT dose index volume (CTDIvol) and dose length product (DLP) of the corticomedullary phase were recorded for radiation dose assessment. CT values (Hounsfield unit [HU]) of the renal cortex were measured on corticomedullary-phase images, and the signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) were calculated. Two board-certified radiologists subjectively evaluated the image quality using a five-point Likert scale, focusing on the conspicuity of the ablation zone. Data are summarized as medians and interquartile ranges (IQR). The Wilcoxon signed-rank test was used for comparison.

RESULTS

The median time interval between EID-CT and PCD-CT examinations was 200 days (IQR, 182-357). The radiation dose was significantly lower in PCD-CT than in EID-CT (CTDIvol: 7.8 mGy [IQR, 7.1-9.0] vs. 14.5 mGy [IQR, 11.5-17.1], p < 0.001; DLP: 258.5 mGy*cm [IQR, 225.0-311.5] vs. 503.7 mGy*cm [IQR, 348.3-579.8], p < 0.001). The CT value of the renal cortex on corticomedullary phase images was significantly higher in PCD-CT than in EID-CT (249 HU [IQR, 207-278] vs. 222 HU [IQR, 190-246], p < 0.001). The SNR and CNR were not significantly different between PCD-CT and EID-CT (SNR: 15 [IQR, 12-18] vs. 14 [IQR, 12-18], p = 0.546; CNR: 17 [IQR, 13-20] vs. 15 [IQR, 12-18]; p = 0.057). The qualitative image analysis scores were not significantly different between PCD-CT and EID-CT for either radiologist (p = 0.336 and p = 0.095 for radiologists 1 and 2, respectively).

CONCLUSION

PCD-CT reduced the radiation dose by nearly half compared to EID-CT in follow-up imaging after renal tumor ablation, with increased contrast enhancement of the renal cortex, comparable image noise levels, and comparable subjective image quality.

CLINICAL RELEVANCE/APPLICATION

Patients undergoing CT-guided renal tumor ablation may receive high cumulative radiation exposure owing to repeated CT scans during the procedure and periodic follow-up after treatment. Regular PCD-CT follow-up imaging in clinical care may contribute to reducing the lifetime radiation dose in these patients without compromising the diagnostic capability.

R2-SPGU-5 ACCURATE PREDICTION OF KIDNEY IMAGING BIOMARKERS FROM NON-CONTRAST MRI USING DEEP NEURAL PATCHWORKS COMBINED WITH KNOWLEDGE TRANSFER FROM CONTRAST-ENHANCED ARTERIAL PHASE MRI

Kai Kastingschafer, MD (*Presenter*)
Anna Fink (*Abstract Co-Author*)
Stephan Rau, MD (*Abstract Co-Author*)
Alexander Rau, MD (*Abstract Co-Author*)
Fabian Bamberg, MD, MPH (*Abstract Co-Author*)
Anna Kottgen (*Abstract Co-Author*)
Elias Kellner (*Abstract Co-Author*)
Marco Reisert (*Abstract Co-Author*)
Maximilian Russe, MD (*Abstract Co-Author*)

PURPOSE

Quantifying structural dimensions of various organs, including total kidney volume (TKV) and corticomedullary differentiation can aid in better detection and monitoring of pathologies such as chronic kidney disease. However, the application of contrast agents for enhancing corticomedullary differentiation is not always possible for example in presence of reduced kidney function. This study used modern deep learning approaches to generate imaging-based biomarkers in non-contrast sequences reflecting characteristics of contrast-enhanced sequences.

METHODS AND MATERIALS

The retrospective study included 200 patients (mean age: 53.4, age range: 20 - 82 years, 50% female) who underwent abdominal MRI scans with axial 3D T1w GRE FS sequences, both contrast-enhanced (CE) and non-contrast enhanced (NCE). Manual subsegmentation of the kidneys (cortex, medulla and sinus; ground truth [GT]) was performed on the CE-T1w sequences. Using multi-mask coregistration, the segmentations were transferred to the NCE-T1w images. A subset of 100 patients was randomly selected to train a Deep Neural Patchworks framework. The trained algorithm was applied to the NCE data of the remaining 100 patients and compared with the GT from the arterial phase. The imaging biomarkers cortex volume (CV), medulla volume (MV), sinus volume (SV) and TKV were calculated and comparative correlations were performed.

RESULTS

The automated prediction accurately delineated kidney cortex, medulla, and sinus structures. High correlations between automated predictions and GT were observed with Spearman correlation coefficients of 0.98 (TKV), 0.94 (CV), 0.88 (MV), and 0.95 (SV), respectively. Bland-Altman analyses indicated no major systematic deviations, although predicted volumes were on average slightly higher compared to GT measurements.

CONCLUSION

The deep learning-based method applied to non-contrast MRI achieved high correlations between the predicted and the contrast-based manually segmented kidney volumes, demonstrating its utility as a viable alternative for situations where contrast agents are contraindicated or unavailable.

CLINICAL RELEVANCE/APPLICATION

Our method removes the need for contrast agents to obtain relevant image-based biomarkers, improving the detection, monitoring and treatment management of kidney disorders and enabling deeper insights into a wide range of diseases.

R2-SPHN-1 FEASIBILITY OF IMPROVING NECK CT IMAGE QUALITY USING WIDE-DETECTOR HIGH-RESOLUTION SCANNING MODE COMBINED WITH DEEP LEARNING IMAGE RECONSTRUCTION ALGORITHM: A HUMAN CADAVER STUDY

Fang Zhou, MD (*Presenter*)
Wenjun Qiao (*Abstract Co-Author*)
Ge Wen (*Abstract Co-Author*)
Yanbing Li (*Abstract Co-Author*)
HU ZHI (*Abstract Co-Author*)
Tong Su, MD (*Abstract Co-Author*)

PURPOSE

This study aimed to investigate the potential of a high-resolution(HT) scanning mode integrated with the ClearInfinity deep learning image reconstruction algorithm to enhance image quality in neck CT scans.

METHODS AND MATERIALS

A wide-detector CT system (NeuViz Epoch Elite CT) was employed to perform neck CT scans on a human cadaver specimen under standard-resolution mode (SRCT, 0.625mm collimation) and high-resolution mode (HRCT, 0.3125mm collimation). Six groups of reconstructed images were generated from these two scanning modes. Both modes utilized an iterative reconstruction algorithm (ClearView 40%CV), while the high-resolution dataset additionally applied a ClearInfinity deep learning image reconstruction algorithm(DLIR-CI) with varying weighting factors. This resulted in six groups of reconstructed images: SRCT-CV40%, HRCT-CV40%, HRCT-CI20%, HRCT-CI40%, HRCT-CI60%, and HRCT-CI80%. The CT values and noise (SD values) of the left thyroid gland and the semispinalis cervicis muscle were measured, with the SD value of the muscle serving as an indicator of the image noise level. Measurements were performed at five layers centered on the isthmus of the thyroid gland, with each region of interest (ROI) measured three times. The signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) of the thyroid gland were subsequently calculated for all six sets of images.

RESULTS

Image noise (SD) decreased progressively with higher CI strength, whereas SNR and CNR exhibited gradually increased. The group HRCT_CI40% algorithm achieved noise levels equivalent to the group SRCT_CV40% (20.03±2.11 vs. 19.52±4.34, P>0.05), HRCT_CI60% (14.12±1.36) and HRCT_CI80% (8.72±1.21) exhibited significantly lower SD values (P < 0.001). The group HRCT_CI60% and HRCT_CI80% demonstrated significantly higher SNR compared to Group SRCT_CV40%(11.66 ±3.61 vs. 7.98±0.78, P < 0.001; 19.71±1.24 vs. 7.98±0.78,P<0.001)with46.11% and 146.99% increase, and The group HRCT_CI80% demonstrated a 97.93% higher CNR(8.61±1.10 vs. 4.35±0.92, P < 0.001).

CONCLUSION

Integrating a high-resolution scanning mode with the ClearInfinity deep learning reconstruction algorithm (DLIR-CI) significantly enhances neck CT image quality.

CLINICAL RELEVANCE/APPLICATION

Cervicothoracic CT imaging is prone to artifacts that may impair radiologists' assessment of anatomical structures. This study demonstrates that integrating a high-resolution scanning mode with a deep learning reconstruction algorithm (ClearInfinity, DLIR-CI) significantly improves neck CT image quality.

R2-SPHN-2 EVALUATION OF DEEP LEARNING BASED IMAGE NOISE REDUCTION AND IMAGE ENHANCEMENT IN DENTAL CBCT

Wojciech Kazimierczak, MD, PhD (*Presenter*)
Roza Wajer, MD (*Abstract Co-Author*)
Natalia Kazimierczak (*Abstract Co-Author*)
Natalia Chwarscianek (*Abstract Co-Author*)
Adrian Wajer (*Abstract Co-Author*)
Zbigniew Serafin (*Abstract Co-Author*)

PURPOSE

To assess the impact of a vendor-agnostic deep learning model (DLM) on image quality parameters and noise reduction in dental cone-beam computed tomography (CBCT) reconstructions.

METHODS AND MATERIALS

This retrospective study was conducted on CBCT scans of 93 patients (41 males and 52 females, mean age 41.2 years, SD 15.8 years) from a single center using the inclusion criteria of standard radiation dose protocol images. Objective and subjective image quality was assessed in three predefined landmarks through contrast-to-noise ratio (CNR) measurements and visual assessment using a 5-point scale by three experienced readers. The inter-reader reliability and repeatability were calculated.

RESULTS

Eighty patients (30 males and 50 females; mean age 41.5 years, SD 15.94 years) were included in this study. The CNR in DLM reconstructions was significantly greater than in native reconstructions, and the mean CNR in regions of interest 1-3 (ROI1-3) in DLM images was 11.12 ± 9.29, while in the case of native reconstructions, it was 7.64 ± 4.33 ($p < 0.001$). The noise level in native reconstructions was significantly higher than in the DLM reconstructions, and the mean noise level in ROI1-3 in native images was 45.83 ± 25.89, while in the case of DLM reconstructions, it was 35.61 ± 24.28 ($p < 0.05$). Subjective image quality assessment revealed no statistically significant differences between native and DLM reconstructions.

CONCLUSION

The use of deep learning-based image reconstruction algorithms for CBCT imaging of the oral cavity can improve image quality by enhancing the CNR and lowering the noise.

CLINICAL RELEVANCE/APPLICATION

This research demonstrates the potential of artificial intelligence in reducing noise in clinical CBCT workflows as a tool to improve diagnostic performance, enhance patient care, and standardize imaging quality in a variety of dental settings.

R2-SPHN-7 PERFORMANCE OF CHATGPT IN HEAD AND NECK CANCER STAGING USING MULTIMODAL DATA ACCORDING TO THE AJCC 8TH EDITION

Daniel Weitz, MD (*Presenter*)
Sevcan Turk, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the accuracy and limitations of ChatGPT in predicting head and neck cancer staging using multimodal radiology data, based on the AJCC 8th Edition criteria.

METHODS AND MATERIALS

A total of 66 radiology reports derived from computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography-computed tomography (PET-CT) were included. These reports were composed to simulate diverse clinical scenarios and anatomical sites, including the pharynx, larynx, oral cavity, maxillofacial structures, cutaneous surfaces, head and neck soft tissues, and thyroid gland, with varying presentations of lymph node involvement and distant metastasis. The dataset included 46 ChatGPT-generated reports, 10 attending-generated reports, and 10 resident-generated reports. Each report was manually staged according to AJCC 8th Edition to establish a reference standard. ChatGPT was then prompted to assign TNM staging for each case, and its outputs were compared with manual staging to determine accuracy and identify error patterns.

RESULTS

The overall staging accuracy of ChatGPT across all reports was 83%. Stratified by report source, ChatGPT achieved a success rate of 93% with its own generated reports, 80% with attending-generated reports, and 60% with resident-generated reports. Errors were most observed in evaluating lymph node characteristics, particularly in assessing nodal size and distinguishing suspicious features such as loss of the fatty hilum or rounded morphology.

CONCLUSION

ChatGPT demonstrates promising performance in staging head and neck cancers using multimodal radiology data, particularly when interpreting well-structured reports. However, variability in performance across report types highlights the need for careful oversight, especially in complex or ambiguously described cases.

CLINICAL RELEVANCE/APPLICATION

While ChatGPT shows potential as a decision support tool in oncologic staging, its limited reliability with different type of report quality underscores the importance of clinician review prior to clinical application.

R2-SPIN-1 INTRA-RATER REPRODUCIBILITY OF MANUAL MRI LESION SEGMENTATION AND HEMORRHAGE CLASSIFICATION IN ACUTE CERVICAL TRAUMATIC SPINAL CORD INJURY

Maxime Bouthillier, MD (*Presenter*)
Jan Valosek (*Abstract Co-Author*)
Naama Rotem-Kohavi (*Abstract Co-Author*)
Suzanne Humphreys (*Abstract Co-Author*)
Nader Fallah (*Abstract Co-Author*)
Mathieu Guay-Paquet (*Abstract Co-Author*)
Kalum Ost (*Abstract Co-Author*)
David Cadotte (*Abstract Co-Author*)
Laurent Letourneau-Guillon, MD, MSc (*Abstract Co-Author*)
Julien Cohen-Adad (*Abstract Co-Author*)

PURPOSE

Manual segmentation and classification labels are commonly used as ground truth references for developing automatic medical image analysis models. While radiology literature frequently reports generally intra- and inter-rater variability depending on the task, this has not been thoroughly investigated in the context of acute cervical traumatic spinal cord injury (tSCI). This study assesses intra-rater reproducibility in manual lesion segmentation and hemorrhage classification as a biomarker in acute cervical tSCI MRI.

METHODS AND MATERIALS

Sagittal T2-weighted MRIs from 127 individuals with acute cervical tSCI (preoperative within 72 hours post-injury, Level 1 trauma center) have been manually segmented twice by a third-year radiology resident using 3D Slicer, six months apart under identical working conditions. Lesion segmentation masks included both edema—i.e. intramedullary T2w hyperintensity relative to normal-appearing spinal cord—and, when present, presumed hemorrhage—i.e. intramedullary T2w hypointensity. Dice similarity coefficients were computed for both labels at once and separately. Hemorrhage identification on sagittal T2w MRI was further evaluated via count of non-empty hemorrhage masks across both sessions. Hemorrhage was also assessed on axial T2* MRIs across two sessions three months apart. Cohen's kappa was used to measure reproducibility. 95% confidence intervals (CI) were reported. Sensitivity and specificity of hemorrhage identification on sagittal T2w imaging were calculated against corresponding T2* axial MRI assessments at both sessions, considered as the reference standard.

RESULTS

On sagittal T2w MRI, the mean (CI) Dice coefficient for total lesion is 0.69 (0.66-0.71). For edema: 0.68 (0.65-0.70); for hemorrhage: 0.37 (0.29-0.45). Hemorrhage was initially diagnosed on T2w in 21 participants, then 31 at 6 months (kappa: 0.66; CI: 0.49-0.84). On axial T2* MRI (n=115), hemorrhage was classified in 27 and 31 participants at initial and final sessions, respectively (kappa: 0.77; CI: 0.61-0.90). Sensitivity and specificity for hemorrhage detection using sagittal T2w versus axial T2* imaging are 0.56 and 0.86 initially, and 0.55 and 0.98 on second evaluation.

CONCLUSION

Intra-rater agreement in sagittal T2w hemorrhage identification was good, whereas axial T2* shows good to very good agreement and stable reproducibility. While sensitivity is low for identifying hemorrhage from sagittal T2w imaging, specificity is high.

CLINICAL RELEVANCE/APPLICATION

Intramedullary hemorrhage is a recognized prognostic imaging biomarker in acute cervical tSCI, associated with poor neurological outcomes. Improving classification reproducibility supports its integration into automated imaging analysis.

R2-SPIN-2 DO LARGE LANGUAGE MODELS (LLM) HAVE A ROLE IN PROVIDING FEEDBACK FOR RADIOLOGY EDUCATION?

Colin J. McCarthy, MD (*Presenter*)
Yiftach Barash, MD (*Abstract Co-Author*)
Seth J. Berkowitz, MD (*Abstract Co-Author*)
Elizabeth Du, MD (*Abstract Co-Author*)
Elisa N. Flower, MD (*Abstract Co-Author*)
Vijay Ramalingam, MD (*Abstract Co-Author*)
Adeel R. Seyal, MD,MBBS (*Abstract Co-Author*)

PURPOSE

To evaluate the role of a large language model (LLM) in the assessment and correction of radiology reports generated by medical students as part of their core clerkship in radiology.

METHODS AND MATERIALS

32 radiology reports generated in a simulated PACS reading environment over a 4-month period by 2nd year medical students were extracted from an Institutional database and anonymized. These represented two versions of 8 reports from a high-complexity case (CTA torso with aortic dissection), and 8 reports from a low-complexity case (chest radiograph with misplaced endotracheal tube). Reports generated prior to and following feedback from an attending radiologist were labeled as "A" and "B", respectively. Student reports were compared with a gold standard official radiology report. Using a few-shot prompting technique, reports were evaluated using Claude Sonnet 3.7 (Anthropic) on the Bedrock platform (AWS). The LLM was asked to provide a comparison between the two versions of the student reports ("A" and "B"), and to compare with the official report. The LLM analysis was assessed by three board-certified radiologists, with questions ranked on a 5-point Likert scale. The model output was assessed on identifying discrepancies, missed findings, professional tone, formatting and other factors. All data were collected using a secure web-based survey tool, tabulated and statistical analysis performed in Stata IC v14.

RESULTS

48 surveys were completed, comprising 3 assessors each reviewing 16 pairs of medical student reports. With regard to the questions addressing the comparsion between the two student versions of the report, the mean score of the LLM-provided analysis was 4.9 (range 4.85 - 4.94). There was no statistical difference between the high and low complexity cases (p = 0.43). For the LLM-analysis between the student and official reports, higher mean scores were noted for the low-complexity cases (4.99, range 4.8 - 5) versus for high complexity cases (4.94, range 4.6 - 5), p = 0.04. No hallucinations were detected. Examples of serious discrepancies detected include laterality errors and missing critical findings. When asked if the LLM-feedback could be used for medical student education, the assessors reported that they "Strongly Agreed" in 94% of cases.

CONCLUSION

An LLM can provide valuable feedback on medical student radiology reports generated during a simulated reading session, and may serve as a complementary tool for educators.

CLINICAL RELEVANCE/APPLICATION

Near instantaneous actionable feedback on preliminary medical student reports is possible with LLMs. Further work will assess implementation barriers, and potential expansion to resident feedback.

R2-SPIN-3 OFTEN WRONG, NEVER IN DOUBT: GPT-4OV'S PERFORMANCE VS. CONFIDENCE AND EXPLANATIONS FOR HEAD CT HEMORRHAGE INTERPRETATION

Briana Malik, BS (*Presenter*)
Dharmam Savani, MS (*Abstract Co-Author*)
Aditya Kulkarni, BEng, MSc (*Abstract Co-Author*)
Andrew D. Smith, MD, PhD (*Abstract Co-Author*)
Paul H. Yi, MD (*Abstract Co-Author*)

PURPOSE

Vision-language models (VLMs) like GPT-4oV can interpret medical images and generate free-text reports, but the reliability of their reasoning is unclear. We evaluated GPT-4oV's diagnostic accuracy for intracranial hemorrhage (ICH) on non-contrast head CT, along with the quality of its visual localization and explanatory logic.

METHODS AND MATERIALS

We tested GPT-4oV on 72 head CT slices (52 ICH-positive) annotated by radiologists with bounding boxes for ICH, including subtype labels (intraparenchymal, intraventricular, subarachnoid, epidural, and subdural). For each image, the model was prompted to provide a binary hemorrhage classification (yes/no), hemorrhage subtype, bounding box coordinates for ICH location, and a free-text explanation of its reasoning. Outputs were compared to radiologist ground truth. We evaluated 1) Diagnostic performance (accuracy, sensitivity, precision, F1-score), 2) Localization accuracy (IoU and containment rate, i.e., whether predicted boxes overlapped with ground truth), and 3) Explanation quality (speculative word ratio and Flesch-Kincaid [FK] readability grade level). To probe reasoning structure, we embedded the explanations using BioBERT, performed unsupervised clustering, and assessed subtype-level consistency.

RESULTS

GPT-4oV showed suboptimal performance in detecting ICH (accuracy: 39%, sensitivity: 39%, F1-score: 0.40). Localization was poor: ICH bounding boxes had large spatial errors (mean IoU: 0.006), with just 3.6% fully contained within ground truth and 10.7% with centers inside. Bounding boxes were also consistently smaller than ground truth, underestimating lesion size. Despite this, the model's free-text explanations clustered cleanly by ICH subtype (100% intra-cluster purity), suggesting distinct reasoning patterns. Textual explanations were linguistically confident (speculative word ratio: 0.06%, i.e., no hedging) and aligned with radiology reporting complexity levels (median FK readability grade: 17), though often factually incorrect (evidenced by incorrect ICH predictions).

CONCLUSION

GPT-4oV was often wrong but seldom in doubt—showing suboptimal diagnostic accuracy, poor localization, and confidently incorrect explanations. Though its language clustered cleanly by hemorrhage subtype, this masked flawed reasoning. The model 'speaks radiology' fluently, but fluency without factual grounding is risky. For informatics, this highlights the need to assess not just what models say about images, but how—and why—they say it.

CLINICAL RELEVANCE/APPLICATION

Fluent AI explanations can mask diagnostic errors, highlighting the need for caution when integrating vision-language models into clinical radiology.

R2-SPIN-4 USING AN AI BASED INFORMATICS APPROACH FOR VISUALIZATION OF CONTRAST ENHANCEMENT IN MULTIPHASE CT PROTOCOLS AT SCALE

Zahra Alyani Nezhad, MSc (*Presenter*)
Dvij Sharma (*Abstract Co-Author*)
John W. Garrett, PhD (*Abstract Co-Author*)
Rachel Bladorn, BS, RT (*Abstract Co-Author*)
Carrie Bartels, RT (*Abstract Co-Author*)
Giuseppe V. Toia, MD, MS (*Abstract Co-Author*)
Meghan G. Lubner, MD (*Abstract Co-Author*)
Timothy P. Szczykutowicz, PhD (*Abstract Co-Author*)

PURPOSE

To assess contrast opacification on a renal donor multiphase CT protocol using an AI-driven auto-segmentation approach to enable evaluation of deviations in scan timing and patient-size on CT enhancement.

METHODS AND MATERIALS

The OSCAR toolkit, an AI-based pipeline, was used to segment the liver and extract median CT numbers. Of 6,079 renal donor multiphase CT scans, 3,723 with three phases were included. The vascular phase auto-triggered at 70 seconds post-injection; the delayed phase was manually started at 180 seconds. Delayed phase scan delay times and patients' water equivalent diameter (WED) were calculated using DICOM metadata and images. Mean, standard deviation, and coefficient of variation (CV) of scan delay were calculated. Vascular and delayed phase liver CT numbers were plotted against baseline (unenhanced) CT numbers, with color coding by scan delay and WED (i.e. a surrogate for patient size). Mann-Whitney U tests were performed to compare vascular and delayed phase CT numbers between groups with baseline liver CT numbers <50 HU vs. =50 HU, and WED <340 mm vs. =340 mm.

RESULTS

Actual delayed phase timing ranged from 100-300 s (median 182 ± 24 s; CV = 13%). Vascular and delayed phase CT numbers increased with higher baseline CT numbers but showed no correlation with scan delay. Significant differences were found between groups with baseline CT numbers <50 HU vs. =50 HU: vascular phase 76 HU vs. 104 HU, delayed phase 89 HU vs. 119 HU ($p < 0.05$). Similarly, significant differences were observed between patients with WED <340 mm vs. =340 mm: vascular phase 105 HU vs. 83 HU, delayed phase 120 HU vs. 96 HU ($p < 0.05$).

CONCLUSION

Despite protocol guidance, manual initiation of delayed phase scans resulted in substantial variability in scan timing. Larger patients exhibited lower liver CT numbers in both vascular and delayed phases, likely due to fixed contrast dosing of the protocol, inadequate for body size, and increased beam hardening. Patients with low baseline liver CT numbers (<50 HU) (either small or large patients), potentially due to hepatic steatosis or other pathology, also showed reduced CT number values. Optimizing image quality in these populations may require patient-specific contrast dosing and protocol adjustments, such as reducing tube potential or increasing contrast volume.

CLINICAL RELEVANCE/APPLICATION

Liver enhancement in multiphase CT is significantly affected by patient size and baseline liver attenuation and very weakly dependent on delayed phase scan timing (i.e., 180 seconds). Enhancement remained relatively flat for tens of seconds variation in delayed scan timing. This AI-based, data-driven approach enables data visualization at scale allowing optimization of iodine contrast protocols across diverse patient populations.

R2-SPIN-5 INVESTIGATE THE ROLE OF INTRASACCULAR THROMBUS IN ABDOMINAL AORTIC ANEURYSMS (AAA): A HEMODYNAMIC PERSPECTIVE

Jingfeng Jiang, PhD (*Presenter*)
Lance Waise (*Abstract Co-Author*)
Seyedmostafa Rezaeitaleshmahalleh (*Abstract Co-Author*)
Xiaoming Zhang, PhD (*Abstract Co-Author*)
Robert McBane, MD (*Abstract Co-Author*)

PURPOSE

Intrasaccular thrombus presents a large fraction of abdominal aortic aneurysms. The role of intrasaccular thrombus is controversial. In this study, we quantify the differences in aneurysmal hemodynamics with or without the intrasaccular thrombus during “patient-specific” computational fluid dynamics (CFD) simulations of a cohort of human AAAs.

METHODS AND MATERIALS

This study utilized computed tomography angiography (CTA) images from a research database at the Mayo Clinic, comprising 63 patients with thrombosed AAAs. Specifically, two geometrical models (i.e., the pre- and post-thrombus models) were generated for each patient in this cohort. CFD simulations were performed to understand the aneurysmal hemodynamic differences in the pre- and post-thrombosed AAA geometries. This study used a combined qualitative and quantitative approach. In addition to wall shear stress-related stressor prediction indices, novel indices derived from quantifying spatiotemporal characteristics of aneurysmal flow vortices and velocity informatics were also obtained by post-processing CFD data. Qualitatively, gross hemodynamic patterns were assessed visually to identify helical flow patterns, a marker for increased rupture risk (Qiu et al., European Journal of Vascular and Endovascular Surgery, 2022).

RESULTS

The number of flow vortices/eddies and helical flow patterns was considerably higher in the pre-thrombosed AAAs than in post-thrombosed AAAs (p-value < 0.05). Moreover, more helical flow patterns were found in the pre-thrombosed AAA group compared to the post-thrombosed AAA group.

CONCLUSION

Overall, we found increased aneurysmal flow disturbance in pre-thrombosed AAAs. Consequently, our preliminary results suggest that the formation of intrasaccular thrombus may be a protective mechanism from the perspective of hemodynamics. Our future work includes considering aneurysmal wall compliance to understand the stress in the aneurysmal wall with and without the presence of intrasaccular thrombus.

CLINICAL RELEVANCE/APPLICATION

This research's insights are promising for identifying specific flow patterns associated with heightened AAA rupture risk, facilitating personalized risk assessments and contributing to personalized management strategies, including timely interventions for high-risk patients with small-sized AAAs.

R2-SPIN-6 AUTOMATED LOCALIZATION OF LINES, DRAINS, AND AIRWAYS ON CHEST RADIOGRAPHS USING YOLO OBJECT DETECTION MODELS

Hailong Li, DPhil (*Presenter*)
Bohan Zhang (*Abstract Co-Author*)
Elanchezhian Somasundaram, PhD, MS (*Abstract Co-Author*)
Steve Standage (*Abstract Co-Author*)
Gary R. Schooler, MD (*Abstract Co-Author*)
Lili He, MD (*Abstract Co-Author*)
Alex Towbin, MD (*Abstract Co-Author*)

PURPOSE

To develop and evaluate a deep learning object detection algorithm for automated localization of five common Lines, Drains, and Airways (LDAs) on chest X-rays (CXRs), including endotracheal tubes (ETTs), left peripherally inserted central catheters (PICCs), right PICCs, lower extremity PICCs, and tracheostomy tubes.

METHODS AND MATERIALS

This study retrospectively analyzed single-view CXRs performed in 2021 from adult and pediatric patients. Under the supervision of a pediatric radiologist, two image analysts manually annotated ETTs, left PICCs, right PICCs, lower extremity PICCs, and tracheostomy tubes using 3D Slicer. The radiologist reviewed all annotated images and made corrections as needed. Bounding boxes for each LDA device were automatically generated from the manual segmentation masks and used as ground truth. All CXRs were normalized to a resolution of 512×512. A You Only Look Once (YOLO) object detection framework was used to localize the five LDA devices by predicting bounding boxes directly from CXRs. The YOLO framework represents a family of real-time object detection models that use fully convolutional networks to divide the input image into a grid and simultaneously predict bounding boxes and class probabilities for each region. In this study, we implemented four versions of YOLO models, including YOLOv8, YOLOv9, YOLOv10, and YOLOv11. We randomly split the dataset into 7:1:2 for model training, validation, and testing at the subject level. Model performance was evaluated using class-specific Average Precision (AP), and overall mean AP (mAP) across all classes.

RESULTS

1,024 CXRs from 551 pediatric and adult patients [mean ± standard deviation age of 4.7 ± 7.8 years, age range: 0.0 to 54.7 years, 238 (43.2%) females] were included. 611 CXRs contain at least one of five targeted LDAs, while 413 CXRs do not contain any of the targeted LDAs. Among the evaluated models, YOLOv9 achieved the highest overall performance with a mAP of 0.72. YOLOv8, YOLOv10, and YOLOv11 achieved mAPs of 0.69, 0.67, and 0.70, respectively. The best-performing YOLOv9 model achieved class-specific AP values of 0.68 for ETT, 0.75 for left PICC, 0.78 for right PICC, 0.68 for lower extremity PICC, and 0.71 for tracheostomy tube. We visualized the ground truth annotations alongside the predicted bounding boxes from the best-performing YOLOv9 model.

CONCLUSION

YOLO-based object detection models demonstrated strong performance in localizing common LDAs on chest radiographs, with YOLOv9 achieving the highest overall accuracy.

CLINICAL RELEVANCE/APPLICATION

Automated bounding box localization of LDAs on adult and pediatric CXRs provides a foundation for real-time clinical decision support tools, aiding device presence verification and workflow efficiency.

R2-SPIN-7 MULTIREADER MULTICASE COMPARISON OF STANDALONE AI VERSUS RADIOLOGISTS FOR DETECTION OF 24 ACUTE FINDINGS ON CT ABDOMEN PELVIS EXAMINATIONS

Pranav Rajpurkar, PhD (*Presenter*)
Julian Acosta (*Abstract Co-Author*)
Deepanshu Jindal (*Abstract Co-Author*)
Michael Moritz (*Abstract Co-Author*)
Sraavya Sambara (*Abstract Co-Author*)
Siddhant Dogra, MD (*Abstract Co-Author*)
Jenanan Vairavamurthy (*Abstract Co-Author*)
Samir Rajpurkar (*Abstract Co-Author*)

PURPOSE

Artificial intelligence (AI) systems capable of detecting acute findings on abdominal and pelvic CT scans at a level comparable to radiologists could enhance diagnostic accuracy, improve clinical workflows for emergent cases, and reduce variability in clinical practice. This study aimed to evaluate the standalone performance of a CT abdomen-pelvis (CTAP) foundation model (a2z-3) in detecting 24 acute radiologic findings, benchmarked against radiologist performance in a multi-reader, multi-case analysis.

METHODS AND MATERIALS

For each of the selected 24 potentially acute findings identifiable on CTAP exams, cases were selected based on initial radiologist reports, including an average of 6.4 definitive cases per finding (standard deviation [SD] 5.1) and 2.8 possibly present cases per finding (SD 1.4). Each CTAP was re-evaluated for quality and accuracy by an abdominal-fellowship trained attending radiologist uninvolved in the reader study, resulting in 121 total cases for review. Cases were loaded onto the RedBrick AI annotation platform and independently reviewed by three attending radiologists. Radiologists assigned a likelihood rating from 1 (unlikely) to 5 (likely), and indicated whether each finding could be definitely ruled out or definitely diagnosed. Each CTAP was also evaluated independently by a transformer-based deep learning model. F1 scores for each of the 24 findings were calculated for the model and radiologists across all 121 cases and compared.

RESULTS

Across the 24 findings, the mean model F1 score was 0.61 (SD 0.19) compared to a mean radiologist F1 score of 0.52 (SD 0.18; p=0.04 via a paired t-test). The AI model outperformed the average radiologist in 19 of 24 findings (79%) and surpassed all radiologists for 13 findings (54%). The model performed best for ureteral stones and diverticulitis (F1=0.84) and had the lowest performance for colitis (F1=0.20).

CONCLUSION

The a2z-3 CTAP foundation model demonstrated robust standalone performance in identifying acute radiologic findings, achieving comparable or superior accuracy relative to experienced radiologists across multiple acute conditions. These results support the model's potential as a reliable tool to aid in CTAP image interpretation and prioritization.

CLINICAL RELEVANCE/APPLICATION

Incorporating a high-performing foundation model into clinical workflows has the potential to enhance diagnostic accuracy, minimize interpretation variability among radiologists, and expedite the recognition and management of acute abdominal and pelvic pathologies.

R2-SPIN-8 ORGAN-BASED TUMOR DISTRIBUTION FOR PREDICTING PROGNOSIS IN SMALL-CELL LUNG CANCER USING FLUORODEOXYGLUCOSE POSITRON EMISSION TOMOGRAPHY/COMPUTED TOMOGRAPHY

Jiwoo Park, MD, PhD (*Presenter*)
Young Han Lee, MD (*Abstract Co-Author*)

PURPOSE

To validate and compare conventional metabolic tumor burden measurements with comprehensive metabolic tumor distribution patterns using [18F] fluorodeoxyglucose positron emission tomography/computed tomography (FDG PET/CT) to predict small-cell lung cancer (SCLC) prognosis.

METHODS AND MATERIALS

This retrospective study included 520 patients with SCLC (mean age±standard deviation, 67±5.6 years; 84.8% men) who underwent PET/CT for staging. Of these, 364 scans were used for training (n=291) and internal (n=73) tests, while 156 other scans were used for external testing. Clinical data (age, sex, and stage) were reviewed. Volumes of interest were manually drawn using a threshold standard uptake value of 2.5 for total lesion glycolysis (TLG) for all tumor lesions on PET. TLG with distribution (TLGd) and Organ-based tumor distribution (metastasis in organs, METAORG) was analyzed from CT-based automatic organ segmentation and overlaid on PET. Four survival prediction models (event and duration) were developed using a Random Forest classifier: (1) clinical factors, (2) tumor TLG, (3) TLGd and METAORG, and (4) combined models.

RESULTS

The top 11 features were selected for prediction models. In the internal test, C-indices for overall survival were 0.611, 0.592, 0.721, and 0.753 for tumor TLG, clinical, METAORG, and combined model, respectively. External test C-indices were 0.637, 0.326, 0.706, and 0.740, respectively. The combined model demonstrated the highest predictive power for both test sets.

CONCLUSION

The combined model outperformed the other models in predicting survival. Application of tumor distribution (TLGd and METAORG) to whole-body tumor distribution pattern analysis shows promise for improving prognosis evaluation, with advantages of quantifiable metastasis stratification.

CLINICAL RELEVANCE/APPLICATION

Integrating organ-based tumor distribution (TLGd + METAORG) with traditional metabolic burden metrics elevates PET/CT-based survival prediction in SCLC, boosting C-index to ~ 0.74 in external validation—substantially better than clinical data or TLG alone. The model's quantifiable, organ-specific metastasis read-out allows clinicians to classify patients into clearer risk tiers, informing decisions on intensified systemic therapy, prophylactic cranial irradiation, or earlier clinical-trial referral. The workflow relies on routine FDG-PET/CT plus automated organ segmentation, making the technique readily adoptable in most oncology centers without extra scans or bespoke software.

R2-SPIN-10 SURGICAL TWIN OF ORTHOGNATHIC SURGERY RESULTS AS POSTOPERATIVE LATERAL CEPHALOGRAMS USING GRAPH NEURAL NETWORKS AND DIFFUSION MODELS

Jae-Woo Park (*Presenter*)
Namkug Kim, PhD (*Abstract Co-Author*)
JiHeon Jeong (*Abstract Co-Author*)
Jisup Lim (*Abstract Co-Author*)

Su-Jung Kim (*Abstract Co-Author*)
Seung-Hak Baek, DDS,PhD (*Abstract Co-Author*)
Junsik Kim (*Abstract Co-Author*)
Yoon-Ji Kim, PhD,DDS (*Abstract Co-Author*)

PURPOSE

Orthognathic surgery (OGS) is increasingly sought for cosmetic purposes. The prediction of OGS is important in patient's decision to receive treatment. Traditionally, the prediction of OGS has been done by tracing lateral cephalograms, which showed low accuracy. We developed a surgical twin using generative prediction for orthognathic surgery using ceph network (GPOSC-Net) for synthetic post-operational lateral cephalogram (spost- ceph).

METHODS AND MATERIALS

707 OGS patients from ten university hospitals were enrolled. We employed graph convolutional neural network (GCNN) to predict appropriate surgical movements from the pre-operational lateral cephalogram (pre-ceph). And, we took the surgical movements, other information from pre-ceph and profile line as inputs to generate spost-cephs using a diffusion model, which was initially trained by using 30k cephalograms. Spost-cephs were validated as follows. A visual Turing test (VTT) was performed with four dentists (DDSs) to differentiate real post-operational lateral cephalograms (post-ceph) from spost-cephs. Landmarks were compared between the post-cephs and corresponding spost-cephs. Spost-cephs were generated with various surgical planning scenarios and evaluated by four DDSs. After being shown spost-cephs generated at guidance of the intended amount of surgical movement (IASM) ranging from under to over setback amounts, they selected the most appropriate images. A survey was performed to evaluate the clinical utility.

RESULTS

VTT achieved an average accuracy of 48%, which indicated that the spost-cephs were plausible. The mean error of the landmarks was 1.5 mm, and the successful prediction rate (errors < 2.0 mm) averaged at approximately 90%. Among various surgical scenarios, DDSs selected images generated at guidance of an average IASM of 1.03±0.31 as the most appropriate. Survey showed the usability of spost-ceph in OGS prediction and patient consultation despite the limitation of surgical planning.

CONCLUSION

We proposed GPOSC-Net using pre-ceph for OGS prediction. The spost-ceph not only accurately predicted the landmark positions but also generated accurate image.

CLINICAL RELEVANCE/APPLICATION

Accurate synthetic cephalograms enhance orthognathic surgery prediction, improving surgical planning and patient consultation by visualizing post-operative outcomes with high realism and landmark precision.

R2-SPIN-11 DECODING IMAGING BIOMARKERS: A SYSTEMATIC REVIEW AND META-ANALYSIS OF RADIOMICS FOR PREDICTING RESPONSE TO TARE

Fereshteh Yazdanpanah, MD, MBA (*Presenter*)
Shakiba Houshi (*Abstract Co-Author*)
Mohammadreza Hosseini-Siyanaki (*Abstract Co-Author*)
Ehsan Ranjbar, MD, MPH (*Abstract Co-Author*)

PURPOSE

Radiomics offers a noninvasive means to predict outcomes after transarterial radioembolization (TARE), yet its reproducibility and performance remain unclear. This systematic review and meta-analysis assesses predictive accuracy, imaging modalities, and modeling strategies, providing tumor type and modality pooled metrics.

METHODS AND MATERIALS

Following PRISMA guidelines, PubMed, Embase, Scopus, and Web of Science were searched through April 2024. Studies using radiomics to predict treatment response or survival after TARE were included. Quality was assessed via QUADAS-2 and Radiomics Quality Score (RQS). Data on tumor type, imaging modality, model type, validation, and performance metrics were extracted. Meta-analysis of 11 externally validated studies was performed using a random-effects model to estimate pooled sensitivity, specificity, and AUC, with subgroup analyses by imaging type and tumor origin.

RESULTS

Out of 608 screened articles, 14 studies (1,423 patients) were included. Tumors studied included HCC (n=9), iCC (n=2), and mCRC (n=3). Imaging sources included CT (n=3), MRI (n=6), and PET (n=2), with some using hybrid or multiparametric inputs. Meta-analysis of 11 studies with quantitative outcomes revealed a pooled AUC of 0.82 (95% CI: 0.78-0.86), sensitivity of 79% (95% CI: 72-85%), and specificity of 75% (95% CI: 67-82%), with moderate heterogeneity (I^2 = 52%). Subgroup analysis demonstrated superior performance in PET-derived models (AUC = 0.87) compared to CT (0.81) and MRI (0.78). Studies integrating radiomics with clinical features (e.g., AFP, tumor burden) achieved higher AUCs (0.85) than radiomics-only models (0.76). Meta-regression showed that studies using external validation and those with higher RQS (>12) had significantly better model robustness ($p < 0.01$). Temporal resolution (e.g., baseline vs. follow-up imaging), feature reduction strategies (e.g., LASSO vs. PCA), and inclusion of shape descriptors were key moderators of model performance. Notably, studies using 3D radiomics and those focusing on texture heterogeneity features (e.g., entropy, GLCM contrast) had better predictive metrics across tumor types. Predicting complete or partial response was more accurate than predicting stable/progressive disease.

CONCLUSION

Radiomics models effectively predict treatment response after TARE, particularly when combined with clinical data and PET imaging. However, methodological variability and reporting gaps underscore the need for standardization and prospective validation.

CLINICAL RELEVANCE/APPLICATION

Radiomics can serve as a noninvasive biomarker to stratify TARE candidates, reduce ineffective treatments, and personalize interventional oncology workflows.

R2-SPIN-12 ENABLING EARLIER DETECTION OF SPINAL LESIONS IN CT IMAGING WITH ARTIFICIAL INTELLIGENCE: A CASE STUDY

Christian Wiedemeyer (*Presenter*)
Marlene Fritzsche (*Abstract Co-Author*)
Patrick Schmidt (*Abstract Co-Author*)
Matthias Kirchler (*Abstract Co-Author*)
Kenneth Schroder (*Abstract Co-Author*)
Lea-Elena Braunschneider (*Abstract Co-Author*)

PURPOSE

To evaluate the potential benefits of integrating an artificial intelligence (AI)-based tool as a second reader for detecting malignant bone lesions on spinal computed tomography (CT) scans.

METHODS AND MATERIALS

Bone is the third most common site of metastasis, signaling poor prognosis. Early detection is critical as osseous metastases impact symptoms, disease progression and therapeutic decisions. Missing skeletal metastases at initial diagnosis can result in suboptimal treatment strategies, impacting patient outcomes, increasing morbidity, and reducing quality of life. AI, especially deep learning algorithms such as CNNs can improve the detection of bone lesions on CT scans. Our nnU-Net segmentation model was trained on 653 cases (516 with malignant lesions) to detect malignancies in the bone. We analysed 200 patients with reported malignant bone lesions in their

spine, identified on CT scans. Retrospectively, we examined earlier scans for each patient where no lesion had been diagnosed. We applied our model to these prior scans, assessing whether AI could have detected the lesion at that earlier time point. A board-certified radiologist independently evaluated AI-flagged cases without, then with, access to AI predictions, confirming lesion visibility and malignancy status. The primary outcome was the proportion of missed cases in which AI successfully identified the lesion before baseline. The secondary outcome was the mean lead time for the AI to detect lesions while they were still not apparent to radiologists.

RESULTS

The AI identified 12 malignant lesions not reported in the original radiology reports. In retrospective review, a board-certified radiologist confirmed that they were not visible without AI assistance at the time. This demonstrates that AI enables true early detection, identifying malignancies on average 228 days earlier—and up to 671 days earlier. An additional 25 malignant lesions detected by AI were also not included in initial reports. Retrospectively, a board-certified radiologist verified that these lesions were visible at the time. This suggests that although they were detectable then, they were missed in the original documentation, indicating reporting gaps.

CONCLUSION

Our AI model shows the potential to detect lesions up to 22 months before they become visible to radiologists, enabling earlier intervention and potentially improving patient outcomes.

CLINICAL RELEVANCE/APPLICATION

Integrating an AI-based second reader into spinal CT interpretation can enhance early detection of malignant bone lesions, influencing therapeutic decisions and improving patient prognosis. Furthermore, AI provides a valuable prompt to radiologists, ensuring comprehensive reporting and enabling earlier intervention.

R2-SPIR-1 EFFICACY OF LOW-INTENSITY FOCUSED ULTRASOUND-AUGMENTED CHEMOTHERAPY AS SECOND-LINE TREATMENT FOR METASTATIC PANCREATIC CANCER

Shuhui Dong (*Presenter*)
Tianqi Zhang (*Abstract Co-Author*)
Xue Han (*Abstract Co-Author*)
Yi-Quan Jiang (*Abstract Co-Author*)
Zhimei Huang (*Abstract Co-Author*)
Jinhua Huang (*Abstract Co-Author*)

PURPOSE

Low-intensity focused ultrasound (LIFU), a lower-energy form of high-intensity focused ultrasound (HIFU), has been reported to enhance the efficacy of chemotherapy and reduce intraoperative pain. The role of LIFU-enhanced chemotherapy in the second-line treatment of metastatic pancreatic cancer (PC) remains unclear. The aim of this study was to evaluate the efficacy and safety of LIFU combined with chemotherapy for patients with metastatic PC after failure of first-line chemotherapy.

METHODS AND MATERIALS

Patients with metastatic PC whose disease progressed after receiving first-line chemotherapy between 2021 and 2024 were included in this retrospective study. Patients were divided into a LIFU combination chemotherapy group and a standard chemotherapy group according to the second-line treatment received. The primary study endpoint was overall survival (OS), and the secondary endpoint was change in pain scores, assessed using the numeric rating scale (NRS). OS was estimated by the Kaplan-Meier method, and paired t-tests were used for comparison of NRS scores.

RESULTS

A total of 108 patients were included in the study, comprising 28 in the LIFU combination chemotherapy group and 80 in the standard chemotherapy group. The baseline characteristics were comparable between the two groups, including gender (male: 20 vs. 46), age =60 years (15 vs. 52), ECOG score 0-1 (26 vs. 74), hepatic metastasis (64.3% vs. 67.5%), number of metastatic organs =2 (67.9% vs. 68.8%), CA19-9 positive (85.7% vs. 82.5%) and tumor size (4.57 ± 1.09 cm vs. 4.68 ± 1.18 cm), all with $P > 0.05$. The median OS was 8.20 months (95% CI: 6.48-9.91) in the LIFU plus chemotherapy group, which was significantly higher than that of the standard chemotherapy group, which was 4.93 months (95% CI: 4.67-5.20) ($P < 0.01$). Regarding pain relief, patients in the LIFU combination chemotherapy group experienced a significant decrease in NRS score from 6.44 before treatment to 0.56 after treatment ($P < 0.001$).

CONCLUSION

LIFU combined with chemotherapy can significantly prolong overall survival and effectively relieve cancer pain in patients with metastatic PC in the second-line setting. Further validation through prospective studies is required.

CLINICAL RELEVANCE/APPLICATION

The findings of this study indicate that adding LIFU to second-line chemotherapy could improve outcomes for patients with metastatic PC after failure of initial therapy. The findings provide preliminary evidence for its clinical use as a second-line treatment strategy, especially for patients with limited treatment options.

R2-SPIR-3 ANALYSIS OF PORTAL VEIN TO INFERIOR VENA CAVA RELATIONSHIP FOR TRANSFEMORAL TRANSCAVAL PORTAL ACCESS

Samad Ashraf (*Presenter*)
Kai Jones, MD (*Abstract Co-Author*)
Kapil Wattamwar, MD (*Abstract Co-Author*)
Yuli Zhu, MD (*Abstract Co-Author*)
Jacob Cynamon, MD (*Abstract Co-Author*)

PURPOSE

Portal vein (PV) access using a transfemoral transcaval (TFTC) approach has been described for PV intervention, serving as an alternative to transsplenic, transhepatic, or transmesenteric access where routine transjugular portal vein access is difficult or impossible. The relationship between the extrahepatic PV (EPV) and the inferior vena cava (IVC) has not previously been studied. This study evaluates the broader applicability of TFTC access in patients requiring PV intervention through an analysis of variables that enable transfemoral access between the IVC and EPV using a 21-guage Chiba needle.

METHODS AND MATERIALS

Since the majority of patients requiring PV access are for TIPS, we reviewed CT scans in patients who underwent TIPS from 2018-2024 at an urban academic center. Inclusion criteria required the availability of pre-procedural scans. Patients were excluded if their CT scans revealed tumors or artifacts that obscured visualization of the EPV and IVC. Initially artificial intelligence (AI) was used to determine the distance between the IVC and EPV. We then reviewed all cases. Two interventional radiologists with experience in TFTC techniques independently reviewed each CT scan in axial, sagittal and coronal views to determine pre-procedural eligibility for TFTC access into the PV. Eligibility criteria included the distance between the EPV and IVC, the presence of intervening blood vessels, organs or tissues preventing direct access, and the length over which the IVC and EPV run parallel. Patients deemed eligible were classified into Types 1,2,3,4 or Not Eligible reflecting increasing levels of difficulty in achieving transcaval access.

RESULTS

105 patients met the inclusion criteria. 6 of the patients had TFTC access to the PV to assist in TIPS procedures. Distances between the IVC and EPV were measured using AI. In the 6 patients who had TFTC access, the median distance was 8.75 mm (range 2.40-18.80). The median distance in the 99 patients who had routine PV access was 11.10 mm (range 2.85-24.89). Among the 99 eligible routine TIPS patients, 4 (4.0%) were classified as Type 1, 9 (9.1%) as Type 2, 6 (6.1%) as Type 2.5,

22 (22.2%) as Type 3, 18 (18.2%) as Type 4 and 20 (20.2%) as Not Eligible. Overall, 85 (81.0%) out of the 105 total patients analyzed met criteria that would allow TFTC access of the PV if needed.

CONCLUSION

TFTC PV access shows potential for facilitated PV intervention in a broader population of patients where conventional access is challenging or unfeasible.

CLINICAL RELEVANCE/APPLICATION

TFTC PV access can be used in situations where routine PV access is difficult or impossible. This study looks at the anatomical applicability of this procedure in the wider population.

R2-SPIR-4 THE EFFICIENCY AND SAFETY OF HEPATIC ARTERIAL INFUSION CHEMOTHERAPY PLUS TYROSINE KINASE INHIBITORS OR IMMUNE CHECKPOINT INHIBITORS FOR ADVANCED HEPATOCELLULAR CARCINOMA

Yu Lei (*Presenter*)

PURPOSE

This retrospective study aimed to evaluate the efficiency and safety of combining hepatic arterial infusion chemotherapy (HAIC) with tyrosine kinase inhibitors (TKIs) or immune checkpoint inhibitors (ICIs) versus HAIC alone for the treatment of advanced hepatocellular carcinoma (HCC).

METHODS AND MATERIALS

A total of 52 consecutive patients with advanced HCC who underwent HAIC and (or) TKIs/ICIs treatments from July 2021 to July 2023 were included in this retrospective study. Based on the different treatment regimens, these patients were divided into HAIC group (n=22) and HAIC+T/I group (n = 30). The laboratory indexes, progression-free survival (PFS), overall survival (OS) and adverse events (AEs) were analyzed. Potential factors affecting PFS and OS were evaluated by univariate and multivariate analyses.

RESULTS

Compared to the HAIC group, the HAIC+T/I group achieved a higher overall response rate (ORR) (56.7% vs. 18.2%, P=0.005), disease control rate (DCR) (93.3% vs. 68.2%, P=0.046) and overall survival (OS) (median OS: 9 vs. 6 months, P=0.006). On multivariate analysis, Prothrombin Time (PT) (hazard ratio [HR]=0.42; 95% confidence interval [CI]: 0.19-0.91; P=0.028), Alanine aminotransferase (ALT) (hazard ratio [HR]=1.03; 95% confidence interval [CI]: 1.01-1.05; P=0.009) and treatment (HAIC+T/I treatment vs. HAIC treatment) (HR=0.25;95% CI:0.10-0.67; P=0.005) were independent prognostic factors of OS. The incidence and severity of AEs related to the treatment between the two groups showed no significant difference.

CONCLUSION

The combination therapy of HAIC with TKIs/ICIs demonstrated good efficiency and safety in patients with advanced HCC.

CLINICAL RELEVANCE/APPLICATION

This study underscores the clinical relevance of combining hepatic arterial infusion chemotherapy (HAIC) with targeted therapies or immunotherapy for advanced hepatocellular carcinoma (HCC). The results highlight improved overall response rates, disease control, and survival outcomes with the combination approach, compared to HAIC alone. This suggests a promising direction for personalized treatment strategies in HCC, potentially offering better efficacy and safety profiles. Further research is needed to optimize and validate these findings in larger, prospective studies.

R2-SPIR-5 ESTABLISHING SELECTION CRITERIA FOR NEW ZEALAND WHITE RABBITS IN INTERVENTIONAL RADIOLOGY RESEARCH: CORRELATIONS OF ORGAN VOLUMES, VESSEL DIAMETERS, AND BODY WEIGHT

Selma Saclier (*Presenter*)
Yubei He (*Abstract Co-Author*)
Justus Klockner (*Abstract Co-Author*)
Justus Ramtke (*Abstract Co-Author*)
Julius Chapiro, MD, PhD (*Abstract Co-Author*)
Richard Ruppel (*Abstract Co-Author*)
Lasse Noack (*Abstract Co-Author*)
Friederike Hesse (*Abstract Co-Author*)
Salma A. Abosabie (*Abstract Co-Author*)
Robin Schmidt (*Abstract Co-Author*)
Lynn J. Savic, MD (*Abstract Co-Author*)

PURPOSE

The VX2 tumor model in New Zealand White (NZW) rabbits is widely used in interventional radiology research due to its reproducibility and suitability for human-sized diagnostic and interventional equipment. However, criteria for animal selection are lacking, leading to increased procedural complications and dropout rates. This study aims at defining selection criteria by correlating body weight and age with abdominal organ and vessel dimensions to identify rabbits anatomically suited for specific radiological research, thereby improving animal welfare and research quality.

METHODS AND MATERIALS

This multi-institutional study included a total of 92 NZW rabbits that underwent cross-sectional imaging of the abdomen between 2017 and 2025, with a subset of scans additionally including the thorax. Specifically, 53 CT and 39 MRI scans were analyzed using the image computing platform 3D Slicer, in combination with an in-house developed segmentation algorithm using the nnU-Net framework for automated liver segmentation. Imaging-based measurements were confirmed by gross anatomy after necropsy in 3 animals and correlated with body weight and age at the time of imaging. Statistical analysis included normality testing and Pearson correlation coefficient.

RESULTS

Body weight ranged from 2.0 to 4.5 kg. Abdominal imaging was available for all, thoracic imaging for 22 animals. Body weight correlated with the volume of the left kidney ($r = 0.70$, $p < 0.01$), right kidney ($r = 0.65$, $p < 0.01$), and liver ($r = 0.42$, $p = 0.00$), as well as the diameters of the a. iliaca interna dextra ($r = 0.58$, $p = 0.01$), a. iliaca interna sinistra ($r = 0.53$, $p = 0.01$), a. iliaca communis sinistra ($r = 0.54$, $p < 0.01$), a. carotis communis dextra ($r = 0.52$, $p = 0.01$), vena cava inferior ($r = 0.52$, $p < 0.01$), a. mesenterica superior ($r = 0.45$, $p < 0.01$), truncus coeliacus ($r = 0.35$, $p < 0.01$), a. hepatica communis ($r = 0.34$, $p = 0.01$), and a. renalis dextra ($r = 0.32$, $p = 0.03$). The segmentation algorithm was trained on 53 manually segmented liver masks over 3 iterative rounds and achieved a Pseudo Dice score of 0.96.

CONCLUSION

These results demonstrate significant correlations between body weight and anatomical structures relevant to interventional procedures in the VX2 model, suggesting a weight-based selection to improve standardization, reduce complications, and enhance animal welfare in preclinical research.

CLINICAL RELEVANCE/APPLICATION

Accurate pre-procedural selection of NZW rabbits based on body weight may improve the success and reproducibility of image-guided interventions by ensuring appropriate anatomical conditions for catheter-based access. This approach contributes to better modeling of human interventions and supports the refinement of preclinical animal research standards.

R2-SPIR-6 ANTECUBITAL VERSUS PECTORAL PLACEMENT OF TOTALLY IMPLANTABLE VENOUS ACCESS PORTS - ANALYSIS OF IMAGE-GUIDED SUPPORT REQUESTS IN CASES OF MALFUNCTION

Kristina Krompass, MD (*Presenter*)
Jan P. Grunz, MD (*Abstract Co-Author*)
Annette Thurner (*Abstract Co-Author*)
Thorsten A. Bley, MD (*Abstract Co-Author*)
Ralph Kickuth, MD (*Abstract Co-Author*)

PURPOSE

This study aimed to analyze functional controls of antecubital and pectoral totally implantable venous access ports, focusing on reasons for referrals for image-guided support and the effectiveness of interventional radiologic management in restoring port function.

METHODS AND MATERIALS

In this retrospective monocentric study, 1,432 functional port controls (751 antecubital, 681 pectoral) performed between January 1, 2008, and June 15, 2022, were evaluated. Patient characteristics, port-specific data, and referral reasons were documented. Additionally, the frequencies of simple puncture errors, thrombotic and mechanical complications, and infections were analyzed and compared between implantation sites.

RESULTS

In the antecubital group, malfunctions occurred later compared with pectoral ports (median 120 days [IQR 43-354] vs. 96 days [IQR 22-404] after implantation; P =.003). Injection resistance was more frequent in antecubital systems (72.2% vs. 62.2%; P <.001), whereas puncture difficulties (2.1% vs. 10.6%; P <.001) and failure to draw blood (2.4% vs. 5.7%; P =.014) were observed more frequently with pectoral ports. Thrombosis represented the most common diagnosis in both groups (35.1% vs. 34.6%; P =.774). Puncture errors were significantly more prevalent in pectoral ports (11.3% vs. 5.2%; P <.001), while infections were diagnosed more often in antecubital systems (4.1% vs. 1.0%; P<.001). Following image-guided management, ports could be used for their intended purpose in the majority of cases (86.2% antecubital vs. 85.5% pectoral; P =.499).

CONCLUSION

Thrombosis and mechanical complications were the predominant causes of impaired port function, irrespective of the implantation site. Image-guided control examinations proved highly effective in restoring port function, underlining the crucial role of interventional radiology in port maintenance.

CLINICAL RELEVANCE/APPLICATION

Functional port controls offer a minimally invasive, yet effective approach to restore venous access and ensure uninterrupted therapy or nutritional support in port patients.

R2-SPMK-1 CLARIFYING DOUBTFUL FRACTURES ON X-RAY WITH AI SUPPORT: A CT-VALIDATED PERFORMANCE STUDY

Marta Epis, MD (*Presenter*)
Francesco Rizzetto, MD (*Abstract Co-Author*)
Caterina B. Monti, MD, PhD (*Abstract Co-Author*)
Gianluca Folco, MD (*Abstract Co-Author*)
Luca A. Carbonaro, MD (*Abstract Co-Author*)
Angelo Vanzulli, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the performance of a commercial artificial intelligence (AI) tool to resolve diagnostic uncertainty in radiographs flagged as "doubtful" for fracture, using computed tomography (CT) as the reference standard.

METHODS AND MATERIALS

In this retrospective study, we included radiographs from the Emergency Department flagged as "doubtful fracture" in the radiology report and followed by CT within 10 days. The AI software (BoneView, Gleamer) categorized each case as "fracture," "doubt fracture," or "no fracture." Diagnostic performance was assessed under two scenarios: treating "doubt fracture" as either positive or negative. An experienced radiologist first reviewed X-rays independently, then re-evaluated them with AI support. CT served as the reference standard. Sensitivity and specificity were calculated, and statistical comparisons were made using the McNemar test.

RESULTS

A total of 96 patients were included, accounting for 689 bone segments, 150 (22%) with and 539 (78%) without fractures on CT. When "doubt fractures" were considered positive, standalone AI sensitivity increased from 55% to 61%, while specificity decreased from 98% to 94% (both $p < 0.001$). Radiologist sensitivity improved from 57% to 64% with AI support ($p = 0.003$), with specificity remaining stable at 98% ($p = 1.00$). The combination of AI assistance and radiologist interpretation yielded the highest overall diagnostic accuracy.

CONCLUSION

In radiographs flagged as "doubtful" for fracture, the integration of AI support significantly improved diagnostic sensitivity while preserving high specificity. The combined assessment by radiologists and AI yielded the most accurate results, reinforcing the utility of AI as a valuable second reader in challenging fracture evaluations.

CLINICAL RELEVANCE/APPLICATION

Artificial intelligence can enhance radiologist performance in cases of equivocal fractures on X-ray, potentially reducing diagnostic uncertainty and improving early fracture detection, especially in emergency settings where CT may not be immediately available.

R2-SPMK-2 SOFT TISSUE, HARD FACTS: ELASTOGRAPHY REDEFINES NEUROMA IMAGING

Giacomo Negro, MD (*Presenter*)
Giovanni Sussan, MD (*Abstract Co-Author*)
Antonio Corso, MD (*Abstract Co-Author*)
Raimondo Angelone, MD (*Abstract Co-Author*)
Carlo D'Alessandro, MD (*Abstract Co-Author*)
Andrea De Grandis, MD (*Abstract Co-Author*)
Carlo Biz (*Abstract Co-Author*)
Alberto Crimi (*Abstract Co-Author*)
Pietro Ruggieri (*Abstract Co-Author*)
Emilio Quaia, MD (*Abstract Co-Author*)
Filippo Crimi, MD, PhD (*Abstract Co-Author*)

PURPOSE

Morton's neuroma is a painful forefoot neuropathy, typically affecting the second and third intermetatarsal spaces. While B-mode ultrasound supports diagnosis, it often lacks specificity in distinguishing neuromas from adjacent bursitis. Strain and shear-wave elastography offer added value by quantifying tissue stiffness. This study assesses their role in improving diagnostic accuracy through enhanced lesion differentiation .

METHODS AND MATERIALS

Sixty-nine suspected Morton's neuromas in 51 patients (45F, 6M; median age 60, range 32-67) were prospectively evaluated. All lesions underwent ultrasound (US) with a linear probe 2-14MHz equipped with strain and shear-wave elastography. The protocol included dorsal and plantar approaches with lateral compression (Mulder sign). B-mode US assessed lesion morphology, size, echotexture, compressibility, Doppler signal, and nerve continuity. Strain elastography provided qualitative assessment via color-coded maps and strain ratio (lesion vs adjacent soft tissue). Shear-wave elastography offered quantitative stiffness measurements in kilopascals (kPa), based on shear wave velocity within defined regions of interest (ROIs).

RESULTS

Of the analyzed cases, 51 were confirmed neuromas and 18 intermetatarsal bursitis. Strain Ratio (SR) was higher in neuromas (median 1.38; IQR: 0.685-2.005) vs bursitis (median 0.895; IQR: 0.670-0.980). Mann-Whitney: $p = 0.0090$; ?median = 0.530 (95% CI: 0.150-0.890). Shear Wave (SW) stiffness was greater in neuromas (median 90.0 kPa; IQR: 78.0-110.75) vs bursitis (median 66.5 kPa; IQR: 49.0-92.0). Mann-Whitney: $p = 0.0090$; ?median = 22.0 kPa (95% CI: 7.0-36.9).

CONCLUSION

Strain and shear-wave elastography significantly improve the diagnostic characterization of intermetatarsal lesions. Both techniques effectively differentiate Morton's neuroma from intermetatarsal bursitis, with neuromas showing greater stiffness. These findings support the integration of elastography into routine ultrasound protocols to enhance diagnostic confidence, especially in inconclusive B-mode cases.

CLINICAL RELEVANCE/APPLICATION

Elastography adds meaningful diagnostic value to conventional ultrasound in the evaluation of Morton's neuroma. By quantifying tissue stiffness, strain and shear-wave techniques enhance the ability to distinguish neuromas from intermetatarsal bursitis, supporting more accurate, non-invasive diagnosis and guiding appropriate clinical management.

R2-SPMK-4 MRI-BASED SOFT-TISSUE TUMOR REPORTING AND DATA SYSTEM (ST-RADS): CLINICAL EXPERIENCE OF PROSPECTIVE IMPLEMENTATION AND DIAGNOSTC ACCURACY

Alex Zhu, BA, BS (*Presenter*)
Enzo Mesarick (*Abstract Co-Author*)
Yasir Mian (*Abstract Co-Author*)
Asim Mohamed (*Abstract Co-Author*)
Flavio Duarte Silva, MD, PhD (*Abstract Co-Author*)
Atul K. Taneja, MD,PhD (*Abstract Co-Author*)
Avneesh Chhabra, MD, MBA (*Abstract Co-Author*)

PURPOSE

To assess the clinical performance associated with implementation of the ST-RADS scoring system and determine its comparison to the traditional descriptive reports.

METHODS AND MATERIALS

Following prospective implementation of ST-RADS scoring in the electronic dictation system, several fellowship-trained musculoskeletal radiologists classified the bone tumors routinely using this system. This retrospective IRB-approved audit study included 238 such consecutive patients who underwent MRI evaluation for soft tissue tumors between January 2023 and May 2024 at a tertiary academic center. Data on patient demographics, imaging findings, lesion characteristics, biopsy results, treatment modalities, and clinical outcomes were collected. Diagnostic accuracy of ST-RADS versus descriptive reporting was compared using McNemar tests, with final pathology and/or clinical follow-up serving as the reference standard.

RESULTS

The cohort (mean age: 54.3 years; 60.8% female) primarily presented with lower extremity (48.3%) and upper extremity (38.7%) tumors. ST-RADS classification distribution included ST-RADS I (2.1%), ST-RADS II (36.9%), ST-RADS III (22.0%), ST-RADS IV (5.9%), ST-RADS V (4.2%), and ST-RADS VI (28.8%). ST-RADS demonstrated superior diagnostic accuracy compared to descriptive reporting overall (99.15% vs. 92.80%, $p = 0.00073$) and also within biopsy-confirmed cases (97.73% vs. 82.95%, $p = 0.00098$). For benign tumors (ST-RADS I-III), ST-RADS achieved 100% accuracy compared to 94.27% for descriptive reporting ($p = 0.0039$). For malignant tumors (ST-RADS IV-VI), ST-RADS also showed higher accuracy compared to descriptive reporting (97.44% vs. 89.74%), although this difference did not reach statistical significance ($p = 0.1094$).

CONCLUSION

Prospective application of the ST-RADS scoring system demonstrated significantly superior accuracy compared to traditional descriptive methods. These results advocate for broader implementation of ST-RADS in clinical practice as a standardized method for classifying musculoskeletal soft tissue tumors , to enhance interdisciplinary communications, and longitudinal data collection for tracking patient outcomes.

CLINICAL RELEVANCE/APPLICATION

Implementation of the ST-RADS system in clinical practice enhances diagnostic accuracy, improves interdisciplinary communication, and supports standardized reporting for musculoskeletal soft tissue tumors.

R2-SPMK-5 MRI CHARACTERISTICS OF PLANTAR FIBROMAS: A LARGE CONSECUTIVE SERIES FROM A TERTIARY CARE CENTER

Natalie Velez (*Presenter*)
Anish Goel (*Abstract Co-Author*)
Avneesh Chhabra, MD, MBA (*Abstract Co-Author*)

PURPOSE

Plantar fibroma or fibromatosis is a painful and dysfunctional benign disorder in which fibrous tissues infiltrate the plantar aponeurosis and, occasionally, the overlying skin. There is a paucity of literature on its MRI characteristics, with the largest study published on only 16 patients to date. The aim is to systematically evaluate MRI characteristics of plantar fibromas from the database of our tertiary care center imaged over a decade with outcomes analysis.

METHODS AND MATERIALS

This retrospective cross-sectional study included 196 cases of MRI-confirmed plantar fibromas interpreted by fellowship trained MSK radiologists and were all re-reviewed by an independent MSK radiologist. The topography of the lesions with respect to cords of plantar fascia, number of lesions, MRI characteristics, largest size, and enhancement characteristics were systematically reviewed. Regional findings of local fracture deformity, regional muscle denervation, and plantar fasciitis were noted. Electronic chart analysis was performed with analysis of clinical findings. Statistical tests included Wilcoxon rank sum test, Chi-squared test, and Fisher exact test.

RESULTS

The most common location was in the central cord (83%) followed by medial cord (15%) and lateral cord (1.5%) with 14% involving multiple cords and only 0.5% involving all 3 cords. 32% of cases showed multiple lesions with 5% showing 4-5 lesions. The majority (68%) were isointense on T1WI and 43-45% lesions were hypointense on fsT2WI and T2WI, respectively. 66% of lesions were heterogeneous with 8.7% showing cystic-necrotic areas, and 64% had solid contrast enhancement. 29% were associated with plantar muscle denervation and 53-56% had plantar spur and fascial thickening. 52% had pain and 9.2% had sensory symptoms with 54% with diabetes mellitus and 4.5% with Charcot neuroarthropathy. No significant correlations were seen with sensory symptoms or foot swelling ($q>0.05$), while T2W and fsT2W signal alterations, enhancement characteristics, and plantar muscle denervation were significant for pain symptoms ($q<0.05$).

CONCLUSION

This large systematic study adds to the body of literature on plantar fibromas, which can affect different fascial cords, can be multiple in up to 1/3 cases, and have contributory MRI features that correlate with foot pain symptoms.

CLINICAL RELEVANCE/APPLICATION

Using MRI features that correlate with foot pain symptoms enables clinicians to use specific imaging characteristics to aid in diagnosing the source of patients' pain.

R2-SPMK-6 A MAMBA-BASED MULTIMODAL DEEP LEARNING FRAMEWORK FOR PRE-TREATMENT PREDICTION OF DISEASE-FREE SURVIVAL IN OSTEOSARCOMA

Ping Yin (*Presenter*)

PURPOSE

Osteosarcoma is an aggressive bone malignancy with high clinical and biological heterogeneity, making prognostic assessment challenging. Conventional markers often fail to capture this complexity. This study aims to develop and validate a novel multimodal deep learning framework (MambaSurv) that integrates pre-treatment MRI, whole-slide histopathology images (WSIs), and clinical data to predict disease-free survival (DFS) in osteosarcoma patients. Additionally, it seeks to explore underlying molecular mechanisms through transcriptomic analysis and in vivo validation.

METHODS AND MATERIALS

A retrospective cohort of 421 osteosarcoma patients from Center 1 was divided into training and internal test sets (70:30 split). An external validation cohort of 70 patients from Center 2 was used to assess generalizability. MambaSurv extracted modality-specific features from pre-neoadjuvant MRI, WSIs, and clinical variables, and fused them via a Bridge Attention mechanism. The model generated DFS risk scores, enabling stratification into high- and low-risk groups. Predictive performance was evaluated through five-fold cross-validation and ROC analysis. Model interpretability was assessed using SHapley Additive exPlanations (SHAP). To investigate biological relevance, transcriptomic analysis (n=20) identified differentially expressed genes and enriched pathways between risk groups. TP53 was functionally validated in an osteosarcoma xenograft mouse model.

RESULTS

MambaSurv achieved an AUC of 0.91 in the internal test set and 0.86 in the external cohort, significantly outperforming unimodal models (MRI: 0.81; WSI: 0.78; Clinical: 0.73; all $p < 0.01$). Kaplan-Meier analysis demonstrated clear separation in DFS between high- and low-risk groups (log-rank $p < 0.001$). SHAP analysis identified tumor volume and peritumoral edema (MRI), nuclear density (WSI), and Enneking stage (clinical) as top contributors. Transcriptomic profiling revealed that high-risk patients exhibited upregulation of TP53, MYC, VEGFA, and CDK4, enriched in cell cycle and angiogenesis pathways. In vivo overexpression of TP53 promoted tumor growth and neovascularization, confirming its functional relevance.

CONCLUSION

The MambaSurv framework enables accurate and interpretable prediction of DFS in osteosarcoma using multimodal pre-treatment data. This approach offers a clinically applicable tool for early risk stratification and individualized treatment planning, supported by molecular and experimental validation.

CLINICAL RELEVANCE/APPLICATION

MambaSurv provides an accurate tool for predicting disease-free survival in osteosarcoma patients, helping with early risk stratification and personalized treatment.

R2-SPMS-1 PHARMACOKINETICS, SAFETY AND EFFICACY OF GADOPICLENOL IN PEDIATRIC PATIENTS UNDER 2 YEARS OLD UNDERGOING MRI

Donna Roberts, MD, MS (*Presenter*)
Justin Chetta, MD (*Abstract Co-Author*)
Jonathan R. Dillman, MD, MSc (*Abstract Co-Author*)
Mathieu Felices (*Abstract Co-Author*)

PURPOSE

To evaluate the pharmacokinetic (PK) profile, safety and efficacy of a single intravenous injection of gadopiclenol at 0.05 mmol/kg body weight, a high-relaxivity gadolinium-based contrast agent for MRI, in children under 2 years old.

METHODS AND MATERIALS

This phase II open-label, multicenter trial included children scheduled to undergo contrast-enhanced MRI of any body region into 3 age groups (3-23 months, 28-89 days and 0-27 days). Three blood samples were collected after gadopiclenol administration, one within each time window (10-60 min, 2-4 hours, 6-8 hours). This pediatric population was integrated into a population pharmacokinetic (popPK) model previously developed for gadopiclenol and including adults and children aged 2 to 17 years with normal renal function and adults with renal impairment, to determine the PK parameters. The efficacy and safety of gadopiclenol, assessed up to 3 months following administration, were evaluated by the on-site radiologists.

RESULTS

A total of 36 patients underwent MRI with gadopiclenol: 33 aged 3-23 months, two aged 28-89 days and one aged 0-27 days (for whom no PK samples could be analyzed). The two-compartment popPK model developed in adults and older children was suitable for children aged <2 years with adjustment for renal function maturation and for proportionally higher extracellular and total body water. Terminal half-life (t 1/2) was comparable across all age groups (median of 1.6 to 1.8 h for adults and pediatric patients 2-17 years and 1.5 to 2.1 h for patients <2 years). Median clearance ranged from 0.08 to 0.10 L/h/kg for adults and 2-17 years and 0.10 to 0.13 L/h/kg for patients <2years. Simulations of plasma concentrations showed minor differences and median area under the curve (AUC 0-8) was 572 mg.h/L for adults, 465 - 638 mg.h/L for pediatrics 2-17 years and 375-495 mg.h/L for children <2 years. One patient (2.8%) experienced a non-serious adverse reaction to gadopiclenol (erythema of mild intensity resolved within 24 h). Lesions visualization (border delineation, internal morphology, and degree of contrast enhancement) was improved with paired (pre-+ post-contrast) images.

CONCLUSION

Gadopiclenol PK in children under 2 years old appears similar to that observed in adults and older children. No adjustment to the dosing regimen is deemed necessary for this population. This study showed no specific safety concerns and confirmed the efficacy of gadopiclenol at 0.05 mmol/kg in this younger pediatric population.

CLINICAL RELEVANCE/APPLICATION

There is no indication for adaptation of gadopiclenol dose based on age, and body weight-based dosing is also suitable for children under 2 years old.

Harrison X. Bai, MD (*Abstract Co-Author*)

PURPOSE

To develop and validate a finely tuned vision-language model (VLM) for automatic whole-body abnormality detection and low-hallucination report generation from PSMA PET/CT.

METHODS AND MATERIALS

We curated a dataset of 344 [^18F]DCFPyL PSMA PET/CT scans from an institution in the United States from 172 patients, with 13 organs manually segmented and abnormalities fully annotated by expert radiologists, yielding 1,327 organ-level image-report pairs. A novel multi-stage fine-tuning pipeline was applied: first, organ-level alignment of visual and textual features using a vision encoder pre-trained on the CT-RATE dataset[1]; second, extension to whole-body multi-organ abnormality detection; and finally, fine-tuning a projection layer integrated with Mistral-Inference 7B for report generation. Model performance was benchmarked against zero-shot, few-shot, and conventional fine-tuning approaches using metrics for organ detection accuracy, benign-versus-malignant classification, and report quality. Report quality was evaluated by F1 score and a fine-grained hallucination evaluation that assesses conceptual accuracy and completeness, detects hallucinations and omissions, and computes a concept-level F1 score. [2]

RESULTS

In the 43-patient test set (675 organs), the proposed model achieved 84.5% accuracy in distinguishing healthy versus abnormal status, outperforming zero-shot (53.2%) and few-shot (62%) baselines. Organ detection accuracy reached 82.4% overall, with lymph node detection at 94.6%. Report generation quality improved modestly over standard fine-tuning (F1 score 0.340 vs. 0.311) while significantly reducing hallucinations (hallucination rate 0.457 vs. 0.408). Notably, zero-shot models failed at organ-level detection, highlighting the importance of fine-grained alignment for modality-specific tasks.

CONCLUSION

Fine-grained, organ-level tuning of VLMs on a modest high-precision dataset enables robust whole-body abnormality detection and trustworthy report generation for PSMA PET/CT, substantially reducing hallucinations and enhancing clinical reliability.

CLINICAL RELEVANCE/APPLICATION

This cross-modal fine-tuning strategy offers a scalable solution for deploying VLMs in specialized imaging domains, delivering clinically meaningful improvements in whole-body assessment with minimal data, and supporting seamless integration into radiology workflows to ease physician workload. R2-SPNMMI-2 HARMONIZATION OF QUANTITATIVE PET DATA ON PET/MR AND PET/CT SYSTEMS

Delphine L. Chen, MD (*Presenter*)
Peter Muzi (*Abstract Co-Author*)
William Hunter (*Abstract Co-Author*)
Robert Miyaoka, PHD (*Abstract Co-Author*)
Alireza Ghodsi, MD (*Abstract Co-Author*)
Amir Iravani, MD (*Abstract Co-Author*)
Paul E. Kinahan, PhD (*Abstract Co-Author*)

PURPOSE

Lack of harmonization has limited the ability to use PET/MR and PET/CT scanners from different vendors together in the same clinical trial for quantitative tumor response assessment. The purpose of this phantom study was to establish the quantitative differences in reconstructions from these scanners to test potential harmonization approaches.

METHODS AND MATERIALS

Phantoms containing 10 mm to 37 mm-diameter spheres that were filled with activity at a concentration of 72.5 kBq/mL and contrast to background of 10:1 were imaged on a United Imaging uPMR PET/MR scanner for 10 minutes then on a GE Discover MI 5-ring PET/CT 30 minutes later for 10 minutes 30 minutes later. The phantom was reimaged on both scanner after activity was added to create a background contrast of 3:1. Images were reconstructed using default parameters for vendor-specific ordered subset expectation maximization (OSEM) with time-of-flight correction and Bayesian penalized likelihood (BPL) reconstruction. Adjusted parameters included simulated scan duration (150 to 600 seconds), filter cutoffs of 3 and 6 mm, and matrix size (150 x150 to 256x256). Size-matched regions were placed over spheres, and 10 6.5 cm-diameter spheres were placed randomly over the background. Standard deviation (SD) characterized background noise, with ANOVA

and Tukey-Kramer post-hoc analysis used to assess for differences. Standard uptake value (SUV) maximum, mean, and peak were measured in all spheres and summarized graphically.

RESULTS

The background SD for the BPL PET/CT images, 0.02±1E-03 for 3:1 and 0.026±6E-06 for 10:1 contrast, was significantly different from BPL PET/MR (0.04±2E-04 for 3:1, 0.04±2E-04 for 10:1). BPL PET/CT and OSEM PET/CT SDs were not significantly different. Background SD for BPL PET/MR images was not different from OSEM PET/MR. The longer duration images reduced background SD to a greater degree for PET/CT than PET/MR (0.02±4E-03 10:1 PET/CT vs 0.04±1E-03 10:1 PET/MR, similar to that observed with 3:1 contrast). Figure 1 shows that variability within the spheres was lowest with SUVpeak for both PET/MR and PET/CT 3:1 contrast data as well as SUVmean with 3:1 contrast. SUVmax was the most variable for all conditions.

CONCLUSION

BPL reconstructions appear effective at minimizing variability in background noise in all tested conditions. Future research will explore whether additional tuning of BPL reconstructions can minimize quantitative measurement differences from both scanners.

CLINICAL RELEVANCE/APPLICATION

BPL reconstructions can reduce variability in quantitative metrics obtained from PET data obtained on PET/CT and PET/MRI scanners, potentially enabling the inclusion of both scanner types in clinical trials for quantitative response assessment.

R2-SPNPM-1 EMPOWER LATINX: EMPOWERING HISPANIC PATIENT'S LUNG CANCER SCREENING UPTAKE

Mahnur Bharucha (*Presenter*)
Omar Gutierrez (*Abstract Co-Author*)
Richard Echeverria (*Abstract Co-Author*)
Leonardo Aguilar-Lopez (*Abstract Co-Author*)
Michael Hoyt (*Abstract Co-Author*)
Sunmin Lee (*Abstract Co-Author*)
Tan Nguyen (*Abstract Co-Author*)
Hari Keshava (*Abstract Co-Author*)
Gelareh Sadigh, MD (*Abstract Co-Author*)

PURPOSE

Lung cancer screening (LCS) rates remain lower among Hispanic populations compared to non-Hispanic whites, despite established guidelines and proven benefits for early detection. This study evaluated the preliminary efficacy of a multi-level, culturally tailored intervention (Empower Latinx) versus enhanced usual care (EUC) to increase LCS uptake among Hispanic patients in a randomized controlled trial.

METHODS AND MATERIALS

Patients aged 50-80 years, identifying as Hispanic or Latino, English or Spanish speaking, with a primary care provider and meeting LCS criteria, were enrolled. Participants completed baseline surveys and were randomized to: (A) EUC, receiving a one-page brochure on LCS risks and benefits; or (B) Empower Latinx, receiving a culturally tailored decision aid, financial support brochure, and reminders for both patients and providers to discuss LCS. Primary outcomes at 4 months included patient- and EMR-reported discussions with primary care providers (PCP) about LCS, LCS orders, and LCS completion.

RESULTS

Thirty-nine patients were enrolled (mean age 61.6 years; 56.4% male; 28% Spanish speaking). Most had Medicaid (64.1%), with others on Medicare (25.6%) or private insurance (7.7%). Key barriers to LCS included scan cost (46.2%), anticipated post-scan expenses (38.5%), and concern about abnormal findings (33.3%). At 4 months, the Empower Latinx group had significantly higher rates of LCS discussions with PCPs (45.0% vs. 10.5%; P=0.01) and LCS orders (50.0% vs. 10.5%; P=0.008) compared to EUC. LCS completion was higher in Empower Latinx (25.0% vs. 10.5%; P=0.24), though not statistically significant, likely due to small sample size.

CONCLUSION

Culturally tailored, multi-level interventions show promise for improving LCS engagement among Hispanic patients, addressing key barriers and supporting guideline-based care. Further research with larger samples and patient navigation may help increase LCS completion and reduce disparities.

CLINICAL RELEVANCE/APPLICATION

A multi-level, culturally tailored intervention can increase lung cancer screening discussions and orders among Hispanic patients, a group with historically lower screening rates. Addressing barriers such as cost and providing targeted support may help reduce disparities and promote earlier lung cancer detection in this population.

R2-SPNPM-2 BIONICLM: MULTI-TIER AI AGENTIC WORKFLOW FOR RADIOLOGY REPORT QUALITY AND EFFICIENCY ENHANCEMENT

Sivasailam Kalyan (*Presenter*)
Harini T (*Abstract Co-Author*)
Vasantha Kumar Venugopal, MD (*Abstract Co-Author*)

PURPOSE

This study introduces BionicLM, an AI-powered two-tier workflow that enhances radiology report quality and efficiency. Deployed across 1,200+ radiologists generating 4,000+ daily reports, BionicLM leverages a dual-agent system for real-time clinical enrichment and quality validation.

METHODS AND MATERIALS

BionicLM operates with two tiers: Tier 1 (Clinical Enrichment Agent) Enhances findings and impressions by cross-referencing clinical history and lab data. Tier 2 (Quality Validation Agent) Detects and corrects errors, ensuring accuracy and aligning with RADPEER criteria.

RESULTS

Descriptive Accuracy (Tier 1) increased from 78.3% to 89.2%, marking a 10.9% improvement. The RADPEER Error Rate (Tier 2) dropped from 9.4% to 2.1%, reflecting a decrease of 7.3%. Report Turnaround Time was reduced from 21 minutes to 10 minutes, a 52% decrease. Clinician Satisfaction rose from 82.5% to 93.4%, showing a 10.9% improvement. Patient Report Readiness increased from 70.8% to 90.5%, an improvement of 19.7%. Tier 1 (Clinical Enrichment Agent): Enhanced descriptive clarity and completeness in 97% of reports. Standardized terminology across 250+ pathologies. Tier 2 (Quality Validation Agent): Identified and corrected 86% of critical errors before final sign-off. Reduced error-related callbacks by 62%.

CONCLUSION

The two-tier AI agentic workflow implemented by BionicLM showcases a scalable model for enhancing radiology report quality and consistency. Its deployment across 1,200+ radiologists and 4,000+ daily reports not only drives efficiency but also standardizes clinical language, minimizes error rates, and accelerates diagnostic timelines—contributing to improved patient outcomes and streamlined clinical operations.

CLINICAL RELEVANCE/APPLICATION

BionicLM integrates AI agents into the radiology reporting process to address issues like inconsistent language, missed findings, and diagnostic delays. By enhancing report quality in real-time and detecting errors, it improves the accuracy, clarity, and speed of reports. Deployed across thousands of radiologists in high-volume centers, it reduces error rates and turnaround times, contributing to better patient safety, faster diagnoses, and more efficient clinical workflows, particularly in resource-constrained environments.

R2-SPNR-1 DISTINGUISHING BETWEEN PARKINSON'S DISEASE AND ESSENTIAL TREMOR THROUGH DTI-BASED BRAIN STRUCTURAL CONNECTIVITY MATRICES USING A GRAPH NEURAL NETWORK

Ahmed Shalaby, PhD (*Presenter*)
Amirreza Alijanpourotaghsara (*Abstract Co-Author*)
Sahil Chilukuri (*Abstract Co-Author*)
Krishna Chitta (*Abstract Co-Author*)
Koorosh Mirpour (*Abstract Co-Author*)
Nader Pouratian (*Abstract Co-Author*)
Jeon Lee (*Abstract Co-Author*)

PURPOSE

Differentiating between Parkinson’s disease (PD) and essential tremor (ET) can pose a challenge in some cases as tremor can be a presenting symptom for both. Facilitating accurate diagnoses can ensure optimal initial treatment. Identifying relative differences between white matter (WM) microstructural changes between PD and ET can aid in differentiating these conditions as well as provide insights into underlying neurobiology. In this study, we developed a graph neural network (GNN) model combined with recursive feature elimination to distinguish between PD and ET subjects using brain structural connectivity matrices derived from diffusion tensor imaging (DTI).

METHODS AND MATERIALS

The study included 57 PD and 43 ET subjects that had deep brain stimulation (DBS) surgery due to moderate to severe motor symptoms. Pretreatment diffusion tensor imaging (DTI) with 64 directions was performed and all scans were acquired at UT Southwestern Medical Center at Dallas, USA (with IRB: STU-2024-0337). As shown in Fig. 1, imaging data were pre-processed and brain structural connectivity matrices were computed using the FMRIB Software Library (FSL) and probabilistic tractography based on the Automated Anatomical Labeling 3 (AAL3) atlas, incorporating 90 regions of interest. These matrices quantified the number of white matter streamlines connecting each pair of regions. A GNN model with recursive feature elimination was developed to identify the most discriminative connections and classify subjects.

RESULTS

The proposed GNN model achieved an area under the receiver operating characteristic curve (AUROC) of 0.86 and a balanced accuracy of 82.5% in distinguishing PD from ET subjects. Feature selection identified key white matter regions contributing most significantly to classification performance, notably connections between the thalamus and supplementary motor area, putamen and primary motor cortex, and cerebellum and prefrontal cortex.

CONCLUSION

Our study effectively investigated WM connections in subjects with PD and ET using a GNN-based model, suggesting the presence of distinct WM microstructural differences in several brain regions, highlighting their potential as discriminatory biomarkers in movement disorder diagnosis.

CLINICAL RELEVANCE/APPLICATION

Accurate differentiation between PD and ET using noninvasive neuroimaging biomarkers can support more precise diagnosis, guiding appropriate treatment strategies and improving patient outcomes.

R2-SPNR-3 EXPLORATION OF CEREBELLUM-SENSORIMOTOR CORTEX DYNAMIC CAUSAL CONNECTIVITY AND FUNCTIONAL REORGANIZATION IN PATIENTS WITH CHRONIC ANKLE INSTABILITY

Yajie Li (*Presenter*)
Hanqiu Liu (*Abstract Co-Author*)
Weiwei Wang (*Abstract Co-Author*)

PURPOSE

To investigate alterations in effective connectivity (EC) between the cerebellum and the cerebral sensorimotor cortex in patients with chronic ankle instability (CAI) during dorsiflexion and plantarflexion tasks using dynamic causal modeling (DCM).

METHODS AND MATERIALS

A total of 26 right-sided CAI patients and 42 age- and education-matched healthy controls were included. Task-based functional magnetic resonance imaging (fMRI) combined with DCM analysis was used to compare alterations in brain network connectivity between the two groups during dorsiflexion and plantarflexion tasks. Based on group-level activation results, the following regions of interest were selected: the left primary somatosensory cortex (S1), bilateral primary motor cortex (M1), bilateral supplementary motor area (SMA), bilateral premotor cortex (PMC), and the right cerebellum. Twelve different connectivity models were systematically constructed, and the optimal EC model was identified using random-effects Bayesian model selection.

RESULTS

For endogenous connectivity, both the patients and control groups exhibited extensive excitatory feedback connections among the sensorimotor cortex ($P < 0.05$, FDR-corrected), with more pronounced positive effects from the left M1 and bilateral SMA to the ipsilateral S1. However, CAI patients showed partial disruption of EC from the sensorimotor cortex to the cerebellum. Under task-related stimulation, the right cerebellum produced an activating effect on the contralateral cortex, and this effect was more pronounced in the CAI group. During the plantarflexion task, CAI patients demonstrated stronger excitatory EC from the left SMA to the ipsilateral M1 (? = 0.297 Hz). Additionally, the bilateral PMC exhibited excitatory inhibition toward other motor cortical areas during task stimulation ($P < 0.05$, FDR-corrected). During dorsiflexion, the right PMC in CAI patients showed a stronger excitatory inhibitory effect on the right SMA and left M1 ($P < 0.01$, uncorrected).

CONCLUSION

The cerebellum plays a dynamic regulatory role in ankle movement tasks in CAI patients. Enhancing cerebellar modulation of the motor cortex and strengthening intrahemispheric coordination between the SMA and M1 may improve movement stability and control.

CLINICAL RELEVANCE/APPLICATION

Incorporating task-oriented dynamic balance training could help optimize cerebellar-cortical neuroregulatory strategies in CAI patients, facilitating personalized rehabilitation.

R2-SPNR-6 CBV-INFORMED MR FINGERPRINTING FOR IMPROVED CLASSIFICATION OF INTRATUMORAL HETEROGENEITY IN POST-TREATMENT GLIOBLASTOMAS

Sree Gongala (*Presenter*)
Shengwen Deng, PHD (*Abstract Co-Author*)
Kaustav Bera, MD (*Abstract Co-Author*)
Mahmoud Omar, MD (*Abstract Co-Author*)
Parisa Arjmand (*Abstract Co-Author*)
Robin Ghotra (*Abstract Co-Author*)
Nisha Korakavi, MD (*Abstract Co-Author*)
Walter Zhao (*Abstract Co-Author*)
Tiffany Hodges (*Abstract Co-Author*)
Prashant Vempati (*Abstract Co-Author*)
Herbert Newton (*Abstract Co-Author*)
Mark A. Griswold, PhD (*Abstract Co-Author*)
Chaitra A. Badve, MD (*Abstract Co-Author*)

PURPOSE

High-grade glioma (HGG) are highly aggressive brain tumor, with tumor recurrence (TR) occurring in 95% of patients after treatment. Differentiating TR from similarly appearing radiation necrosis (RN) on follow-up MRI scans is difficult but offers significant potential for guiding longitudinal therapy. While dynamic susceptibility contrast (DSC)-MRI has shown some success in distinguishing TR from RN (e.g., with an area under the curve (AUC) of 0.64-0.92), this technique fails in patients with hemorrhage, calcification, metals, and mixed tumor lesions. Thus, we explored the utility of the quantitative MRI technique known as MR fingerprinting (MRF) to differentiate between TR and RN regions in these patients.

METHODS AND MATERIALS

We analyzed 27 post-treatment high-grade glioma (HGG) patients in this IRB-approved retrospective study. The diagnoses included 5 patients with TR, 9 with RN, and 13 with mixed tumor types. All the patients underwent multiparametric MRI, DSC-MRI, and MRF scans at the time of imaging progression. The MRF scans were reconstructed to generate T1 and T2 maps. Image preprocessing was conducted using the Cancer Imaging Phenomics Toolkit (CaPTk), and delta relaxometry maps were generated using MATLAB (version R2022b). Statistical analyses, including descriptive statistics, generalized linear modeling (GLM), and Youden's index, were performed using R (version 4.3.2).

RESULTS

The voxel distribution in the RN group was found to be more skewed compared to the TR group. Reflectively, the mode voxel values across different MRF contrast maps showed vast differences between TR and RN groups (Mode values were as follows: for T1-Pre, TR-1312.7 ms, RN-846 ms; T2-Pre, TR-100.3 ms, RN-78.3 ms). A single parametric GLM analysis conducted on image contrast-based descriptive statistics yielded an AUC, sensitivity, and specificity of 0.88, 0.9, and 0.75, respectively, with T2-Pre skewness. Additionally, a multiparametric GLM prediction analysis achieved a higher AUC of 0.92, along with a sensitivity of 0.81 and a specificity of 0.91. This multiparametric prediction model utilized four parameters: T2-Pre skewness, T2-Pre kurtosis, delta-T2 kurtosis, and delta-R2 maximum values.

CONCLUSION

This preliminary analysis demonstrates the promising ability to distinguish between TR and RN regions in post-treatment HGG patients using MRF, and achieving an impressive sensitivity of 0.81 and specificity of 0.91

CLINICAL RELEVANCE/APPLICATION

Accurate differentiation between TR and RN significantly aids in early and effective clinical decisions in post-treatment glioma patients, such as aggressive treatments for TR versus a conservative approach for RN patients.

R2-SPNR-7 EFFECT OF BASELINE BRAIN HEALTH ON SURVIVAL OUTCOMES IN GLIOBLASTOMA PATIENTS

Sree Gongala (*Presenter*)
Robin Ghotra (*Abstract Co-Author*)
George Wang (*Abstract Co-Author*)
Franco Alonso (*Abstract Co-Author*)
Yilun Sun (*Abstract Co-Author*)
Parisa Arjmand (*Abstract Co-Author*)
Haley Perlow (*Abstract Co-Author*)
Tiffany Hodges (*Abstract Co-Author*)
Chaitra A. Badve, MD (*Abstract Co-Author*)

PURPOSE

Structural and volumetric changes across different brain regions during glioblastoma treatment have been noted in prior studies. However, the effect of baseline brain health on survival outcomes is unknown. To address this gap, we assessed the association between baseline quantitative imaging-based brain health metrics, clinical parameters, and glioblastoma survival outcomes.

METHODS AND MATERIALS

This IRB-approved retrospective study was performed on 223 IDH1-wildtype glioblastoma patients. Clinical and molecular parameters were collected through chart reviews. Pre-surgical multiparametric MR images were used to measure quantitative brain metrics including include gyrification index (GI), cortical thickness, sulcal depth, and both grey (GM) and white matter (WM) volumes of the brain. Preprocessing, tumor volume segmentation, volumetric, and surface-based segmentations were performed using Cancer Imaging Phenomics Toolkit (CaPTk) and Computational Anatomy Toolbox (CAT12), respectively. Statistical analysis was performed using MATLAB(R2022b) and R version 4.3.2.

RESULTS

In comparison to elderly, non-elderly patients had significantly higher GM volumes (Median (in mL) - 162.12 vs 140.47 in elderly, $p<0.001$). No differences were noted in WM volumes (Median (in mL) - 139.93 vs 140.02 in elderly, $p = 1$). Significant differences among elderly and non-elderly were also seen in GI (median (in mm) 27.92 vs 27.59 in elderly, $p<0.001$), but not in thickness (median (in mm) 1.68 vs 1.70 in elderly, $p=0.56$) and depth (median (in mm) 10.1 vs 10.38 in elderly, $p=0.82$). Multivariable Cox analysis showed that larger GI, larger thickness, and smaller sulcal depth significantly decreased the mortality risk in glioblastoma patients, irrespective of age.

CONCLUSION

This study suggests that the baseline brain health of glioblastoma patients contributes to survival outcomes, irrespective of patient age. In particular, parameters indicating better cortical health are associated with improved survival outcomes.

CLINICAL RELEVANCE/APPLICATION

Baseline brain health parameters show significant potential as biomarkers for predicting and understanding the prognosis of glioblastoma patients.

R2-SPNR-8 ATYPICAL MRI FEATURES OF PRIMARY CNS LYMPHOMA IN IMMUNOCOMPETENT PATIENTS - A RETROSPECTIVE DESCRIPTIVE STUDY

Lutof Zreik, MD (*Presenter*)
Ayelet Eran, MD (*Abstract Co-Author*)

PURPOSE

Primary central nervous system lymphoma (PCNSL) in immunocompetent patients typically exhibits characteristic magnetic resonance imaging (MRI) features. In contrast, atypical features—such as absent or heterogeneous enhancement, lack of diffusion restriction, hemorrhagic components, and elevated perfusion parameters—are commonly described in immunocompromised individuals but are considered rare in the immunocompetent. This study aims to evaluate the prevalence of these atypical MRI features in immunocompetent, compare it to the prevalence of typical imaging findings, and reassess the assumption that atypical features are indeed rare in this group.

METHODS AND MATERIALS

A retrospective review was conducted using electronic medical records at a tertiary care center from 2007 to 2024. Inclusion criteria were: immunocompetent status, biopsy-proven PCNSL, no evidence of secondary CNS lymphoma, and availability of pre-treatment MRI. MRI features were evaluated by a senior neuroradiologist and included diffusion restriction, enhancement pattern, susceptibility-weighted imaging (SWI) findings for hemorrhage, and MR perfusion parameters.

RESULTS

Preliminary analysis identified 53 patients who met the inclusion criteria, all with histological diagnosis of diffuse large B-cell lymphoma. Of these, 25 (47.2%) showed typical MRI features (mean age 65), while 28 (52.8%, 95% CI: 39.8%-65.6%) presented with at least one atypical feature (mean age 66). Among the atypical cases, two were intravascular PCNSL and one presented with isolated leptomeningeal involvement. Nine had one atypical feature; 16 had two or more. Across the entire cohort, 17 (32%) showed non-classical enhancement patterns, 17 (32%) showed no restricted diffusion, and 12 (43%) exhibited hemorrhagic foci on SWI. Of the eight patients who underwent MR perfusion, three (38%) demonstrated increased perfusion parameters.

CONCLUSION

Atypical MRI features in immunocompetent PCNSL are significantly more prevalent than previously reported, comprising over half of the cases in our cohort. This challenges the traditional assumption that such findings are rare in immunocompetent individuals.

CLINICAL RELEVANCE/APPLICATION

PCNSL in immunocompetent patients may frequently present with atypical imaging features that may mimic other neoplastic or infectious processes. While histopathology remains the gold standard for diagnosis, recognizing this broader imaging spectrum is essential for neuroradiologists to refine differential diagnosis and guide timely and appropriate clinical management.

R2-SPNR-9 AUTOMATED DELTA RADIOMICS-BASED MRI ANALYSIS FOR RISK STRATIFICATION OF DISEASE PROGRESSION IN POST-RESECTION GLIOBLASTOMA MULTIFORME

Paul F. D'Cunha, MD (*Presenter*)
Abhishek Midya (*Abstract Co-Author*)
Brent D. Weinberg, MD, PhD (*Abstract Co-Author*)
Anant Madabhushi, PhD (*Abstract Co-Author*)
Jinsuh Kim, MD (*Abstract Co-Author*)

PURPOSE

To develop (1) a fully automated approach integrating clinical, genetic, and radiomics models with whole tumor deep learning segmentation for risk-stratification of post-resection glioblastoma multiforme (GBM) patients, and (2) to explore delta radiomics (post-radiotherapy (RT) minus pre-RT features) and its prognostic value compared to single-timepoint radiomics.

METHODS AND MATERIALS

Retrospective analysis included GBM patients from Emory University who underwent resection and RT. Clinical (age, sex) and genetic (MGMT promoter methylation, IDH status) data were collected. Whole-tumor segmentation was automatically performed on post-resection MRI using nnUNet (trained on 1621 post-resection patients from BraTS 2024). 1502 radiomic features for pre-RT, post-RT, and delta radiomics (post-RT - pre-RT) were extracted via PyRadiomics. After features underwent initial univariable screening, LASSO Cox regression identified predictive features for progression-free survival (PFS). Models were evaluated using concordance index (C-index) for radiomics alone (C R -index) and combined with clinical and genetic variables (C R+C -index). Radiomic scores were used to stratify patients (median split) for Kaplan-Meier survival analysis, along with calculated Hazard ratios with 95% confidence intervals. P values were calculated using log-rank tests.

RESULTS

A total of 114 GBM patients (69 training, 45 testing) were analyzed. Delta radiomics showed best prognostic performance using T1-contrast features: test C R -index=0.63, p=0.023; C R+C -index=0.70, p<0.001; training C R -index=0.815, C R+C -index=0.66. Post-RT radiomics optimal model used only FLAIR features: test C R -index=0.64, p=0.003; C R+C- index=0.66, p=0.107; training C R -index=0.79, C R+C -index=0.79. Pre-RT radiomics best performance occurred with features from FLAIR+T1+T2+ADC: test C R -index=0.62, p=0.014; C R+C -index=0.67, p=0.001; training C R -index=0.83, C R+C -index=0.91. Median risk scores enabled significant Kaplan-Meier risk stratification for all of the best models for pre-RT, post-RT and delta radiomics.

CONCLUSION

A fully automated approach combining nnUNet-based segmentation with clinical, genetic, and delta radiomics enables objective, manual-free prognostic risk stratification in post-resection GBM patients.

CLINICAL RELEVANCE/APPLICATION

PFS is crucial for assessing GBM treatment response, yet clinical adoption of radiomics is limited by manual segmentation. This study integrates deep learning automation and clinical-radiomic modeling incorporating the novel concept of delta radiomics to add post-resection prognostic information to guide therapeutic planning.

R2-SPNR-12 VASARI FEATURES TO PREDICT CDKN2A/B HOMOZYGOUS DELETION IN IDH-MUTANT ASTROCYTOMAS:A MULTICENTER STUDY

Zhengyang Zhu, MD (*Presenter*)
Huiquan Yang, PhD (*Abstract Co-Author*)
Mengying Xu, MD (*Abstract Co-Author*)

Xin Zhang (*Abstract Co-Author*)
Bing Zhang, PhD (*Abstract Co-Author*)

PURPOSE

Cyclin-dependent kinase inhibitor (CDKN) 2A/B homozygous deletion holds an important value in the prognostic analysis of IDH-mutant astrocytomas. This study aimed to develop and validate a prediction model based on Visually AcceSAble Rembrandt Images (VASARI) MRI features for identifying CDKN2A/B homozygous deletion status in IDH-mutant astrocytomas.

METHODS AND MATERIALS

Preoperative MRI images of 122 astrocytoma patients (101 without CDKN2A/B homozygous deletion, and 21 with CDKN2A/B homozygous deletion) were retrospectively collected as training set. Eighteen patients with astrocytomas from another center (14 without CDKN2A/B homozygous deletion, and 4 with CDKN2A/B homozygous deletion) were enrolled as external test set. VASARI features in MRI images of astrocytoma patients were evaluated by radiologists. Prediction models for identifying CDKN2A/B homozygous deletion status based on clinical and VASARI features were constructed using logistic regression.

RESULTS

Multivariate regression analysis showed that age (OR: 1.057, p = 0.038) and definition of enhancing margin (OR: 15.672, p = 0.001) were independent predictors of CDKN2A/B homozygous deletion in IDH-mutant astrocytomas. The prediction model in the training set exhibited an AUC of 0.84 (95% CI: 0.73-0.95), 89.3% accuracy, 52.4% sensitivity, and 97.0% specificity. The prediction model in the external test set showed an AUC of 0.86 (95% CI: 0.63-1.00), 83.3% accuracy, 50.0% sensitivity, and 92.9% specificity.

CONCLUSION

The prediction model based on the VASARI MRI features was useful for preoperative identification of CDKN2A/B homozygous deletion status in IDH-mutant astrocytomas.

CLINICAL RELEVANCE/APPLICATION

This research may help radiologists identify CDKN2A/B homozygous deletion status of astrocytomas in the reading room.

R2-SPNR-13 INTEGRATING GLOBAL RISK AND LOCAL PRECISION: A DUAL-MODEL RADIOMICS STRATEGY FOR POSTOPERATIVE GLIOBLASTOMA RECURRENCE

Yan Li (*Presenter*)
Zekun Jiang, PhD (*Abstract Co-Author*)
Su Lv, MD (*Abstract Co-Author*)
Min Wu (*Abstract Co-Author*)

PURPOSE

To develop a dual-model radiomics framework that predicts early glioblastoma (GBM) recurrence at the patient level and spatially maps high-risk regions on postoperative Magnetic resonance imaging (MRI) at pixel level, overcoming the limitations of conventional imaging in distinguishing tumor infiltration from edema.

METHODS AND MATERIALS

This retrospective multi-center study analyzed postoperative MRI scans from 184 GBM patients. The dual-model framework integrated two components: a patient-level model predicting early recurrence (=6 months) using radiomic features from the entire tumor region on postoperative Fliud Attenuated Inversion Recovery (FLAIR) sequences, and a pixel-level model localizing high-risk subregions through supervoxel analysis (9×9×9 voxel cubes) within peri-cavity areas defined by contrast-enhanced T1-weighted imaging to ensure anatomical correspondence with recurrence regions. Radiomic features extracted from FLAIR images underwent a three-step feature selection process. First, the Mann-Whitney U test ($p < 0.05$) retained features with significant group differences. Second, Spearman correlation analysis (SCC > 0.9) excluded redundant features. Finally, feature contributions were quantified using SHapley Additive exPlanations (SHAP) values derived from a trained Random Forest classifier, with the top 10 most impactful features retained for model construction. Eight machine learning classifiers were trained on 116 patients and validated on 29 patients. The optimal Random Forest model was evaluated on an independent test set (n=39), with supervoxel-based predictions aggregated to generate spatial heatmaps for recurrence localization.

RESULTS

The patient-level model achieved an Area Under Curve (AUC) of 0.76, while the pixel-level model demonstrated robust performance with an AUC of 0.80 in the independent test set. Spatial heatmaps generated by the pixel-level model showed clinically meaningful alignment with ground-truth recurrence regions. The dual-model framework exhibited strong overall performance, providing both risk stratification and spatial guidance.

CONCLUSION

This study establishes a novel dual-model framework that integrates patient-level recurrence risk prediction with voxel-wise spatial mapping, offering a practical tool for personalized radiotherapy targeting and high-risk patient management.

CLINICAL RELEVANCE/APPLICATION

By simultaneously identifying high-risk patients and recurrence-prone subregions, this framework may enhance precision in adjuvant therapy planning, reduce unnecessary interventions, and improve postoperative surveillance efficiency.

R2-SPNR-14 A COMPARATIVE ANALYSIS OF DEEP LEARNING QUANTITATIVE NETWORKS AND GAUSSIAN MODELS FOR IDH MUTATION STATUS IN ADULT DIFFUSE GLIOMAS

Jiamin LI (*Presenter*)
Dairong Cao, MD (*Abstract Co-Author*)

PURPOSE

Isocitrate dehydrogenase (IDH) mutations are pivotal biomarkers for molecular classification and prognosis in adult diffuse gliomas . However, accurately determining IDH mutation status before surgery remains a major challenge in neuro-oncology. To address this, we compared conventional Gaussian modeling with a novel deep learning-based metabolite quantification network (DM) to develop a magnetic resonance spectroscopy (MRS)-based framework for non-invasive IDH prediction.

METHODS AND MATERIALS

This retrospective study involved 285 adult patients with diffuse gliomas (WHO grades II-IV) who had preoperative 3T MRS data (TE = 30 ms). Metabolite ratios were quantified using deep learning-based DM and Gaussian decomposition (Gauss). The DM model identified 19 metabolite ratios, including 2HG/tCr and GPC/tCr, while the Gauss model quantified 9 ratios. Significant metabolites were determined via univariate analysis ($P < 0.05$). Three models were compared: Model 1: 9 ratios from Gauss; Model 2: Subset of DM ratios matching Gauss; Model 3: 19 DM-exclusive ratios plus 10 additional biomarkers. Statistical analyses were performed using IBM SPSS Statistics 25.0, while ROC analysis and DeLong's test were performed in R 4.2.1 using the pROC package.

RESULTS

The DM model detected 29 metabolites, whereas the Gauss model identified 10 metabolites. In the individual analysis of metabolite ratios within the DM model, the AUC value for Glu/tCr was the highest, reaching 0.811. The AUC value for the key metabolite 2HG/tCr was also substantial, at 0.728. In the Gauss model, the AUC value for GSH/tCr was the most robust, reaching 0.761. When comparing the predictive performance of the models, Model 1 (AUC = 0.888) and Model 2 (AUC = 0.847) exhibited

comparable performance (P = 0.109). In contrast, Model 3 (AUC = 0.929) significantly outperformed Model 2 (P = 0.004), highlighting the superior predictive capacity of the DM model for IDH mutation status.

CONCLUSION

The DM model demonstrated superior performance in detecting a broader spectrum of metabolites compared to the Gaussian model, while both models exhibited comparable predictive accuracy for overlapping metabolites. The enhanced sensitivity and predictive capacity of the DM model suggest its potential for improving non-invasive IDH mutation prediction in adult diffuse gliomas.

CLINICAL RELEVANCE/APPLICATION

By enabling the identification of a broader range of metabolites, DM provides more comprehensive metabolic profiling, thereby improving the accuracy of preoperative molecular diagnosis. These advancements hold important implications for personalized treatment planning and more effective clinical management of glioma patients.

R2-SPNR-15 ASSOCIATION OF MRI SURVEILLANCE FREQUENCY ON OVERALL & PROGRESSION-FREE SURVIVAL IN GLIOBLASTOMA: A REAL-WORLD COMPARATIVE EFFECTIVENESS STUDY

Zain Hussain, MD (*Presenter*)
Andrew Lee (*Abstract Co-Author*)
David Baskin, MD (*Abstract Co-Author*)
Bin S. Teh, MD (*Abstract Co-Author*)
Jeffrey J. Critchfield, MD (*Abstract Co-Author*)
Steve H. Fung, MD (*Abstract Co-Author*)

PURPOSE

MRI surveillance is central to post-treatment management of glioblastoma (GBM), yet the optimal frequency remains unclear. We compared clinical outcomes across varying MRI intervals, every 4 weeks (q4), 8 weeks (q8), and 12 weeks (q12), in surgically treated GBM patients who received chemoradiation therapy using a multi-institutional real-world dataset.

METHODS AND MATERIALS

Using a de-identified electronic health record network, we identified adult patients with GBM who received radiation and chemotherapy. Three cohorts were formed based on post-RT MRI surveillance frequency: q4 (every 4 weeks, n=217), q8 (every 8 weeks, n=343), and q12 (every 12 weeks, n=220) for at least 9 months. Outcomes included salvage surgery, all-cause mortality, composite palliative care/mortality, subsequent chemotherapy, and a composite progression-free survival proxy. During sensitivity analysis, the index date was redefined from completion of chemoradiation to the date of last known follow-up MRI, to evaluate for immortal time bias. We further validated our outcomes by matching for multifocal disease, MGMT methylation status, TERT and EGFR alterations. Kaplan-Meier analysis and Cox proportional hazards models assessed time-to-event outcomes.

RESULTS

All-Cause Mortality : Similar mortality across comparisons (q4: 77.5%; q8: 75.4%; q12: 77.6%), with no survival advantage observed (q4 vs q8 HR 0.99, p =0.92; q4 vs q12 HR 1.00, p =0.74). Palliative Care / Mortality Composite : Outcomes were nearly identical between groups (q4 vs q8: 85.1% vs 83.2%, p =0.58; q4 vs q12: 85.1% vs 84.9%, p =0.97). Progression-Free Survival Proxy : High rates of composite progression events in all cohorts (q4: 90.3%, q8: 88.3%, q12: 88.2%) with no statistical difference in time to event (p >0.39 for all comparisons). Sensitivity Analysis After redefining the index event to the last known follow-up MRI, survival and treatment outcomes remained non-significant across all cohorts. Genomic/Multifocal Matching After matching on MGMT, TERT, EGFR, and multifocal status, outcome differences across cohorts remained non-significant.

CONCLUSION

In this multi-cohort, real-world study of GBM patients, more frequent post-RT MRI surveillance (every 4 weeks) was not associated with survival, progression, or treatment escalation benefit compared to surveillance every 8 or 12 weeks. These findings could suggest that extending MRI intervals may offer similar clinical outcomes while reducing healthcare costs associated with frequent imaging.

CLINICAL RELEVANCE/APPLICATION

Optimizing imaging frequency to every 2-3 months may maintain clinical efficacy while potentially curbing frequent imaging and reducing healthcare costs.

R2-SPPD-1 EVALUATION OF A NOVEL 4D MOTION-RESOLVED MRI TECHNIQUE FOR PEDIATRIC CONTRAST ENHANCED ABDOMINAL IMAGING: A COMPARATIVE STUDY WITH STANDARD NON-CARTESIAN FREE-BREATHING T1-WEIGHTED SEQUENCES

Navaira Shoaib, MBBS (*Presenter*)
Sebastian Gallo-Bernal, MD (*Abstract Co-Author*)
Valeria Pena-Trujillo, MD (*Abstract Co-Author*)
Teresa Victoria, MD, PhD (*Abstract Co-Author*)
Eugene Milshteyn, PhD (*Abstract Co-Author*)
Xinzeng Wang (*Abstract Co-Author*)
Patricia Lan (*Abstract Co-Author*)
Evan J. Zucker, MD (*Abstract Co-Author*)
Michael S. Gee, MD, PhD (*Abstract Co-Author*)

PURPOSE

To assess the diagnostic quality of a novel 4D motion-resolved technique compared to a standard free-breathing, non-cartesian post-contrast T1-weighted sequence for pediatric abdominal MRI.

METHODS AND MATERIALS

This IRB-approved study prospectively recruited 11 pediatric patients (median age 9±5.7 years; range 12-16 years) undergoing clinically indicated contrast-enhanced abdominal MRI. All patients underwent free-breathing (FB) post-contrast T1-weighted imaging using an FDA-approved non-cartesian steady-state gradient echo sequence with intermittent fat suppression and 3D stack-of-stars encoding (LAVA Star, GE Healthcare). Scans were performed on a 1.5T SIGNA Artist or 3T SIGNA Premier MRI scanner (GE Healthcare). For the experimental 4D motion-resolved technique, respiratory motion was addressed by deriving a motion surrogate signal from k-space center data, which was retrospectively divided into ten respiratory-correlated phases, offering a comprehensive anatomical view throughout the respiratory cycle. Three fellowship-trained pediatric radiologists blindly and independently evaluated the image quality of both sequences on a 1-5 Likert scale based on five criteria: motion artifacts, sharpness of small hepatic structures, ability to detect liver/pancreatic lesions, overall diagnostic quality, and the ability to assess small subdiaphragmatic anatomical structures like adrenal glands and vessels. The results were pooled and statistically compared using nonparametric tests.

RESULTS

The 4D motion-resolved sequence demonstrated significantly fewer motion artifacts (median 5 ± 1 vs. 4 ± 1, $p<0.001$, with images showing fewer disruptions than the standard sequence. For evaluating small anatomical structures like the adrenal glands, the 4D sequence provided more precise visualization (median 5 ± 1 vs. 4 ± 1, $p=0.012$). There was a trend towards improved ability to detect liver and pancreatic lesions (median 4 ± 1 vs. 4 ± 2, $p=0.074$) and overall diagnostic quality (median 4 ± 1 vs. 4 ± 2, $p=0.054$. No significant differences were observed in the sharpness of small hepatic structures such as bile ducts and vessels (median 4 ± 1 vs. 4 ± 2, $p=0.245$).

CONCLUSION

4D motion-resolved images displayed significantly reduced motion artifacts and improved the visualization of small subdiaphragmatic structures (i.e., adrenal) compared to the standard free-breathing T1-weighted sequence, with promising trends in lesion detection and overall diagnostic quality.

CLINICAL RELEVANCE/APPLICATION

4D motion-resolved MRI enables high-quality imaging in children by reducing motion artifacts and improving diagnostic accuracy without additional acquisition time, sedation or breath-holding.

R2-SPPD-2 DOSE OPTIMIZATION FOR PEDIATRIC CHEST CT: A COMPARATIVE STUDY OF ENERGY-INTEGRATING AND PHOTON-COUNTING DETECTOR CT USING 100 KV PROTOCOLS WITH TIN FILTRATION REGARDING IMAGE QUALITY AND DOSE EXPOSURE

Greta Thater (*Presenter*)
Stefan O. Schoenberg, MD, PhD (*Abstract Co-Author*)
Meike Weis (*Abstract Co-Author*)

PURPOSE

Pediatric chest imaging is particularly challenging due to small body size and the need for minimized radiation exposure. Photon-counting CT (PCCT), the latest CT technology, promises substantial dose reduction while maintaining high image quality. This study compares radiation dose and image quality between PCCT and energy-integrating CT (EICT) using clinical data.

METHODS AND MATERIALS

139 pediatric chest CT scans (PCCT: n = 72; EICT: n = 67), acquired from 2021-2024 with 100Sn protocols, were retrospectively analyzed. Patients ranged from 1 to 213 months. Radiation exposure was assessed via CTDIvol and DLP. Image quality was evaluated objectively (signal-to-noise ratios for lung and soft tissue) and subjectively using a 4-point Likert scale.

RESULTS

The PCCT group was younger (mean age 54.7 months) than the EICT group (76.6 months). CTDIvol was comparable (PCCT: 0.26 ± 0.12 mGy; EICT: 0.22 ± 0.18 mGy), Fig.1. PCCT showed significantly better image quality: SNR for lung (-6.93 vs. -4.28) and soft tissue (1.03 vs. 0.35), $p<0.05$. Subjective evaluation favored PCCT for lung ($p<0.0001$) and soft tissue ($p=0.0009$) visualization, Fig.2.

CONCLUSION

PCCT achieves significantly improved image quality at similar radiation doses compared to EICT. Ongoing protocol adjustments are essential in pediatric radiology to optimize the balance between dose and diagnostic quality.

CLINICAL RELEVANCE/APPLICATION

This study highlights how PCCT can enhance pediatric chest imaging by improving image quality and enabling potential dose reduction compared to conventional EICT.

R2-SPPD-3 APPLICATION OF TWO CT-BASED MACHINE LEARNING (ML) ALGORITHMS FOR ASSESSING ACUTE PULMONARY EMBOLI IN CHILDREN

Seyedehelaheh Hosseini, MD (*Presenter*)
Javier Contreras Yametti, MD (*Abstract Co-Author*)
Anushree M. Burade, MBBS (*Abstract Co-Author*)
Chelsea Dunning, PhD (*Abstract Co-Author*)
Julian Anhaus (*Abstract Co-Author*)
Andrei Chekkoury (*Abstract Co-Author*)
Saikiran Rapaka, PhD (*Abstract Co-Author*)
Parisa Kaviani, MD (*Abstract Co-Author*)
Lina Karout, MD (*Abstract Co-Author*)
Mannudeep K. Kalra, MD (*Abstract Co-Author*)
Pallavi Sagar, MBBS (*Abstract Co-Author*)

PURPOSE

Most ML algorithms target adult patients and do not have regulatory clearance for use in children. Therefore, we compared the performance of two ML algorithms for detecting pulmonary emboli on routine chest CT (rCT) and pulmonary embolism CT (peCT) in pediatric and adult patients.

METHODS AND MATERIALS

Our retrospective human subject study included two consecutive cohorts of rCT and peCT examinations in 259 children (age range 3- 20 years; female: male 146:113) and 400 consecutive adults (age =>20 years; female: male 158:242) from multiple primary outpatient- to quaternary inpatient- care settings. All thin-section, anonymized, CT DICOM image datasets were processed with two ML algorithms (from Avicenna.ai and Siemens Healthineers) to obtain information on the presence and absence of emboli. Two radiologists (one independent of ML outputs; the other with ML-aided findings) established the ground truth on the presence of emboli using an AI validation platform (CARPL.ai, India). For all ML-failure cases, we assessed the presence of artifacts and the level of contrast enhancement. We obtained descriptive statistics, F1 scores and ROC AUCs for different comparison groups, stratifying between age groups and rCT and peCT.

RESULTS

There was 45/259 emboli-positive CT (17%) in children and 5% (21/400) emboli-positive CT in adult patients. The relative performance of the two ML algorithms in children: ML1 - 0.71 F1-score, AUC of 0.91 (95% CI: 0.88-0.97), 88.8 % accuracy; ML2 - 0.78 F1-score, AUC of 0.86 (95% CI:0.78-0.94), 93% accuracy; and adult patients: ML1 - 0.63 F1-score, AUC of 0.9 (95% CI:0.82-0.97), 89% accuracy; ML2 - 0.48 F1-score, AUC of 0.82 (95% CI:0.69-0.94), 96% accuracy. Although there was a significant difference in the two ML performances ($p=0.02$), there was no performance difference in the two ML algorithms between children and adults, or between rCT and peCT exams ($p>0.1$). Most missed emboli were subsegmental, and in patients with marked motion artifacts or poor contrast enhancement.

CONCLUSION

Although ML algorithms can effectively detect emboli on chest CT in adults and children, there is a substantial variation in the performance between the two algorithms.

CLINICAL RELEVANCE/APPLICATION

ML algorithms are trustworthy in detecting emboli on chest CT in children, with limitations related to chest CT with suboptimal contrast enhancement and motion artifacts.

R2-SPPH-2 IMPROVED DUAL-ENERGY SEGMENTATION OF IODINE AND CALCIFIED PLAQUE WITH AI-BASED SPECTRAL RECONSTRUCTION

Nathan Huber, PhD (*Presenter*)
Karst Adriaansens (*Abstract Co-Author*)
Enas Ahmed, MD (*Abstract Co-Author*)
Christopher P. Favazza, PhD (*Abstract Co-Author*)
Tim Leiner, MD, PhD (*Abstract Co-Author*)

PURPOSE

The purpose of this study is to test the feasibility of dual-energy segmentation of calcified atherosclerotic plaque and iodine while using an AI-based spectral reconstruction technique.

METHODS AND MATERIALS

Dual-energy ratio (DER) is defined here as low-energy signal divided by high-energy signal (DER = Signal 50keV / Signal 150keV). A routine body protocol (120 kVp, 200 mAs) was used to scan a multi-energy phantom (Gammex) with inserts containing human equivalent adipose, liver, blood mixed with iodine (4.0 mg/ml), and calcium (50 mg/ml). Phantom data was reconstructed using filtered back projection (FBP), the current clinical standard iterative reconstruction (IR: iDose-6, Philips) and an experimental AI-based spectral reconstruction (Spectral AI Reconstruction-Smooth, Philips). For each insert, 50 keV and 150 keV virtual monoenergetic images (VMI) were generated for direct calculation of DER. One reader selected on a sliding scale a near optimal DER threshold of 4.7 for image-based segmentation of iodine (DER > 4.7) and calcified plaque (DER < 4.7). For reader assessment, DER segmentation of plaque and iodine was applied to five arterial phase contrast-enhanced patient exams. Two readers rated conventional image quality and segmentation quality on a 5-point Likert scale (1: very poor, 5: very good) for FBP, IR and AI reconstruction conditions.

RESULTS

Phantom measurements were conducted to assess the impact of FBP, IR, and AI reconstruction on DER calculation. Adipose tissue and liver had the lowest DER of 1.5 and 1.6, respectively. The calcium insert had a DER of 2.0. The iodine insert had the highest DER of 5.3. Relative to FBP, standard deviation variability of DER was reduced by 66% using AI. Both readers rated AI (4.2±0.6) higher than IR (2.9±0.9) and FBP (2.6±0.7) with regard to conventional CT image quality for vascular assessment. Readers also rated AI (3.9±0.6) higher than IR (2.8±0.8) and FBP (2.9±0.6) for iodine and calcium segmentation quality.

CONCLUSION

This study indicates that AI-based spectral reconstruction has potential to improve vascular assessment and dual-energy segmentation capabilities of Spectral CT. Phantom measurements indicated increased precision of DER calculation when using AI, relative to IR and FBP. DER precision is critical when employing DER-based segmentation techniques. Reader assessment of patient exams indicated that AI-based spectral reconstruction outperformed IR and FBP for image quality as well as segmentation quality.

CLINICAL RELEVANCE/APPLICATION

AI-based spectral reconstruction has the potential to improve vascular characterization and automatic segmentation of calcified plaque, which may aid in the diagnosis and monitoring of atherosclerotic disease.

R2-SPPH-3 DEEP LEARNING IMAGE RECONSTRUCTION IN ULTRA-LOW-DOSE CHEST CT FOR LUNG CANCER SCREENING: COMPARISON WITH STANDARD-DOSE CT IN LUNG-RADS ASSESSMENT

Siqi Qu (*Presenter*)
Zhiming Xiang (*Abstract Co-Author*)
Qiuxing Chen (*Abstract Co-Author*)
Kun Ma (*Abstract Co-Author*)

PURPOSE

To explore the feasibility of different reconstruction techniques in ultra-low-dose chest CT for improving image quality and ensuring accurate Lung-RADS assessment

METHODS AND MATERIALS

This prospective study included patients with suspected pulmonary nodules who underwent both standard-dose CT (SDCT; 100 kVp/smart MA) and ultra-low-dose CT (ULDCT). The ULDCT scans were subdivided into two groups, UL-A and UL-B, based on different dose settings. SDCT served as the reference standard and was reconstructed using adaptive statistical iterative reconstruction at 50% (ASIR-V50%). ULDCT images were reconstructed using four different techniques: ASIR-V50%, filtered back projection (FBP), and two variations of deep learning image reconstruction (DLIR) at medium (DLIR-M) and high (DLIR-H) strengths. Lung-RADS classifications were determined by computer-aided detection (CAD) software. Image quality was evaluated using the Kruskal-Wallis one-way analysis, and agreement with the reference was assessed through weighted kappa (Kw) statistics.

RESULTS

A total of 193 patients (mean age 58 ± 14 years; 99 males) with 869 pulmonary nodules were enrolled. The effective dose (ED) for SDCT was 3.62 ± 1.40 mSv, while for UL-A and UL-B, the ED was 0.88 ± 0.19 mSv and 0.48 ± 0.11 mSv, respectively, corresponding to dose reductions of 73.58% and 85.96% ($P < 0.001$). DLIR significantly outperformed both ASIR-V50% and FBP in reducing lung tissue and background noise (standard deviation, SD) and improving both signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) ($P < 0.001$). Among the DLIR methods, DLIR-H showed superior performance compared to DLIR-M in decreasing SD and enhancing both SNR and CNR ($P < 0.001$). Additionally, image quality was notably better in the UL-A group than in the UL-B group ($P < 0.001$). There were no significant differences in Lung-RADS classification agreement (weighted kappa, Kw) between SDCT and the ULDCT reconstructions across both dose groups ($P > 0.001$):

for the UL-A group, the values were ASIR-V50% (0.971), DLIR-M (0.971), DLIR-H (0.957), and FBP (0.957); for the UL-B group, the values were ASIR-V50% (0.981), DLIR-M (0.981), DLIR-H (0.975), and FBP (0.970).

CONCLUSION

ULDCT showed high agreement with SDCT in Lung-RADS classification, with no significant effect of dose on nodule risk. DLIR improved image quality at ultra-low doses, with a positive correlation between dose and quality. DLIR-M outperformed DLIR-H and FBP in Lung-RADS assessment.

CLINICAL RELEVANCE/APPLICATION

Lung-RADS standardizes CT-based lung cancer screening and management. ULDCT reduces radiation exposure while maintaining high consistency in Lung-RADS classification, supporting its use in clinical practice.

R2-SPPH-4 APPLICATION OF DEEP LEARNING IMAGE RECONSTRUCTION IN ULTRA-LOW-DOSE CHEST CT FOR PULMONARY NODULE SCREENING BASED ON BMI STRATIFICATION

Siqi Qu (*Presenter*)
Zhiming Xiang (*Abstract Co-Author*)
Qiuxing Chen (*Abstract Co-Author*)
Kun Ma (*Abstract Co-Author*)

PURPOSE

This study aims to assess the feasibility and effectiveness of an ultra-low-dose chest CT (ULDCT) protocol for pulmonary nodule screening in adults, where scan doses are optimized based on body mass index (BMI) categories. The focus is on evaluating image quality and nodule detection performance using a deep learning image reconstruction (DLIR) algorithm across various BMI groups, with the goal of confirming its ability to maintain high detection sensitivity while significantly reducing radiation exposure.

METHODS AND MATERIALS

A prospective cohort of 95 adult patients underwent both standard-dose CT (SDCT; 100 kVp/smart MA)and ULDCT. The tube current for ULDCT was adjusted based on the patients' BMI categories as follows: underweight (L: <18.5 kg/m², 25 mAs), normal weight (M: 18.5-23.9 kg/m², 35 mAs), overweight (H: 24-27.9 kg/m², 45 mAs), and obese (F: =28 kg/m², 55 mAs), while all other scan parameters were consistent with those used for SDCT. SDCT scans served as the reference and were reconstructed using adaptive statistical iterative reconstruction-Veo (ASIR-V). ULDCT images were reconstructed with ASIR-V, DLIR at medium and high strengths, and filtered back projection (FBP). Pulmonary nodule detection and image quality

RESULTS

The effective dose (ED) of SDCT was 2.48±0.42 mSv for the L group, 2.86±0.54 mSv for the M group, 3.83±1.02 mSv for the H group, and 5.07±1.38 mSv for the F group. ULDCT achieved significant reductions in radiation dose compared to SDCT across all BMI groups: by 76.78%, 71.47%, 73.12%, and 76.13%, respectively, with effective doses of 0.57±0.07 mSv, 0.79±0.06 mSv, 0.98±0.10 mSv, and 1.14±0.08 mSv (P<0.001). SDCT detected a total of 680 pulmonary nodules, serving as the reference. The detection rates for ASIR-V, DLIR-M, DLIR-H, and FBP were 99.85% (679/680), 99.85% (679/680), 100% (680/680), and 99.71% (678/680), respectively. Across all BMI groups, ULDCT maintained a nodule detection rate of over 99%, with DLIR-H demonstrating the highest detection rate among the reconstruction methods. DLIR-H also significantly reduced the standard deviation (SD) of lung and subcutaneous fat tissues and enhanced both the signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) compared to ASIR-V and FBP (P<0.001) across all BMI categories.

CONCLUSION

In a BMI-stratified ULDCT protocol, DLIR-H consistently provides superior image quality across all BMI categories and achieves the highest pulmonary nodule detection rate, reaching 100% in adult patients.

CLINICAL RELEVANCE/APPLICATION

Adjusting ULDCT parameters based on BMI reduces radiation exposure while maintaining detection sensitivity. The application of DLIR enhances image quality, underscoring its value in ULDCT.

R2-SPPH-5 IMPACT OF POSITION AND BIT-DEPTH ON CT NUMBER VARIATIONS FOR HIGH-Z MATERIALS

James J. Sohn, PhD (*Presenter*)
Gyujin Seo (*Abstract Co-Author*)
Hyunji Kim (*Abstract Co-Author*)
Indra Das, PhD (*Abstract Co-Author*)
Siyong Kim, PhD (*Abstract Co-Author*)

PURPOSE

This study aims to investigate how Computed Tomography (CT) number (i.e., Hounsfield Unit, HU) varies dependent on both scan position and bit-depth, especially for high atomic number (high-Z) materials.

METHODS AND MATERIALS

A Gammex 467 phantom containing tissue-equivalent rods and high-density inserts (e.g., titanium, stainless-steel) was scanned at nine different positions within the CT bore: center, ±6.5 cm, and ±10.5 cm in both lateral and anterior-posterior directions, by physically shifting the phantom. This setup allowed the inserts to be positioned at varying locations across the field of view (FOV), ranging from the isocenter to the periphery. Scans were performed using a clinical CT simulator (Philips Brilliance Big Bore RT), and images were reconstructed using both 12-bit and 16-bit settings under identical acquisition parameters. HU values were extracted for each material and position to evaluate variability associated with position and bit-depth.

RESULTS

For high-Z materials, 12-bit reconstructions exhibited clear HU saturation (maximum 3071 HU), limiting their ability to capture actual density differences between titanium and stainless-steel. In contrast, 16-bit reconstructions preserved HU fidelity. Notably, the stainless-steel insert showed HU variations up to 1,532.42 HU across positions in 16-bit images, compared to only 2.34 HU due to saturation in 12-bit images. Similarly, titanium showed up to 368.13 HU variability in 16-bit compared to only 64.94 HU in 12-bit.

CONCLUSION

In 12-bit images, saturation limited the visibility of position-dependent HU variations. In contrast, 16-bit reconstructions better preserved these differences. Accordingly, the use of 16-bit imaging and accurate patient centering may be important factors in improving the precision of relative electron density conversion for increased dose calculation accuracy in radiotherapy planning.

CLINICAL RELEVANCE/APPLICATION

This study supports the adoption of 16-bit CT imaging and precise patient positioning in radiotherapy planning, particularly for patients with metallic implants. By minimizing HU saturation and capturing position-dependent density variations more accurately, these practices can improve the reliability of relative electron density conversion and enhance dosimetric accuracy.

R2-SPPH-6 ANALYSIS OF CT IMAGE QUALITY AND RADIATION DOSE FOR PANCREATIC DUCTAL ADENOCARCINOMA PATIENTS IN ABDOMINAL DUAL ENERGY AND SINGLE ENERGY CT EXAMINATIONS

Keisuke Fujii, PhD (*Presenter*)
Keiichi Nomura, PhD (*Abstract Co-Author*)
Yoshihisa Muramatsu, PhD, RT (*Abstract Co-Author*)
Saeko Mochinaga, RT (*Abstract Co-Author*)
Hiroyuki Ota, RT (*Abstract Co-Author*)
Yutaka Chiba (*Abstract Co-Author*)
Yuichi Nagai (*Abstract Co-Author*)

PURPOSE

The aims of this study are to determine the virtual monochromatic (VM) energy that provides higher contrast-to-noise ratio (CNR) for late arterial phase images of pancreatic ductal adenocarcinoma (PDAC) patients in abdominal dual energy CT (DECT) examinations, and to compare CNR and patient doses in the DECT examinations with them in the conventional single energy CT (SECT) examinations.

METHODS AND MATERIALS

We evaluated image quality of 40-100 keV VM and SECT images of late arterial phase for each 20 PDAC patient (average BMI for the both: 22.8 kg/m 2) with the administration of iodine contrast agent (Iopamidol 370, Bayel) in abdominal 80/135 kVp DECT examinations (effective energy: 66 keV) using Aquilion ONE / PRISM Edition (Canon Medical Systems) and the 120 kVp SECT examinations (effective energy: 50 keV) using Aquilion ONE / ViSION Edition, respectively. VM and SECT images were reconstructed with deep learning reconstruction algorithm of Spectral Body and adaptive iterative dose reduction (AIDR) 3D algorithm, respectively. We set region of interests (ROIs) of 20×20 pixels on normal pancreatic and PDAC region of the VM and SECT images, and evaluated image contrast from the differences between CT values of the two regions. We also set ROIs of 40×40 pixels on the liver region, and evaluated apparent noise from standard deviation of the mean CT values calculated using moving average filters in the ROIs. Apparent CNR was defined as the ratio of image contrast and apparent noise. Next, Monte Carlo (MC) simulation was performed to evaluate patient doses in abdominal SECT and DECT examinations using ImpactMC (Advanced Breast CT, GmbH) software, and liver doses were evaluated from the dose distribution images obtained by MC simulation.

RESULTS

Image contrast of VM images decreased as VM energy increased, and image contrast of 70 keV VM images was similar to that of SECT images. Apparent noise of 70 keV VM images was approximately 40% lower than SECT images. Apparent CNR of 70 keV VM images was higher than the other keV VM images, which was approximately 75% higher than SECT images. Liver doses in abdominal DECT examinations were 19 mGy, which were approximately 25% lower than in the SECT examinations.

CONCLUSION

70 keV VM images from abdominal DECT examinations provided 75% higher apparent CNR than SECT images while the DECT examinations provided 25% lower liver doses than SECT examinations.

CLINICAL RELEVANCE/APPLICATION

This study can be useful for the determination of VM energy which provide higher CNR for PDAC patients in abdominal DECT examinations, and shows that DECT examinations provide higher CNR and lower patient doses than SECT examinations.

R2-SPPH-7 QUANTITATIVE ANALYSIS OF LIVER FAT DISTRIBUTION BY SPECTRAL CT IN PATIENTS WITH IMPAIRED GLUCOSE TOLERANCE

He Qing Wang, MSc (*Presenter*)
Anjie Xie (*Abstract Co-Author*)
Jinhui Zhang (*Abstract Co-Author*)
Suping Chen (*Abstract Co-Author*)
Jianjun Zhou (*Abstract Co-Author*)

PURPOSE

To compare the abdominal fat distribution measured on spectral CT imaging between patients with and without impaired glucose tolerance (IGT) from the health-screen population.

METHODS AND MATERIALS

This study retrospectively included 48 individuals who underwent upper abdominal spectral CT scan and fasting plasma glucose (FPG) examination. According to FPG results, they were divided into two groups: IGT group (n=17), normal glucose tolerance (NGT) group (n=31). On spectral CT images, fat volume fractions (FVF) in left lobe of liver (FVF L), right anterior lobe of liver (FVF RA) and right posterior lobe of liver (FVF RP) were measured using multi-material decomposition (MMD) technique, the mean value was calculated as liver fat fraction (FVF liver). FVFs of pancreas (FVF PH for head, FVF PN for neck, FVF PB for body and FVF PT for tail) were also measured using MMD and the mean value (FVF panc) was calculated. Abdominal visceral fat area (FA AV), fat fraction (FF AV) and abdominal wall fat area (FA AW) at the level of L3 transverse process were measured by an auto software, and the ratio of FA AV to FA AW (FA AV /FA AW) was also calculated. Two-sample t test was used for comparison, statistical difference was determined by $p<0.05$. Receiver operating curves were used for analyzing diagnostic efficacy.

RESULTS

There was no statistical difference in age and BMI between IGT and NGT groups. For liver fat quantification, IGT group had higher FVF RP (IGT vs. NGT: 6.2±6.8% vs. 1.4±3.2%, p=0.015), FVF RA (6.1±7.7% vs. 1.1±2.9%, p=0.019), FVF liver (5.3±6.7% vs. 1.1±2.6%, p=0.021) than NGT group, while FVF L was not statistically different between the two groups. In addition, FVF PH , FVF PN , FVF PB , FVF PT and FVF panc for pancreas fat quantification, FA AV , FF AV for abdominal visceral, FA AW for abdominal wall and FAAV/FAAW for both visceral and wall showed no statistical difference between two groups (all $p>0.05$). To identify IGT, FVF RP , FVF RA and FVF liver showed sensitivities of 80.0%, 60.0% and 80.0%, specificities of 89.5%, 84.2% and 78.9%, at optimal thresholds of 1.68%, 0.5% and 0.59%, respectively.

CONCLUSION

IGT patients had a higher MMD-measured liver fat volume fraction, which could be used to diagnose IGT, with good performances.

CLINICAL RELEVANCE/APPLICATION

This study demonstrates the association between a higher liver fat fraction and impaired glucose tolerance, which is valuable for better understanding the underlying mechanism for diabetes. In addition, liver fat fractions measured using the MMD technique may be novel radiological markers for identifying IGT, which is an early symptom of diabetes, providing valuable information for diabetes diagnosis, therapy, and follow-up.

R2-SPPH-8 INVESTIGATION OF THE DIFFERENT KEV MONOCHROMATIC ENERGY IMAGE QUALITY OF ABDOMINAL KV/MA DUAL-SWITCH ENERGY SPECTRAL SCANNING WITH DIFFERENT ADAPTIVE STATISTICAL ITERATIVE RECONSTRUCTION-VEO ALGORITHM

Chunlong Yan (*Presenter*)

PURPOSE

To explore effects on the different keV monochromatic energy image quality of abdominal kV/mA dual-switch energy spectral scanning with different Adaptive Statistical Iterative Reconstruction-Veo Algorithm.

METHODS AND MATERIALS

A prospective study enrolled 18 patients who required abdominal CT scans. The GE Apex CT scanner was used for energy spectral imaging mode scanning, using a new kV/mA dual-switch energy spectral scanning mode, with rapid switching of tube voltage 80-140 kV, tube current using Assist mA, and noise index (NI=9). After scanning, three sets of images were reconstructed using different weights of ASiR-V (0%, 40%, and 80%) with a slice thickness of 1.25 mm. The venous phase images of abdomen were selected, and regions of interest (ROI) of area 50-150 mm2 were drawn on the same level of the abdominal CT images. The CT values and noise of the spleen, aorta abdominali, portal vein, and left vertical muscle in 50 keV, 70 keV and 90 keV monochromatic energy images were measured and post-processed to obtain using GSI Viewer post-processing software, and to calculate the signal-to-noise ratio further. One-way ANOVA was used to compare the differences in SD and SNR among the groups of the different keV monochromatic energy images reconstructed with different weights of ASiR-V, with a statistically significant difference defined as $P < 0.05$.

RESULTS

In the same monochromatic energy images, there was no statistical difference in CT values $P>0.05$, with the ASiR-V weight increased. For ASiR-V 0%, ASiR-V 40%, and ASiR-V 80%, the CT values of the liver for 70keV monochromatic energy images were (65.58±5.18)Hu, (65.52±5.01)Hu and (65.16±4.66) Hu, respectively. Meanwhile, the SD value showed a progressive decrease, and the SNR showed an increase, and the image quality improved. For ASiR-V 0%, ASiR-V 40% and ASiR-V 80%, the SD values of the liver for 70keV monochromatic energy images were (23.57±2.55) Hu, (17.41±2.32) Hu, and (9.90±1.76) Hu, respectively; SNRs were (4.65± 0.66), (6.51±0.58), and (11.50±1.77), respectively. And the differences in SD and SNR were statistically significant between groups $P<0.05$. 50 keV and 90 keV monochromatic energy images showed similar trends and statistical results as 70 keV $P<0.05$.

CONCLUSION

Adaptive Statistical Iterative Reconstruction-Veo Algorithm based on a new kV/mA dual-switch energy spectral scanning mode can optimize the different keV monochromatic energy spectral image quality in abdomen.

CLINICAL RELEVANCE/APPLICATION

The abdominal monochromatic energy spectral image quality can be further improved without increasing the radiation dose and changing the image CT value using an Adaptive Statistical Iterative Reconstruction-Veo Algorithm based on a new kV/mA dual-switch energy spectral scanning mode.

R2-SPPH-9 ENHANCED INTRAMURAL HEMATOMA CHARACTERIZATION USING SUBTRACTION-BASED DARK-BLOOD IMAGING: A COMPARATIVE CT STUDY

Ke Wei, MD (*Presenter*)

PURPOSE

To evaluate a novel subtraction-based dark-blood imaging (DBI) technique for improving intramural hematoma (IMH) assessment, comparing its diagnostic performance against true non-contrast (TNC) and arterial phase (AP) CT.

METHODS AND MATERIALS

Twenty-four IMH patients undergoing whole-aorta spectral CTA (August 2023-2024) were retrospectively analyzed (mean age 65.8±10.2 years; 75% male). Subtraction-based DBI is derived from weighted subtraction of virtual non-contrast and contrast-enhanced images. Image contrast-to-noise ratio (CNR image), image signal-to-noise ratio (SNR image) and wall thickness (WT) were quantified across TNC, subtraction-based DBI, and AP. Two radiologists independently graded lesion visualization (4-point Likert scale). Interobserver agreement was assessed via Cohen’s kappa. Regions of interest (ROIs) were propagated across modalities using a copy-paste protocol, with statistical analysis performed via Friedman tests.

RESULTS

Subtraction-based DBI and AP demonstrated superior CNR i mage (IQR: 12.01 [8.88, 15.75] and 24.41 [16.01, 31.29] vs. 0.39 [0.11, 1.16], respectively) and SNR image (IQR: 18.15 [11.79, 22.00] and 33.98 [21.19, 39.91] vs. 8.38 [5.43, 10.57], respectively) compared to TNC ($P<0.05$). Qualitatively, subtraction-based DBI outperformed both TNC and AP in lesion visualization ($P<0.05$). DBI yielded significantly larger WT measurements (IQR 9.62 [7.79, 10.78] mm vs. TNC: 8.06 [6.58, 9.58] mm and AP: 7.85 [6.86, 9.71], $P<0.05$). Interobserver agreement was moderate to substantial (?=0.63-0.778).

CONCLUSION

Subtraction-based DBI enhances IMH evaluation through superior quantitative metrics and qualitative visualization, enabling precise aortic wall thickness measurements unachievable with conventional CT.

CLINICAL RELEVANCE/APPLICATION

By mitigating beam-hardening artifacts inherent to AP imaging, DBI improves IMH lesion delineation accuracy, offering critical advantages for vascular pathology diagnosis and monitoring.

R2-SPPH-10 QUANTITATIVE ASSESSMENT OF PARASPINAL MUSCLE DEGENERATION AND GENDER DIFFERENCES IN AGING USING THE MUSCLE-WATER DECOMPOSITION TECHNIQUE WITH RAPID KVP SWITCHING DECT

Muqing Luo (*Presenter*)
Suping Chen (*Abstract Co-Author*)
Kun Zhang, MD (*Abstract Co-Author*)

PURPOSE

To quantitatively assess paraspinal muscle degeneration and gender-related differences during aging in adults using rapid kVp switching dual-energy computed tomography (DECT).

METHODS AND MATERIALS

A total of 156 healthy adults underwent lumbar DECT scans were prospectively grouped into young (20-39 years), middle-aged (40-59 years), and elderly (60-79 years) groups. Muscle density (MD), cross-sectional area (CSA), muscle content (MC), and water content (WC) were measured using virtual monoenergetic images and muscle-water decomposition images for the bilateral erector spinae (ES) at the L1/2 to L4/5 levels and bilateral multifidus (MF) and psoas (PS) at the L2/3 to L5/S1 levels. The Kruskal-Wallis H test and one-way ANOVA were used to compare paraspinal muscle parameters among different age groups. Spearman correlation analysis was used to evaluate the relationship between paraspinal muscle parameters and age.

RESULTS

Across age groups, significant differences in paraspinal muscle MD and WC were observed ($P <0.01$), with MD negatively and WC positively correlated with age at lower lumbar levels for both MF and ES ($P <0.001$). In females, except for the L5/S1 PS, WC differences between the middle-aged and elderly groups were significant ($P<0.05$), but not between the young and middle-aged groups ($P >0.05$). In males, multifidus MC at L4/5 decreased with age ($P <0.05$), while in females, multifidus MC at L3/4 and L5/S1 were the highest in the middle-aged group and lowest in the elderly group ($P <0.05$). PS CSA at L4/5-L5/S1 showed a moderate negative correlation with age ($P <0.001$).

CONCLUSION

The muscle-water decomposition technique using rapid kVp switching dual-energy CT enables noninvasive, quantitative assessment of lumbar paraspinal muscle degeneration. Metrics such as muscle density (MD), cross-sectional area (CSA), and muscle content (MC)—which may reflect alterations in the extracellular matrix—

decreased with age, while water content (WC) increased, serving as potential early imaging biomarkers. In females, MC peaked in middle age and declined in older age.

CLINICAL RELEVANCE/APPLICATION

Our results highlight the value of DECT as a potential noninvasive modality for early identification of muscle degeneration, with possible practical value in high-risk screening, sex-specific intervention planning, and preoperative assessments. The age- and sex-specific reference values derived from healthy individuals may provide valuable clinical benchmarks for evaluating muscle deterioration in sarcopenia or degenerative spinal disorders.

R2-SPPH-11 EFFICIENT AND ROBUST AUTO-IDENTIFICATION OF 3D CEPHALOMETRIC LANDMARKS USING TWO-STAGE SEGMENTATION MODEL IN CONE-BEAM COMPUTED TOMOGRAPHY

Sangah Park (*Presenter*)
Jongjun Won, BS (*Abstract Co-Author*)
Jae-Woo Park (*Abstract Co-Author*)
Hyunseok Lim, MS (*Abstract Co-Author*)
Namkug Kim, PhD (*Abstract Co-Author*)

PURPOSE

Cone-beam computed tomography (CBCT) has become increasingly prevalent in dental fields, particularly for orthodontics, orthognathic surgery and temporomandibular joint (TMJ) evaluation. However, methods for comprehensive 3D craniofacial analysis using CBCT remain underexplored. Conventional analysis relies on manual identification of cephalometric landmarks, making the process time-consuming and labor-intensive. We propose a deep learning method for automatically detecting cephalometric landmarks in CBCT scans, enabling more efficient and reproducible analysis.

METHODS AND MATERIALS

A total of 268 CBCT scans were used for training and 40 for testing. Thirty cephalometric landmarks were manually annotated by an expert orthodontist. To train the segmentation framework with nnUNet, two sets of spherically diluted masks with radii of 4 mm and 1.8 mm were generated for each landmark and used in a two-stage cascade approach, progressing from the first stage with large-radius labels to the second stage with small-radius labels. Final landmarks were extracted as the centroids of the predicted masks. Intra-observer variability was assessed by having the same orthodontist annotate 40 randomly selected scans. Model performance was evaluated by the mean absolute error (MAE) of landmark coordinates, Euclidean distance, angular measurements (AM), and linear measurements (LM).

RESULTS

For the 30 landmarks, the intra-observer MAEs (mean ± SD in mm) were 0.547 ± 0.474, 0.437 ± 0.451, 0.438 ± 0.502, and 0.996 ± 0.757 for the x-, y-, z-axes, and Euclidean distance, respectively. The corresponding MAEs of AI prediction were 0.529 ± 0.438, 0.420 ± 0.374, 0.474 ± 0.435, and 0.978 ± 0.640, respectively. For AM, errors of the intra-observer and AI prediction were 1.062° ± 0.205° and 0.956° ± 0.295°, respectively. For LM, those were 0.822 ± 0.430 mm and 0.851 ± 0.400 mm, respectively.

CONCLUSION

The proposed AI approach using nnUNet segmentation achieved landmark detection accuracy comparable to human intra-observer variability, demonstrating its feasibility for three-dimensional cephalometric analysis using CBCT.

CLINICAL RELEVANCE/APPLICATION

This AI model could accurately predict automatic cephalometric landmark detection in CBCT scans. By enabling consistent evaluation of craniofacial malformations and reducing the manual burden of landmark annotation, this system has the potential to streamline clinical workflows for cephalometric analysis for orthodontic diagnosis, orthognathic surgical planning, and postoperative assessment.

R2-SPVA-1 ENLARGE WHAT REALLY COUNTS: SPATIAL RESOLUTION. SHARPER CONVOLUTION KERNELS IMPROVE FIBULAR PERFORATOR ARTERIES ASSESSMENT IN ULTRA-HIGH RESOLUTION PHOTON-COUNTING DETECTOR CT ANGIOGRAPHIES

Philipp Gruschwitz, MD (*Presenter*)
Kristina Krompass, MD (*Abstract Co-Author*)
Jan-Lucca Hennes, MD (*Abstract Co-Author*)
Henner Huflage, MD (*Abstract Co-Author*)
Pauline Pannenbecker, MD, BA (*Abstract Co-Author*)
Viktor Hartung (*Abstract Co-Author*)
Thorsten A. Bley, MD (*Abstract Co-Author*)
Jan P. Grunz, MD (*Abstract Co-Author*)

PURPOSE

Aim was to evaluate the influence of the convolutional kernel used on the objective image quality and delineation of perforator arteries (PA) in photon-counting detector CT angiograms (PCD-CTA) performed preoperatively before fibular transplantation surgery (FTS).

METHODS AND MATERIALS

All PCD-CTAs performed between Jan 2023 and Dec 2024 prior to scheduled FTS were investigated. Scans were performed in ultra-high resolution mode (120×0.2mm) with tube voltage of 140kVp, pitch factor of 1, and rotation time of 0.5s with IQ64 (˜50mAs). Images were reconstructed using three different vessel-specific convolution kernels of increasing sharpness (Bv36, Bv48, and Bv56) with a slice thickness/increment of 1mm. For objective evaluation, the attenuation within the arterial lumen, the musculature and the standard deviation in the fat tissue were measured and the contrast-to-noise ratio was calculated. Overall image quality, arterial contrast/sharpness, and delineation of PA were subjectively assessed by five radiologists, and diagnostic confidence was rated (5-point scale, 1=poor; 5=excellent). Interrater agreement was calculated using Kendall W.

RESULTS

During two years 14 preoperative PCD-CTAs were performed and 9 patients (60+/-8years; 3 females) were included (4 patients underwent alternative surgery; 1 patient incomplete data set). The remaining. Average radiation dose used was 6.3±0.4mGy. The mean absolute attenuation values in arterial lumen, muscle and fat tissue showed no kernel-dependent differences (p>.050), while the noise increased significantly with increasing sharpness (Bv36 7.9±1.0HU vs. Bv5: 18.0±2.3HU; p<.001). Correspondingly, the CNR decreased significantly (Bv36 57.3±11.5 vs. Bv58 26.2±5.4; p<.001). In contrast to the objective results, the sharp kernel (Bv56) was subjectively rated the best in terms of vessel contrast/sharpness (5; 4-5 vs. Bv48 3; 3-4 / Bv36 3; 3-3; p<.050) and delineation of perforating vessels (5; 4-5 vs. Bv48 3; 3-3/Bv36 3; 2-3; p<.050) with excellent diagnostic confidence (5; 5-5 vs. Bv48 3; 3-4/Bv36 3; 3-3; p<.050). Interrater agreement was good (W=0.65-0.76)

CONCLUSION

Despite objectively lower CNR, a sharp kernel (Bv56) with higher spatial resolution is preferred due to the improved vessel sharpness and delineation of the perforator arteries, resulting in excellent diagnostic confidence.

CLINICAL RELEVANCE/APPLICATION

Ultra-high resolution PCD-CTA combined with sharp kernels allows excellent delineation of the fibular perforators, optimizing preoperative diagnostic with the option of 3D planning/printing.

R2-SPVA-2 OUTCOMES AND CLINICAL VALUE OF IVUS GUIDED SALVAGE CENTRAL VENOUS MAPPING FOR HEMODIALYSIS ACCESS IN HIGH-RISK END STAGE RENAL DISEASE PATIENTS

Daniel Raskin, MD (*Presenter*)
Mia Zivkovic (*Abstract Co-Author*)
Abraham Levitin, MD (*Abstract Co-Author*)
Jon Quatromoni, MD (*Abstract Co-Author*)
Jennifer Montgomery, MD,PhD (*Abstract Co-Author*)
Sasan Partovi, MD (*Abstract Co-Author*)

PURPOSE

Certain end-stage renal disease (ESRD) patients are considered unsuitable for arteriovenous fistula (AVF) or graft (AVG) creation after standard venous mapping with duplex and venography. These patients remain dependent on tunneled dialysis catheters for hemodialysis, which poses significant risks and is associated with long term unfavorable outcomes. This research study quantified the added value of intravascular ultrasound (IVUS) as a secondary central venous mapping tool in this high-risk patient population.

METHODS AND MATERIALS

Medical records and imaging data of ESRD patients deemed "no-option" for AVF/AVG who underwent combined venography and IVUS between January 2024 and February 2025 were retrospectively analyzed in this study. Those who received IVUS for indications other than presurgical planning were excluded. The final cohort included 14 patients, 8 male and 6 female, with a mean age of 56 years. It was determined whether each individual patient went on to receive surgical dialysis circuit vascular access creation after salvage mapping with IVUS. Short- and long-term surgical outcomes of the vascular access were assessed as well. Functionality of the access site was monitored for up to 13 months post-AVF or AVG creation, with functional maturation defined as use of the access for dialysis within 3 to 6 months.

RESULTS

8/14 patients (57%) proceeded to access surgery after IVUS. The remaining six patients opted out of vascular access surgery or remained not suitables candidates for AVF or AVG. All eight AVF/AVG creations were technically successful, with thrill noted in the postoperative vascular surgery report. Functional maturation within 3 to 6 months was documented in 5/8 (63%) of surgically created AVF or AVGs. Two accesses are still within the maturation window at the time of analysis. One graft failed and was later explanted secondary to infection and thrombosis.

CONCLUSION

In “no vascular access option” ESRD patients, IVUS enabled successful AVF/AVG creation in 57% of patients, with 63% of those accesses reaching the maturation stage for functional use by 6 months. Without the use of IVUS in venous mapping, none of these patients would have been candidates for surgical AVF or AVG creation. Therefore, IVUS has the potential to improve dialysis access and decrease catheter dependence in high risk ESRD patients deemed previously unsuitable for surgical AVF/AVG creation with standard venous mapping techniques.

CLINICAL RELEVANCE/APPLICATION

IVUS adds valuable anatomic detail for central venous mapping, while decreasing contrast and and radiation exposure. As such, it should be considered in salvage central venous mapping algorithms aimed at reducing long-term catheter dependence in “no vascular access option” ESRD patients.

R5A-SPBR-1 MODELING THE UTILITY OF BREAST IMAGING IN SYMPTOMATIC PATIENTS WITH NORMAL CLINICAL BREAST EXAM

Matthew Common, BEng, MD (*Presenter*)
Cathal McCarthy, BMBS, BMedSc (*Abstract Co-Author*)
Pat Rohan, MBBS (*Abstract Co-Author*)
Niamh Hambly, MBBCh, FFR(RCSI) (*Abstract Co-Author*)
Neasa Ni Mhuircheartaigh, MBBCh, FFR(RCSI) (*Abstract Co-Author*)
Jennifer Kerr, MBBCh,FFR(RCSI) (*Abstract Co-Author*)
Arnold D. Hill (*Abstract Co-Author*)
Nuala A. Healy, MD, MEd (*Abstract Co-Author*)
Deirdre M. Duke, MBBCh (*Abstract Co-Author*)

PURPOSE

Attendance at symptomatic breast centres has increased exponentially over the last 10 years. While many of these patients have a normal clinical breast examination, the majority undergo breast imaging. The purpose of this study is to examine the current use of breast imaging in symptomatic patients with normal clinical breast examinations, and to devise a clinical decision rule to guide the referral of patients for imaging.

METHODS AND MATERIALS

This retrospective observational study examines consecutive patients attending the Beaumont Breast Centre symptomatic service over 8 years who have a normal examination at clinical assessment. Logistic regression modelling was performed in order to predict cancer risk based on age and symptom.

RESULTS

Over the 8-year period 16,696 consecutive symptomatic patients who presented for imaging with a normal clinical breast examination. After application of exclusion criteria, 12212 were included in the study, 81% of whom (9870/12212) had imaging. Radiology results were as follows: benign [R1/2] - 9293/9870 (94%), warranting biopsy but likely benign [R3] - 578/9870 (5%), and suspicious [R4/5] - 117/9870 (1%). A total of 85 pathologically confirmed breast cancers were diagnosed following surgical management, yielding a cancer detection rate (CDR) of 0.86% (95% CI: 0.68 - 1.04) in patients undergoing imaging. Subgroup analysis for <45yrs yields a CDR of 0.35% (0.17 - 0.53) and a benign biopsy rate of 95%. Age was the only statistically significant predictor of malignancy (OR 1.65 [1.38 - 1.97]), whereas mastalgia (OR 0.31 [0.17-0.58]) and reported lump (OR 0.48 [0.25-0.92]) were protective. Model-based risk prediction to determine need for imaging was shown to have fair discriminative ability (Receiver Operator Characteristic area under the curve = 0.70), and decision curve analysis demonstrated a net benefit of 0.03 vs imaging all/none.

CONCLUSION

This study demonstrates that patients <45 years-of-age with a normal breast exam are unlikely to benefit from breast imaging and are more likely to experience over-investigation and overtreatment, including benign biopsy and excision. The proposed model-driven approach reduces the number needed to image and biopsy, thereby reducing harms to patients and improving healthcare resource allocation.

CLINICAL RELEVANCE/APPLICATION

Results suggest that a model-driven imaging strategy could improve efficiency by applying a risk threshold that aligns with existing screening benchmarks. For example, selectively imaging patients with predicted risk >0.71% may reduce unnecessary investigations in low-risk groups (e.g., mastalgia <45 years) while preserving sensitivity in higher-risk symptom-age profiles.

R5A-SPBR-2 PERFORMANCE OF DIAGNOSTIC MAMMOGRAPHY AND ULTRASOUND FOR PREGNANT PATIENTS

Abigail Keller (*Presenter*)
Bowman Brown (*Abstract Co-Author*)
Mai A. Elezaby, MD (*Abstract Co-Author*)
Lonie R. Salkowski, MD, PhD (*Abstract Co-Author*)
Amy M. Fowler, MD, PhD (*Abstract Co-Author*)

PURPOSE

To assess the diagnostic accuracy of mammography (MG) and/or breast ultrasound (US) in detecting pregnancy-associated breast cancer (PABC) for symptomatic pregnant patients at a single academic institution.

METHODS AND MATERIALS

An IRB-approved, HIPAA-compliant retrospective chart review was performed, which included pregnant patients who underwent MG and/or breast US from 2013 to 2024 at a single academic institution. Diagnostic performance was assessed in patients with histopathologic confirmation or =2 years of clinical or radiologic follow-up. Rates of BI-RADS 3 (probably benign) assessments, biopsies, and follow-up adherence were also analyzed. Patients without histopathology or <2 years of clinical or radiologic follow-up were excluded from diagnostic performance calculations.

RESULTS

Of 241 pregnant patients who underwent imaging, 216 met inclusion criteria (mean age 32 ± 5 years, range 19-48). The most common symptom was a palpable lump (80%, 173/216), followed by breast pain (15%, 33/216). Most were evaluated with ultrasound (US) alone (95%, 206/216; mean age 31 ± 5), while 5% (10/216; mean age 37 ± 5) underwent combined mammography and ultrasound (MG+US), with 3 biopsies and one false positive. Breast density was extremely dense in 60% (130/216) and heterogeneously dense in 30% (65/216). Imaging most often occurred in the second trimester (median gestational age 20 ± 10 weeks). Two cases of pregnancy-associated breast cancer (PABC) were detected (ages 36 and 37) during the first and second trimesters, both BI-RADS 5 on MG+US. BI-RADS 3 was assigned

in 12% (26/216) with a 77% follow-up rate. Biopsies were performed in 19% (41/216). For US-alone, specificity was 82% and NPV 100%. For MG+US, sensitivity was 100%, specificity 75%, PPV 50%, and NPV 100%.

CONCLUSION

This study demonstrates that diagnostic breast imaging in symptomatic pregnant patients has high sensitivity and NPV for detecting PABC. Despite established safety guidelines, mammography remains underutilized in this population, likely due to ongoing misconceptions regarding radiation exposure to the fetus. The limited number of patients receiving mammography in this cohort underscores the need for increased awareness of the American College of Radiology's appropriate use guidelines among referring providers and patients.

CLINICAL RELEVANCE/APPLICATION

Diagnostic mammography and ultrasound are effective for detecting PABC, even with pregnancy-related increased breast density. The underuse of mammography highlights the need for greater clinical awareness and clarification of its safety during pregnancy. Educating providers on evidence-based imaging is crucial for timely diagnosis and appropriate care in pregnant patients with breast symptoms.

R5A-SPBR-4 PREDICTIVE FACTORS OF AXILLARY PATHOLOGICAL COMPLETE RESPONSE IN HER2 POSITIVE BREAST CANCER PATIENTS TREATED WITH NEOADJUVANT CHEMOTHERAPY

Marta Rodriguez De Trujillo, MD (*Presenter*)

PURPOSE

To identify predictive factors for axillary pathologic complete response (pCR-axillary) in HER2-positive (HER2+) breast cancer patients with biopsy-confirmed axillary involvement, treated with neoadjuvant chemotherapy (NAC) followed by surgery, aiming to avoid unnecessary axillary lymph node dissection (ALND).

METHODS AND MATERIALS

This retrospective cohort study included HER2+ breast cancer patients with biopsy-confirmed axillary involvement, treated with NAC followed by surgery between October 2015 and November 2022 at Reina Sofía University Hospital (Córdoba, Spain). Data were collected from medical records, radiology, and pathology reports. The variables analyzed included age, tumor size, tumor grade, hormone receptor status, Ki67 index, radiologic and pathologic response in the breast (rCR-breast, pCR-breast) and axilla (rCR-axillary, pCR-axillary), number of suspicious lymph nodes and type of axillary surgery. Statistical analysis was performed using univariate and multivariate logistic regression models to identify independent predictors of pCR-axillary.

RESULTS

This pCR-axillary was achieved in 85% of patients. In univariate analysis, only rCR-axillary was significantly associated with pCR-axillary (OR = 5.83; 95% CI 1.30-26.12; p=0.021). Multivariate analysis identified both rCR axillary (OR = 17.98; 95% CI: 1.43-225.93; p = 0.025) and Ki67 index (OR = 0.90; 95% CI: 0.82-0.99; p = 0.045) as independent predictors of pCR-axillary. The predictive model showed excellent discrimination (AUC = 0.92; p < 0.001).

CONCLUSION

Our rCR-axillary and Ki67 index are independent predictors of axillary pCR-axillary in HER2+ breast cancer patients treated with NAC. The identification of these factors may allow clinicians to avoid unnecessary ALND in patients with complete radiologic response, reducing surgical morbidity without compromising oncologic outcomes.Incorporating imaging response and tumor biologil into clinical decision-making may help identify candidates for axillary surgery de-escalation and safely avoid ALND in selected patients.

CLINICAL RELEVANCE/APPLICATION

Our findings reinforce the growing body of evidence supporting the de-escalation of axillary surgery in patients achieving pCR-axillary. The use of targeted axillary dissection (TAD) instead of ALND in patients with rCR-axillary could significantly reduce surgical morbidity while maintaining oncologic safety.

R5A-SPBR-5 HIGH-RESOLUTION ULTRAFAST DCE-MRI HETEROGENEITY FEATURES-BASED MACHINE LEARNING MODEL FOR PREDICTING AXILLARY LYMPH NODE METASTATIC BURDEN IN BREAST CANCER

Wenlong Yang (*Presenter*)
Hong Bing Luo, MD (*Abstract Co-Author*)

PURPOSE

To analyze intratumoral and peritumoral heterogeneity features from high-resolution ultrafast DCE-MRI and develop a machine learning model for preoperative predicting axillary lymph node metastatic burden in breast cancer.

METHODS AND MATERIALS

A retrospective analysis was conducted on breast cancer cases with preoperative MRI and postoperative pathology data. Patients were categorized into low-burden (=2 metastatic lymph nodes) and high-burden (>2 metastatic lymph nodes) groups based on postoperative pathological findings. Quantitative heterogeneity features of intratumoral and peritumoral regions were extracted from all high-resolution ultrafast DCE-MRI dynamic sequences through voxel clustering. Combined with conventional MRI features, machine learning algorithms including LR, SVM, RF, k-nearest neighbors, decision trees, neural networks, XGBoost, and LightGBM were evaluated. The optimal algorithm was selected via 5-fold cross-validation to build the final model, with performance assessed using ROC curves.

RESULTS

A total of 368 invasive breast cancer patients were included, of whom 71 (19.3%) had high-burden axillary lymph node metastasis. The final maching learning model, constructed using the optimal LR algorithm based on 5-fold cross-validation, achieved AUCs of 0.900 and 0.839 in the training and testing cohorts, respectively. On the entire dataset, the model’s AUC was 0.882, significantly outperforming the conventional MRI model (AUC 0.754). Furthermore, the model demonstrated superior calibration and higher clinical benefit in decision curve analysis.

CONCLUSION

The machine learning model based on high-resolution ultrafast DCE-MRI heterogeneity features enables accurate prediction of axillary lymph node metastatic burden in breast cancer, providing valuable guidance for personalized axillary surgical strategies.

CLINICAL RELEVANCE/APPLICATION

This study developed a machine learning model based on intratumoral and peritumoral kinetic heterogeneity features derived from high-resolution ultrafast DCE-MRI, which provides a non-invasive and more accurate preoperative prediction of axillary lymph node metastatic burden in breast cancer. Building on these findings, this approach could further offer imaging-based guidance for tailoring axillary surgical strategies in breast cancer patients.

R5A-SPBR-6 CONTRAST ENHANCED MAMMOGRAPHY -A PROBLEM SOLVING TOOL WHEN NO CURRENT PROCEDURE HELPED

Nidhi Sibal, FRCR, MBBS (*Presenter*)
Eman Hafez, MBBCh, FRCR (*Abstract Co-Author*)
Chao Jin Ho, MBBCh, BSc (*Abstract Co-Author*)
Claire Taylor, BSc, MSc (*Abstract Co-Author*)

PURPOSE

Contrast-enhanced mammography (CEM) is an emerging, viable alternative to breast MRI. MRI breast remains the gold standard for identifying occult disease in dense breast. However, there are occasions when MRI imaging is either not feasible or accessible or limitation of non-contrast conventional mammogram and ultrasound imaging. This study aims to share situations where CEM can help to provide a better diagnostic outcome by reviewing several examples of CEM use in our breast unit.

METHODS AND MATERIALS

Retrospective study of the uses of CEM over a 12 months trial phase period since July 2023. Case were abstracted from PACS. 54 CEM are evaluated for the use as an alternative study to MRI.

RESULTS

Our trial found CEM to be useful in: 1. Patients with Pacemaker or MRI incompatible devices: CEM provides a valuable alternative contrast study to assess the extent of breast malignancy in patients with dense breasts. 2. Patients unable to tolerate MRI: Claustrophobic or have physical limitations (patients with back problems, overweight or unable to lie still). MRI imaging will be affected by motion artefact or inability to complete the study. 3. Post MRI Second Look US: CEM will be useful if done before 2 nd look US of additional lesion identified on MRI staging. CEM aid in identifying the location of the enhancing lesions especially that CEM images are static and show depth and relation of lesions. The site of additional enhancing lesions was more comparable to CEM on MLO and CC views as opposed to MRI. 4. Magnetic pre-surgical localiser: we have moved to using Magnetic seeds as our breast cancer localisers. However, magnetic seeds create huge MRI artefacts and can hinder the assessment of post NAC (neoadjuvant chemotherapy) treatment response on MRI. Thus, magnetic localisers are recommended to be inserted only after post NAC MRI. In contrast, magnetic localiser does no create artefacts on CEM and can be inserted before NAC treatment. 5. CEM guided biopsy as an alternative to MRI Biopsy: MRI guided biopsy is expensive, difficult to organise, time consuming and uncomfortable for the patient. Instead, lesions can be identified on CEM and then cross referenced for Stereo/Tomosynthesis-guided biopsy.

CONCLUSION

CEM has potential use in many situations particularity when standard imaging has limitations. CEM was found to be the only alternative contrast study for staging claustrophobic patients or patients who cannot tolerate MRI.

CLINICAL RELEVANCE/APPLICATION

CEM can be a problem-solving tool to improve diagnostic accuracy and confidence of diagnosis especially in cases with dense breast or multifocal disease and patients who can't have an MRI.

R5A-SPCA-1 ROLE OF 4D FLOW MRI ESTIMATION FOR CONNECTIVE TISSUE DISEASE ASSOCIATED PULMONARY ARTERIAL HYPERTENSION (CTD-PAH); A PROSPECTIVE ANALYSIS BASED ONTHE 2022 ESC/ERS GUIDELINE

Toshihiro Sakamoto, MD (*Presenter*)
Yoshiko Hayashida, MD (*Abstract Co-Author*)
Koshi Setoyama (*Abstract Co-Author*)
Sho Shin (*Abstract Co-Author*)
Masaharu Kataoka (*Abstract Co-Author*)
Takatoshi Aoki, MD, PhD (*Abstract Co-Author*)

PURPOSE

In the 2022 ESC/ERS guideline, the definition of pulmonary hypertension (PH) was changed from mean pulmonary arterial pressure (mPAP) >25 mmHg to 20 mmHg and a new definition of exercise PH (mPAP <20mmHg, mPAP/cardiac output (CO) slope >3mmHg/L/min) was proposed. The purpose of this study is to evaluate the utility of 4D flow MRI in classifying patients with connective tissue disease-associated pulmonary arterial hypertension (CTD-PH) into three groups based on exercise stress right heart catheterization (RHC) results according to the new ESC/ERS guideline.

METHODS AND MATERIALS

In this prospective study, from November 2022 to January 2025, consecutive CTD patients clinically suspected PH were included. They all examined with exercise-stressed RHC and underwent 4D flow MRI at 3T. Based on the RHC data, the patients were divided into PH group, exercise PH group, and non-PH group. Eight 4D flow MRI parameters were analyzed, including the absolute volume, the area, wall shear stress (WSS), and oscillatory shear index (OSI) both at the pulmonary trunk (PT) and bilateral main pulmonary arteries (mPA). Absolute volumes and areas were set 20 mm proximal to the pulmonary artery bifurcation and 15 mm distal for bilateral mPA branches. WSS and OSI were measured using cylindrical volumes of interest (VOIs): a 30 mm VOI at PT 20 mm proximal and 20 mm VOIs distal to the bifurcation for bilateral mPA branches. Spearman's rank correlation analysis and Kruskal-Wallis test with post hoc DSFC multiple comparison analysis used for statistical analysis.

RESULTS

Total of 54 CTD patients (mean age 65.9, 4 male) were evaluated. The PH, exercise PH, and non-PH groups consisted of 26, 20, and 8 patients, respectively. Correlation analysis revealed significant correlations between mPAP and both the absolute volume and area measurements:Significant correlations were found for the absolute volume of the PT (rho = 0.299, P = 0.02) and the mPA (rho = 0.34, P = 0.01), as well as the areas of the PT (rho = 0.32, P = 0.01) and the mPA (rho = 0.36, P < 0.01). Comparisons among the three patient groups demonstrated a significant difference in the area of the PT between the PH group and the non-PH group (P < 0.05). Although there was no statistical difference, the average WSS value of mPA in the exercise PH tended to be smaller than that in non-PH, and the average OSI value of mPA in the exercise PH tended to be larger than that of non-PH.

CONCLUSION

Quantification using 4D flow MRI may be useful for predicting PH groups in CTD-PH patients according to the new ESC/ERS guideline.

CLINICAL RELEVANCE/APPLICATION

Parameters derived from 4D flow MRI could be a new noninvasive screening biomarker for PH, and may minimize the need for invasive exercise-stressed RHC.

R5A-SPCA-3 ASSOCIATION OF OBESITY WITH MYOCARDIAL FIBROSIS AND ADVERSE CARDIAC OUTCOMES IN DUCHENNE MUSCULAR DYSTROPHY: A CMR BASED PROSPECTIVE COHORT STUDY

Xinyuan Zhang (*Presenter*)
Shan Huang, MD (*Abstract Co-Author*)
Huayan Xu (*Abstract Co-Author*)

PURPOSE

Cardiomyopathy progression remains the predominant cause of mortality in Duchenne muscular dystrophy (DMD), with myocardial fibrosis serving as its central pathological hallmark. While obesity is highly prevalent in DMD patients and correlates with clinical outcomes, its specific role in cardiac deterioration remains undetermined. Therefore, our study aims to investigate the association between obesity and myocardial fibrosis, as well as its prognostic impact on clinical cardiac outcomes in Chinese DMD patients.

METHODS AND MATERIALS

A prospective cohort study was conducted using cardiac magnetic resonance imaging (CMR) assessment. Obesity was defined by BMI z-scores =95th percentile for age. Myocardial fibrosis was determined through late gadolinium enhancement (LGE) on CMR. Composite cardiac endpoints included dilated cardiomyopathy, left ventricular ejection fraction (LVEF) <50%, heart failure hospitalization, recurrent angina, ventricular arrhythmias, or all-cause mortality. Multivariable linear regression and Cox proportional hazards models were employed to identify independent predictors.

RESULTS

A total of 198 boys with DMD (age: 8.0 years [IQR 7.0, 10.0]) were included, of whom 26.3% were classified as obese (median BMI: 21.3 [IQR 20.4-23.0]). Multivariable linear regression analysis revealed a significant association between obesity and LGE (adjusted OR: 3.57, 95% CI: 1.66, 7.71, p = 0.001). During a mean follow - up period of 38.3 ± 14.1 months, 28 boys reached cardiac endpoint. Multivariable Cox model analysis indicated that obesity (adjusted HR: 3.75, 95% CI: 1.57, 8.97, p = 0.003) and baseline LVEF (adjusted HR: 0.90, 95% CI: 0.85, 0.97, p = 0.003) were independently associated with cardiac endpoint.

CONCLUSION

Obesity independently associates with myocardial fibrosis and adverse cardiac outcomes in Chinese DMD patients. These findings underscore the imperative for early weight management strategies in multidisciplinary DMD care.

CLINICAL RELEVANCE/APPLICATION

Obesity independently predicts myocardial fibrosis and adverse cardiac outcomes in DMD, highlighting the need for early weight management in multidisciplinary care.

R5A-SPCA-4 VIABILITY BEYOND SCAR: PREDICTING CARDIAC RECOVERY IN STEMI PATIENTS WITH NON-VIABLE MYOCARDIUM ON LGE MRI USING FDG PET

Eun-Jung Kong, MD (*Presenter*)

PURPOSE

Late gadolinium enhancement (LGE) magnetic resonance imaging (MRI) is widely used to assess myocardial viability in patients with acute myocardial infarction (AMI), yet it may overestimate non-viable myocardium in the acute phase. ^18F-fluorodeoxyglucose (FDG) positron emission tomography (PET) offers a metabolic assessment of viability, but data directly comparing its prognostic utility to MRI remain scarce. To investigate whether FDG PET can predict cardiac functional recovery in ST-segment elevation myocardial infarction (STEMI) patients with non-viable myocardium identified on LGE MRI following successful primary percutaneous coronary intervention (PCI).

METHODS AND MATERIALS

This retrospective study included 36 STEMI patients (mean age 62 ± 11 years) who underwent FDG PET/MRI within 7 days after successful PCI between 2016 and 2023. All patients exhibited non-viable myocardium in the culprit territory on LGE MRI. Patients were classified based on FDG PET into three groups: viable myocardium (n=19), non-viable myocardium (n=9), and paradoxical uptake (n=8). Cardiac function was evaluated by transthoracic echocardiography at baseline and at 3-9 months post-PCI, assessing regional wall motion score index (RWMSI), number of abnormal segments (NoRWS), and left ventricular ejection fraction (LVEF).

RESULTS

The viable group demonstrated significantly greater improvements in RWMSI (?RWMS: -0.3 ± 0.4 vs. 0.1 ± 0.2, p=0.003), NoRWS (?NoRWS: -3.4 ± 3.4 vs. -1.6 ± 3.6, p=0.042), and LVEF (?EF: 7.5 ± 6.1% vs. 2.8 ± 4.0%, p=0.061) compared to the non-viable group. The paradoxical uptake group showed a functional trajectory more similar to the viable group, with notable improvements in RWMSI, NoRWS, and LVEF. BMI was higher and diabetes more frequent in the paradoxical group, though without significant impact on overall outcomes.

CONCLUSION

FDG PET provides important complementary viability assessment in STEMI patients, even when LGE MRI suggests non-viability. Preservation of FDG uptake in infarcted myocardium is associated with significant recovery of cardiac function. The paradoxical FDG uptake pattern also appears to portend favorable outcomes, warranting further investigation.

CLINICAL RELEVANCE/APPLICATION

FDG PET provides critical prognostic information in STEMI patients with LGE-defined non-viable myocardium, guiding post-MI management by identifying patients likely to experience meaningful functional recovery.

R5A-SPCA-5 INCREMENTAL DIAGNOSTIC VALUE OF HEART FAILURE WITH PRESERVE EJECTION FRACTION IN HYPERTENSIVE HEART DISEASE PATIENTS BY CARDIC MR FEATURE-TRACKING

Xiaolin Mu (*Presenter*)

PURPOSE

To investigate the incremental value of cardiac magnetic resonance feature tracking (CMR-FT) for diagnosing HHD-HEpEF, and to ascertain optimal diagnostic parameter.

METHODS AND MATERIALS

30 HHD-HFpEF patients, 32 HHD patients, and 30 healthy controls who met the enrollment criteria were retrospectively analyzed.Myocardial strain and rate were measured and compared among the three groups by CMR-FT(Figure 1). Logistic regression method was employed to analyze the factors influencing HHD-HFpEF, and the optimal strain parameters for its identification were ascertained by using ROC curve.

RESULTS

Compared to the HHD and healthy controls, the HHD-HFpEF group demonstrated significantly impaired of LVGPLS (-12.0%±3.5%), LV d GLSR (0.6±0.21/s), LV s GLSR (-0.71/s , IQR -0.9to -0.61/s), LA es (17.7%±6.9%), ee (9.2%, IQR 6.4% to 10.5%), ea (8.6%±3.4%), SRs (1.0±0.3 1/s), SRe (-0.7 1/s , IQR -1.1to-0.5 1/s), SRa (-1.1±0.41/s)(all p-values <0.001). LA es (p=0.020), ee (p=0.004), SRs (p=0.015), SRe (p<0.001) were significantly impaired in the HHD group when compared with healthy controls(Table1,Figure 2). Linear regression analysis revealed moderately correlations between LA es, ee, LVGPLS and NT-proBNP (all p-values<0.001),as well as between LA es, ee, ea and LVGPLS (all p-values<0.001)(Figure 3).LA es showed the highest diagnostic efficacy for identifying HHD-HFpEF, with an AUC of 0.873, sensitivity of 71.4%, specificity of 93.3%, and cut-off value of 19.25%(Table2,3,Figure 4).

CONCLUSION

CMR-FT is a reliable and promising tool for evaluating subtle dysfunction in HHD-HFpEF. Notably, LA es demonstrates potential incremental value for identifying HFpEF.

CLINICAL RELEVANCE/APPLICATION

CMR-FT proves to be a reliable and promising tool for evaluating subtle dysfunction in HFpEF.

R5A-SPCA-6 MULTIPARAMETRIC CARDIAC MRI FOR THE DETECTION OF CHIMERIC ANTIGEN RECEPTOR T-CELL THERAPY ASSOCIATED MYOCARDIAL CHANGES

Dmitrij Kravchenko, MD (*Presenter*)
Alexander Isaak, MD (*Abstract Co-Author*)
Narine Mesropyan, MD (*Abstract Co-Author*)
Leon Bischoff, MD (*Abstract Co-Author*)
Muhammad Taha Hagar, MD (*Abstract Co-Author*)
Giuseppe Tremamunno, MD (*Abstract Co-Author*)
Milan Vecsey-Nagy, MD, PhD (*Abstract Co-Author*)
Akos Varga-Szemes, MD, PhD (*Abstract Co-Author*)
Tilman S. Emrich, MD (*Abstract Co-Author*)
Julian A. Luetkens, MD (*Abstract Co-Author*)

PURPOSE

New chimeric antigen receptor (CAR)-T cell therapy has demonstrated advantages over traditional cancer therapies for treatment of highly refractory or relapsing hematological malignancies. Unfortunately, there is a paucity of data regarding cardiotoxic cardiac MRI (CMR) findings of therapy associated cytokine release syndrome

(CRS).

METHODS AND MATERIALS

Consecutive patients were enrolled for CAR-T cell therapy and received a standard 1.5 T CMR examination consisting of functional cines, parametric mapping, late gadolinium enhancement (LGE), and featuring tracking strain, before therapy (baseline), during acute cytokine release syndrome (CRS; as determined by treating oncologist and lab parameters), and at 6-month follow-up (mean 184±20 days). Data was compared using RM-ANOVA with Tukey's posthoc test.

RESULTS

29 patients were available for analysis (mean age 60±15 years, 23 males [79%]). The most common malignancy was diffuse large B-cell lymphoma (13 [45%]). CRS was observed at a median time of one day (IQR 1-2 days) after CAR T-cell therapy and reached a median degree of 1 (IQR 1-2). One patient passed away due to non-cardiac related CRS. One patient developed therapy associated heart failure. No new instances of LGE were observed in any cases. There were no differences from baseline to CRS or to follow-up scans for left ventricular ejection fraction (61±5 vs 60±6 vs 59±7%, p =0.39), T1 relaxation times (969±18 vs 988±26 vs 972±22 ms, p =0.11), T2 relaxation times (53.3±2.4 vs 54.0±3.0 vs 52.9±1.8 ms, p =0.36), global longitudinal strain (-16.3±2.2 vs -15.6±2.4 vs -14.9±2.8, p =0.18), global circumferential strain (-12.5±2.9 vs -13.0±2.7 vs -12.2±1.8, p =0.51), or global radial strain (28.3±12.5 vs 29.2±8.1 vs 30.5±6.0, p =0.67).

CONCLUSION

CAR T-cell therapy related low degree CRS does not produce significant myocardial changes on multiparametric CMR from baseline to acute CRS or follow-up.

CLINICAL RELEVANCE/APPLICATION

Current CAR-T cell therapies may induce low-grade CRS but do not cause significant myocardial changes on CMR, supporting their classification as a cardiologically safe treatment option.

R5A-SPCA-7 BEYOND CAC: INSIGHTS FROM A LARGE-SCALE CCTA STUDY OF CAD RISK IN OVER 1200 WOMEN

Surabhi Agarwal, DNB,MBBS (*Presenter*)
Zeynep Nur Akyol Sari, MD (*Abstract Co-Author*)
Om B. Panta, MD (*Abstract Co-Author*)
Yuval Liberman, MD, MMedSc (*Abstract Co-Author*)
Ivan Diogo Queiros, MD (*Abstract Co-Author*)
Santosh Maharjan, MBBS, MD (*Abstract Co-Author*)
Gilad Borisovsky, MD (*Abstract Co-Author*)
Diana Litmanovich, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the association between coronary artery plaque characteristics, stenosis severity, coronary artery calcium (CAC) score and clinical risk factors in women undergoing coronary CT angiography (CCTA), and to assess the diagnostic limitations of CAC in identifying high-risk plaque and significant coronary artery disease (CAD).

METHODS AND MATERIALS

This HIPAA-compliant, IRB-approved study reviewed data from 2,296 women who underwent CCTA between 2006 and 2022, with 1,241 patients included after excluding those with coronary artery bypass surgery, coronary stenting, or non-diagnostic image quality. Clinical risk factors were extracted from medical records. Images were reviewed by two radiologists, with a third resolving discrepancies. Coronary arteries were analyzed using a 10-segment model (LM-1, LAD-3, RCA-3, LCX-3 segments) for stenosis severity (CAD-RADS; significant stenosis defined as =50%), plaque type (non-calcified, partially calcified, calcified), and high-risk features (low attenuation, napkin-ring sign, spotty calcifications, positive remodeling). A subset of 1181 patients with CAC scores, quantified using the Agatston method were evaluated to assess the association between CAC and CADRADS. ROC curve analysis evaluated the diagnostic performance of CAC in detecting significant stenosis.

RESULTS

Of 1241 women, 241 (19.4%) had significant coronary stenosis (CAD-RADS >2). Among plaques, 43.5% (230) were calcified, 32.8% (174) partially calcified, and 23.6% (125) non-calcified. 32.8% (174) of stenotic plaques showed =2 high-risk features. The average CAD-RADS was highest for partially calcified plaques (3.6), compared to calcified (3.3) and non-calcified (3.4) demonstrating a potential association between plaque composition and stenosis severity. CAC significantly correlated with CAD-RADS ($r = 0.36$, $p < 0.0001$), and showed strong predictive value for CAD-RADS >2 (AUC = 0.87). Patients with calcified plaques were older (69 years) than those with partially (61 years) or non-calcified plaques (63 years). Younger women had more partially and non-calcified plaques with higher CADRADS despite low calcium. Among 366 patients with CAC score 0, 23 (6.3%) had CAD-RADS >2. Clinical risk factors did not improve prediction over CAC alone.

CONCLUSION

CAC score may underestimate CAD in women by failing to detect non-calcified, high-risk plaques. CCTA-based plaque analysis adds valuable information in risk stratification, especially when CAC scores are low or zero.

CLINICAL RELEVANCE/APPLICATION

Our findings suggest a potential limitation of the CAC score in identifying women at risk for CAD and support the growing importance of detailed qualitative plaque analysis to improve risk stratification in women.

R5A-SPCA-8 ARTIFICIAL INTELLIGENCE-BASED ASSESSMENT OF CORONARY ARTERY CALCIFICATION GROWTH AND ITS IMPACT ON ADVERSE EVENTS: INSIGHTS FROM NATIONAL LUNG CANCER SCREENING

Won Gi Jeong, MD, PhD (*Presenter*)
Gongyoung Jin, MD, PhD (*Abstract Co-Author*)
Yun-Hyeon Kim, MD (*Abstract Co-Author*)

PURPOSE

Coronary artery calcification (CAC) growth is a crucial but underexplored factor in cardiovascular risk assessment. This study aimed to evaluate the CAC growth rate and its association with adverse cardiovascular events (ACEs) in individuals undergoing lung cancer screening (LCS).

METHODS AND MATERIALS

Participants who underwent LCS low-dose chest computed tomography (LDCT) between April 2017 and December 2023 with available follow-up LDCT scans were included. CAC score was assessed using AI-based software (AVIEW CAC, Coreline Soft, South Korea) following the Agatston method. The annual CAC progression rate was estimated using a mixed-effects linear regression model with an interaction term. CAC growth was defined as either incident CAC in participants with negative baseline CAC or an annual progression of >15% in those with positive baseline CAC, based on baseline and last LDCT scans. ACEs were categorized into major and minor events. Cox regression analysis was conducted to evaluate the association between CAC growth and ACEs, adjusting for baseline age and CAC status.

RESULTS

A total of 193 participants (mean age: 61.6 ± 5.2 years, all male) were included. ACEs occurred in 15.5% of participants (major: 4.1%, minor: 11.4%) during follow-up. The annual CAC progression rates according to baseline severity were: 0.406 (none), 6.789 (mild), 54.907 (moderate), and 54.249 (severe). A significant correlation was observed between CAC severity and its growth rate ($p<0.001$). CAC growth was independently associated with a higher incidence of total ACEs (adjusted HR: 2.4,

95% CI: 1.13-5.09, p=0.023). Participants with moderate or severe baseline CAC had a significantly higher incidence of ACEs compared to those with no baseline CAC (adjusted HR: 2.86, 95% CI: 1.11-7.38, p=0.030).

CONCLUSION

The study underscores the strong association between CAC growth and ACEs, emphasizing the need for monitoring CAC progression in individuals undergoing LCS.

CLINICAL RELEVANCE/APPLICATION

AI-based CAC growth assessment serves as a predictive tool for cardiovascular risk in LCS participants. Integrating CAC growth evaluation in routine LCS programs may enhance risk stratification and facilitate early cardiovascular interventions.

R5A-SPCA-10 ASSOCIATION BETWEEN CORONARY MONOSODIUM URATE DEPOSITS AND HIGH-RISK CORONARY PLAQUE PHENOTYPES IN GOUT PATIENTS USING DUAL-ENERGY CT AND CT-ANGIOGRAPHY

Pietro Giacomo Lacaita, MD (*Presenter*)
Andrea Klauser, MD (*Abstract Co-Author*)
Gerlig Widmann, MD, MSc (*Abstract Co-Author*)
Gudrun Feuchtner, MD (*Abstract Co-Author*)

PURPOSE

Dual-energy computed tomography (DECT) detects monosodium urate (MSU) deposits in joints. However, the correlation between coronary atherosclerosis phenotypes and MSU-positive (+) lesions in the cardiovascular system remains unclear. The aim of our study was to correlate coronary MSU+ plaques on non-enhanced DECT with the coronary atherosclerosis profile assessed by coronary CT angiography (CTA).

METHODS AND MATERIALS

150 rheumatologic were enrolled into our prospective gout-study. A subset underwent non-enhanced DECT and 128-dual source coronary CTA. CTA analysis included coronary stenosis severity (CADRADS), high-risk-plaque (HRP) phenotypes, and the coronary artery calcium (CAC) score.

RESULTS

Of the 60 patients included (mean age 63.7 +/- 8.09 years, 7 (11.7%) females), 37 (61%) had gout, 9 (15%) had hyperuricaemia, and 14 (23.3%) had other rheumatological diseases. By using DECT, 11 (18.3%) had coronary MSU+ lesions (24 lesions in total: LAD=12, RCA=10, CX=1, LM=1). HRP phenotypes were identified in 14 of 60 patients (23.3%). Among the coronary MSU+ patients, 7/11 (63.6%) had HRP, compared to 7 of 49 (14.2%) MSU-negative patients. The prevalence of HRP was higher in MSU+ than MSU-negative patients (63.3% vs.14.2%; p=0.003; OR 9.911; 95% CI: 2.297-48.41). CADRADS and CAC were correlated with the number of MSU lesions (r=0.412;p<0.001; 95% CI: 0.167-0.609) and r=0.412; (95% CI:0.169-0.609)p<0.001). None of the major cardiovascular risk factors (smoking, hypertension, dyslipidemia or diabetes) were associated with MSU+ lesions.

CONCLUSION

There is an association between coronary MSU+ lesions and HRP-phenotypes, and a correlation with stenosis severity and calcium burden. MSU+ lesions may serve as biomarkers from non-enhanced spectral CT scans for increased cardiovascular risk.

CLINICAL RELEVANCE/APPLICATION

The clinical implications of these findings might be following. Incorporating advanced imaging techniques, such as DECT, into the routine cardiovascular risk assessment of gout and hyperuricemia patients could aid in the early identification of those at heightened risk of adverse cardiovascular outcomes and, consecutively, prompt more aggressive primary preventive measures with regards to the management of cardiovascular risk factors and the implementation of targeted therapies to mitigate this risk.

R5A-SPCA-11 ECV DEPENDS ON CARDIAC FUNCTION REGARDLESS OF MYOCARDIAL IODINE VALUE

Masaya Kisohara, MD, PhD (*Presenter*)
Nobuo Kitera, RT, MSc (*Abstract Co-Author*)
Haruna Sagoh (*Abstract Co-Author*)
Tatsuya Kawai, MD, PhD (*Abstract Co-Author*)
Akio Hiwatashi, MD, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate whether cardiac function correlates with the blood pool iodine value used to calculate the CT-derived extracellular volume fraction (ECV).

METHODS AND MATERIALS

We selected patients who underwent a delayed phase scan at 7 minutes after contrast injection, intended to evaluate cardiac amyloidosis, between March 2023 and October 2024. A dual-source photon-counting detector CT scanner was used, employing a dual-source rapid-pitch scan protocol with a contrast dose of 550 mgI/kg. From the acquired data, an iodine map was reconstructed with both the section thickness and increment set to 1 mm. We then selected the section where the left ventricular blood pool area was visually largest and measured the iodine values of the blood pool (iodine BP) and the interventricular septum of the left ventricle (iodine Myo) using elliptical ROIs. Using these measured values along with the hematocrit value obtained closest to the time of the CT examination, we calculated the ECV. To compare with cardiac function, we recorded the left ventricular ejection fraction (LVEF) from the echocardiogram performed closest to the CT examination. We then assessed the correlation between iodine BP and iodine Myo with LVEF using Spearman's correlation analysis.

RESULTS

A total of 95 patients were enrolled, with a median age of 84.0 years (IQR [80.0-88.0]) and 17 men (15.8%). The LVEF, iodine BP , iodine Myo , and ECV were 63.3 ± 12.0%, 1.87 ± 0.37 mgI/mL, 0.85 ± 0.22 mgI/mL, and 29.1 ± 6.4%, respectively. While significant correlations were observed between LVEF and iodine BP , as well as between LVEF and ECV (r = 0.30 and -0.29; p = 0.013 and 0.015), the correlation between LVEF and iodine Myo was not significant (r = 0.01, p = 0.93).

CONCLUSION

At 7 minutes after contrast injection, there is a negative correlation between cardiac function and ECV. This correlation likely arises from low iodine values in the blood pool, indicating that we may be measuring reduced contrast agent perfusion due to impaired cardiac function, rather than accurately evaluating the true ECV.

CLINICAL RELEVANCE/APPLICATION

An ECV assessment performed at 7-minutes scan may not accurately reflect the true state of normal myocardium. In the iodine-based method, myocardial fibrosis and edema should be evaluated using the iodine value of the myocardium itself—without involving the blood pool—under standardized conditions such as a uniform scanning phase and contrast agent dosage.

R5A-SPCA-14 EXTRACELLULAR VOLUME FRACTION FROM DUAL-ENERGY CT PREDICTS RECURRENCE OF NON-PAROXYSMAL ATRIAL FIBRILLATION AFTER ABLATION

Shuangxiang Lin, MSc (*Presenter*)
Xinhong Wang (*Abstract Co-Author*)
Jianzhong Sun, MMed (*Abstract Co-Author*)

Jiaxing Wu (*Abstract Co-Author*)
Shuyue Wang (*Abstract Co-Author*)

PURPOSE

To determine whether myocardial extracellular volume fraction (ECV) derived from preoperative delayed-phase cardiac computed tomography angiography (CTA) can predict recurrence of non-paroxysmal atrial fibrillation (AF) following radiofrequency ablation (RFA).

METHODS AND MATERIALS

This retrospective study included 399 patients with non-paroxysmal AF who underwent RFA. Preprocedural dual-energy cardiac CTA was performed, with delayed-phase images acquired five minutes post-contrast. Left ventricular ECV was calculated. Patients were stratified by an ECV cutoff identified through receiver operating characteristic (ROC) analysis. Cox proportional hazards models and Kaplan-Meier curves assessed associations between ECV and AF recurrence. Predictive models incorporating ECV and clinical variables were evaluated using concordance index (C-index), net reclassification index (NRI), and integrated discrimination improvement (IDI).

RESULTS

During a median follow-up of 10.1 months (IQR, 8.1-13.6), 91 patients (22.8%) experienced AF recurrence after post-ablation. Higher ECV was significantly associated with recurrence (37.6% ± 5.05% vs. 32.6% ± 2.05%; $p < 0.01$). An ECV cutoff of 34.69% achieved an AUC of 0.85 (95% CI: 0.79-0.90). Multivariate Cox analysis confirmed ECV as an independent predictor of recurrence (HR = 1.59; 95% CI: 1.36-1.85; $p < 0.01$). The inclusion of ECV in clinical risk models significantly improved predictive performance, with a C-index of 0.82 (95% CI: 0.74-0.86), an IDI of 0.66 (95% CI: 0.41-0.91), and an NRI of 0.55 (95% CI: 0.26-0.61).

CONCLUSION

Left ventricular ECV measured by dual-energy CT is an independent predictor of AF recurrence after RFA in patients with non-paroxysmal AF. ECV assessment may enhance pre-ablation risk stratification and inform clinical management.

CLINICAL RELEVANCE/APPLICATION

Incorporating ECV assessment into pre-ablation imaging protocols improves risk assessment in patients undergoing RFA for non-paroxysmal AF, potentially guiding personalized treatment strategies.

R5A-SPCH-2 CT RADIOMICS-BASED MODEL FOR PREDICTING PULMONARY INVASIVE MUCINOUS ADENOCARCINOMA SPREAD THROUGH AIR SPACES

Shaoqing Jia (*Presenter*)
Qian Xu (*Abstract Co-Author*)
Miao Miao Yu (*Abstract Co-Author*)

PURPOSE

This study aimed to develop and validate a CT radiomics model for predicting the spread through air spaces (STAS) as well as stratifying the STAS risk in pulmonary invasive mucinous adenocarcinoma (IMA).

METHODS AND MATERIALS

This retrospective study included 168 pathologically confirmed IMA patients (84 STAS-positive, 84 STAS-negative) from January 2017 to July 2024, matched 1:1 by age and sex via propensity score matching. The patients were randomized into a training set (n=117) and a validation set (n=51, 7:3 ratio). The traditional imaging features (tumor location, density, lobulation, spiculation, pleural indentation, pleural attachment, air bronchogram, and bronchial cut-off signs) were extracted. Using the 3D-slicer, the region of interest included the primary tumor and a 5-mm peritumoral margin on the thin-section arterial-phase CT. Pyradiomics extracted 1,037 radiomics features, which were selected via the max relevance-min redundancy and least absolute shrinkage and selection operator algorithms. Logistic regression models were constructed for the primary tumor (PT) and peritumoral (PTM) radiomics. The combined model also integrated the traditional features. The performance was evaluated via ROC curves (AUC), with net reclassification improvement (NRI) and integrated discrimination improvement (IDI) assessing the incremental value. A nomogram was developed for the optimal model, with calibration and decision curve analyses.

RESULTS

The solid tumor density and air bronchogram sign were independent risk factors for STAS (multivariate logistic regression, P <0.05). Feature selection identified 14 PT and 18 PTM radiomics features. The model performance was as follows:PT radiomics model: training AUC=0.723; validation AUC=0.722.PTM radiomics model: training AUC=0.802; validation AUC=0.804.PT combined model (radiomics+traditional features): training AUC=0.732; validation AUC=0.735.PTM combined model: training/validation AUC=0.810 (both sets), with the highest NRI (0.60 P <0.01) and IDI (0.12, P <0.01) versus other models.

CONCLUSION

The CT-based radiomics model (PTM combined model)demonstrated the highest predictive values among all investigated models for the STAS status of pulmonary IMA.

CLINICAL RELEVANCE/APPLICATION

Clinically, the CT-based radiomics model (PTM combined model) can offer essential data for thoracic surgeons and pulmonologists during the preoperative evaluation of pulmonary invasive mucinous adenocarcinoma. It enables a more precise prediction of STAS status, facilitating personalized treatment strategies.

R5A-SPCH-3 FUNCTIONAL LUNG MRI WITH 3D UTE IN SYSTEMIC SCLEROSIS: CORRELATION WITH PULMONARY FUNCTION TESTS

Silke Westphale, MD (*Presenter*)
Simona Rose (*Abstract Co-Author*)
Johannes Kaes (*Abstract Co-Author*)
Viktor Hartung (*Abstract Co-Author*)
Michael Gernert (*Abstract Co-Author*)
Thorsten A. Bley, MD (*Abstract Co-Author*)
Herbert Koestler, PhD (*Abstract Co-Author*)
Julius F. Heidenreich, MD (*Abstract Co-Author*)

PURPOSE

Pulmonary involvement is a frequent and clinically significant manifestation of systemic sclerosis, contributing substantially to morbidity and mortality. Diagnosis of interstitial lung disease relies on pulmonary function tests and high-resolution computed tomography (HRCT), which assess function and structure separately. This separation creates a diagnostic gap, as CT cannot directly evaluate functional impairment. Functional lung MRI offers the potential to bridge this gap by providing regional, noninvasive assessment of pulmonary function alongside structural imaging. This project aims to assess the feasibility of functional lung MRI in systemic sclerosis and its correlation with pulmonary function tests.

METHODS AND MATERIALS

Fourteen patients with systemic sclerosis (mean age: 59 ± 14 years) underwent lung MRI using a breath-hold 3D ultra-short echo time (UTE) sequence with spiral acquisition trajectory in inspiration and expiration. Lung tissue was segmented using a previously trained nnUNet model. Non-rigid image registration (elastix toolbox) was performed to align images from inspiration and expiration. Signal-based fractional ventilation was calculated alongside with, MR-based ventilation inhomogeneity (VI) and ventilation defect percentage (VDP). These quantitative metrics were compared to pulmonary function test results (forced expiratory volume [FEV1%], forced vital capacity [FVC%], diffusing capacity of carbon monoxide [DLCO%], carbon monoxide transfer coefficient, [KCO%]).

RESULTS

Lung MRI was performed successfully in all patients. VI correlated negatively with DLCO% (Pearson’s r=-0.73, 95% confidence intervals [-0.92, -0.26], p=0.007) and KCO% (r=-0.78, 95% CI[-0.94, -0.38], p=0.003), but not with FEV1% or FVC% (r=-0.16 and 0.10, respectively). Similar correlations were observed between VDP and DLCO% (r=-0.70, 95% CI [-0.910, -0.219], p=0.01).

CONCLUSION

Breath-held functional lung MRI was successfully performed in patients with systemic sclerosis albeit their known respiratory limitations and breath-hold compliance. Functional analysis revealed a negative correlation between MRI-based ventilation inhomogeneity and DLCO. Although proton-based lung MRI cannot directly measure gas exchange, this is an important finding emphasizing the potential of functional lung MRI in imaging of interstitial lung diseases.

CLINICAL RELEVANCE/APPLICATION

By enabling visualization of regional ventilation deficits, functional lung MRI may bridge the diagnostic gap between structural imaging and pulmonary function testing, supporting earlier detection and monitoring of pulmonary involvement in systemic sclerosis.

R5A-SPCH-4 CT-BASED RADIOMICS MODEL FROM SOLID COMPONENTS TO PREDICT SPREAD THROUGH AIR SPACES IN SOLID-PREDOMINANT STAGE I LUNG ADENOCARCINOMA: A MULTICENTER STUDY

Xiao-Ling Ma (*Presenter*)

PURPOSE

Spread though air spaces (STAS) is an independent prognosticator for lung adenocarcinoma, signifying a higher risk of relapse and a worse outcome. We aim to investigate the value of CT-based radiomics and clinical-semantic risk predictors for identifying STAS in solid-predominant stage I lung adenocarcinoma.

METHODS AND MATERIALS

This retrospective study enrolled 409 patients pathologically-confirmed stage I lung adenocarcinoma with consolidation-to-tumor ratio greater than 0.5 from three independent institutions. The CT-based radiomics signature predictive of STAS was developed to extract radiomics features from solid components of tumors in training cohort (n=237), and verified in independent validation cohort (n=102) and external test cohort (n=70). Patients' clinical characteristics and CT semantic features were documented. Clinical-semantic (CS) risk predictors were incorporated to construct a CS model and a clinical-semantic-radiomics (CSR) model along with radiomics signature using univariate and multivariate logistic regression analysis. Model performance was evaluated by AUC, sensitivity, specificity, calibration curve, and decision curve analysis.

RESULTS

The radiomics signature achieved the AUC of 0.817 (95% CI: 0.762, 0.864) in training cohort, 0.803 (95% CI: 0.713, 0.875) in independent validation cohort and 0.716 (95% CI: 0.596, 0.818) in external test cohort. The AUC for CS model was 0.786 (95% CI: 0.728, 0.836), 0.788 (95% CI: 0.696, 0.863) and 0.727 (95% CI: 0.608, 0.827) across the respective cohorts, inferior to those of radiomics signature. Encouragingly, the combined CSR model achieved the highest AUC of 0.837 (95% CI: 0.783, 0.881), 0.829 (95% CI: 0.741, 0.896) and 0.748 (95% CI: 0.630, 0.844) across all three cohorts, indicating the incorporation of radiomics signature provided an incremental benefit over CS model. The calibration curves and decision curve analysis further verified the clinical utility of CSR model.

CONCLUSION

The CSR model based on clinical-semantic risk predictors and radiomics signature offers a promising predictive performance in predicting STAS, offering a valuable complement to individual CS model.

CLINICAL RELEVANCE/APPLICATION

The proposed model combining clinical-semantic risk predictors and radiomics signature holds significant potential as a noninvasive tool for preoperative assessment of STAS, which might serve as a helpful tool in directing surgical strategy and informing therapeutic decision-making.

R5A-SPCH-5 PROFILING THE INTRATUMOR SPATIAL HETEROGENEITY OF RESECTABLE NSCLC PATIENTS TREATED WITH NEOADJUVANT CHEMOIMMUNOTHERAPY BASED ON A NOVEL HABITAT-BASED RADIOMICS MODEL

Qin Peng (*Presenter*)
Jing Gong, PhD (*Abstract Co-Author*)

PURPOSE

Non-small cell lung cancer (NSCLC) is a highly heterogeneous disease with complex tumor microenvironments, which poses significant challenges for treatment efficacy. Neoadjuvant chemoimmunotherapy has emerged as a promising approach to enhance the response to surgery in resectable NSCLC patients. However, the intratumoral spatial heterogeneity (ISH) within NSCLC tumors can significantly influence treatment outcomes. This multi-center study aims to investigate the association between habitat-based radiomics profiling and ISH in NSCLC patients undergoing neoadjuvant chemoimmunotherapy.

METHODS AND MATERIALS

The study utilized advanced radiomics techniques to analyze pre-treatment computed tomography (CT) scans of 394 resectable NSCLC patients from three different centers. Habitat-based radiomics profiling was performed to identify distinct tumor habitats within the tumors and to quantify their spatial distribution and heterogeneity. The primary outcome was the association between radiomics features and ISH, while secondary outcomes included the correlation of these features with pathological response and overall survival.

RESULTS

Our results demonstrated that habitat-based radiomics profiling could effectively delineate ISH in NSCLC tumors. Specific radiomics features were significantly associated with ISH, including the complexity of tumor habitats and their spatial arrangement. Furthermore, these radiomics features were found to be predictive of pathological response and survival outcomes in patients treated with neoadjuvant chemoimmunotherapy.

CONCLUSION

This study highlights the potential of habitat-based radiomics profiling as a non-invasive tool for assessing ISH in NSCLC, which could aid in the stratification of patients for personalized treatment strategies. Future research will focus on validating these findings in larger cohorts and exploring the integration of radiomics with other omics data to further enhance predictive accuracy.

CLINICAL RELEVANCE/APPLICATION

As radiomics and multi-omics approaches continue to evolve, they may play a pivotal role in the future of precision oncology.

R5A-SPCH-6 UTILITY OF PREOPERATIVE CT-BASED RADIOMICS FOR PREDICTION OF MATURE TERTIARY LYMPHOID STRUCTURES FOLLOWING NEOADJUVANT IMMUNOTHERAPY IN NSCLC

Fangyuan Qu, MD (*Presenter*)
Fan Liu (*Abstract Co-Author*)
Jingyi Yang (*Abstract Co-Author*)
Xiaoting Cai (*Abstract Co-Author*)
Qiliang Wang (*Abstract Co-Author*)
Ying Liu (*Abstract Co-Author*)
Zhaoxiang Ye (*Abstract Co-Author*)

PURPOSE

To develop a radiomics model based on preoperative CT images to identify mature tertiary lymphoid structures (TLS) status in patients with IB-IIIA non-small-cell lung cancer (NSCLC) following neoadjuvant immunotherapy.

METHODS AND MATERIALS

Eligible patients who had undergone neoadjuvant immunotherapy followed by radical surgery were recruited from two institutions. The maturation and abundance of TLS were assessed using immunohistochemistry (IHC) staining. Based on the degree of TLS maturation, patients were stratified into low-maturation group (=5 mature TLS) and high-maturation group (>5 mature TLS). Preoperative CT images after 2-4 cycles of neoadjuvant immunotherapy were used to extract radiomics features. Tumor/tumor bed boundary was delineated manually on nonenhanced CT images using 3D-slicer software. A total of 1834 radiomics features were extracted from the preoperative CT. Radiomics signature was constructed using LASSO regression analysis, with 5-fold cross-validation. Model performances were evaluated using area under the curve (AUC), sensitivity (SEN), and specificity (SPE).

RESULTS

Between November 2018 and May 2024, 238 patients were retrospectively recruited (Training set=119 and internal testing set=52 from institution A; external testing set= 57 from institution B). High-maturation TLS were identified in 48.74%, 48.08%, and 45.61% of patients across the three datasets. The radiomics model incorporating seven radiomics features demonstrated favorable predictive performance in assessing mature TLS status across the training cohort (AUC 0.719, 95% CI 0.628-0.810; SEN, 0.638; SPE, 0.689), internal validation cohort (AUC 0.738, 95% CI 0.597-0.878; SEN, 0.720; SPE, 0.667), and external validation cohort (AUC 0.736, 95% CI 0.606-0.866; SEN, 0.385; SPE, 0.835).

CONCLUSION

The preoperative CT-based radiomics model demonstrated robust predictive capability in determining the status of mature TLS among NSCLC patients undergoing neoadjuvant immunotherapy, thereby providing a novel tool to facilitate personalized therapeutic strategies.

CLINICAL RELEVANCE/APPLICATION

The preoperative CT-based radiomics model demonstrated considerable potential for clinical utility in assessing the status of mature TLS for NSCLC patients receiving neoadjuvant immunotherapy regimens.

R5A-SPCH-9 ANATOMIC CORRELATION OF 0.55T LUNG MRI TO CHEST CT FOR COMMON THORACIC ABNORMALITIES: A READER PERFORMANCE STUDY

Felicia Tang, BA, BS (*Presenter*)
Timothy L. Chen, MD (*Abstract Co-Author*)
Sayedomid Ebrahimzadeh, MD (*Abstract Co-Author*)
Brandon K.K. Fields, MD (*Abstract Co-Author*)
Yoo Jin Lee, MD (*Abstract Co-Author*)
Jonathan A. Liu, MD (*Abstract Co-Author*)
Adam J. Yen, MD (*Abstract Co-Author*)
Kiara Bowers (*Abstract Co-Author*)
Richard Schonour, BS (*Abstract Co-Author*)
Pan Su (*Abstract Co-Author*)
Pedro Itriago-Leon (*Abstract Co-Author*)
Omar Darwish (*Abstract Co-Author*)
Peder E. Larson, PhD (*Abstract Co-Author*)
Yang Yang, PhD (*Abstract Co-Author*)
Jae Ho Sohn, MD, MS (*Abstract Co-Author*)

PURPOSE

MRI has seen limited adoption in lung imaging due to inherently weak signals caused by the lung’s low proton density and susceptibility artifacts at air-tissue interfaces, hindering visualization of the pulmonary parenchyma. However, the development of mid-field MRI (0.55T) offers theoretical advantages in reducing these artifacts, presenting a potential radiation-free alternative for lung imaging. The clinical diagnostic utility of 0.55T MRI in thoracic imaging, however, remains uncertain. This study aims to compare the image quality and diagnostic performance of 0.55T MRI with chest CT in detecting common lung pathologies.

METHODS AND MATERIALS

28 participants were prospectively enrolled and underwent same-day chest CT and 0.55T MRI using respiratory-triggered T2-weighted axial BLADE and T1-weighted ultra-short echo time sequences. 6 radiologists assessed 0.55T MRI images using a Likert-type scale for overall image quality and evaluated for common lung abnormalities (nodule, consolidation, ground-glass opacity, reticulation, lymphadenopathy, bronchiectasis, emphysema, and pulmonary artery dilation). Pathology visibility was categorized as excellent (detected by =4 readers), intermediate (detected by >2 to <4 readers), or poor (detected by =2 readers). Fleiss’ ? was calculated to measure interreader agreement.

RESULTS

28 participants (mean age, 59 ± 19 years; 17 women) were analyzed. Of 168 total image quality scores, 79.8% (134/168) were rated as "good" or higher. 0.55T MRI achieved excellent visibility for consolidations, large nodules (>7 mm), and pulmonary artery dilation; intermediate visibility for pleural effusions, ground-glass opacities, reticulation, lymphadenopathy, and bronchiectasis; and poor visibility for small nodules (=7 mm) and emphysema. Interreader agreement for pathology detection using MRI was moderate (? = 0.51; 95% CI: 0.37-0.61). Ground-glass opacities and lymphadenopathy showed the greatest variability between readers and had the highest false-positive detection rates.

CONCLUSION

0.55T MRI demonstrated excellent diagnostic performance for consolidation and large nodules (>7 mm), and intermediate performance for several other pathologies. Detection of small nodules and emphysema remains limited.

CLINICAL RELEVANCE/APPLICATION

0.55T MRI shows promise as a complementary imaging modality to chest CT, particularly for soft tissue characterization in patients who are radiation-sensitive and require frequent follow-up and cancer surveillance. However, detection limitations for nodules =7 mm—especially when ground-glass or located near the lung bases—highlight the need for further protocol optimization and sequence development to improve spatial resolution at 0.55T.

R5A-SPCH-11 THE DIAGNOSTIC PERFORMANCE OF AN AI-BASED CADX SYSTEM FOR PULMONARY NODULES WITH LOCALIZATION AND MEASUREMENT: A MULTI-CENTER CLINICAL TRIAL AND VALIDATION STUDY

Gucheol Jung (*Presenter*)
Juyoung Lee (*Abstract Co-Author*)
Kibok Nam (*Abstract Co-Author*)
Dahye Lee (*Abstract Co-Author*)
Burnyoung Kim (*Abstract Co-Author*)
Hoseok I, MD, PhD (*Abstract Co-Author*)
Yeon Joo Jeong, MD, PhD (*Abstract Co-Author*)

PURPOSE

We evaluated the diagnostic performance of a CADx system, which provides information on the type (solid, ground-glass opacity and part-solid), size, malignancy classification, lung-RADS category, localization and measurement of pulmonary nodules in LDCT images.

METHODS AND MATERIALS

We conducted two retrospective multi-center studies in South Korea to evaluate the CADx system, involving a total of 804 participants. The clinical trial included 455 participants across three institutions from 2019 to 2023. The validation study included 349 participants across four institutions from 2023 to 2024. In both studies, the reference standard was established by eight board-certified thoracic radiologists, with two radiologists independently assigned to each participating institution. The CADx system (DEEP:LUNG, DEEPNOID Inc., Seoul, Korea) then analyzed the LDCT images. Primary endpoints were localization-adjusted sensitivity and specificity for nodule detection and sensitivity and specificity for malignancy classification. Secondary endpoints included performance stratified by lung-RADS category and nodule size comparison between CADx predictions and radiologist annotations. Additionally, we performed an analysis of sensitivity across different Dice similarity coefficient thresholds.

RESULTS

In the clinical trial, the CADx system achieved a localization-adjusted sensitivity of 91.7% and specificity of 93.1%. Malignancy classification sensitivity and specificity were 85.7% and 87.5%, respectively. In the validation study, sensitivity and specificity were 90.6% and 80.0%, while malignancy classification sensitivity and specificity were 92.2% and 91.0%. The sensitivities for lung-RADS categories 1, 2, 3, 4A and 4B were 86.9%, 68.9%, 17.1%, 50.7% and 84.7%, respectively, across both studies. The intraclass correlation coefficient (ICC) for nodule size between CADx and radiologists was 0.86 (95% CI, 0.84-0.87) and Bland-Altman analysis demonstrated acceptable agreement.

CONCLUSION

The CADx system demonstrated robust and consistent diagnostic performance in both the clinical trial and real-world validation settings. It offers reliable support for pulmonary nodule localization and malignancy risk classification in LDCT screening, although further improvement is warranted for part-solid nodules. However, performance for Lung-RADS category 3 was relatively suboptimal, likely due to the heterogeneous and borderline nature of such nodules.

CLINICAL RELEVANCE/APPLICATION

An AI-based CADx system can consistently assist pulmonary nodule detection and malignancy classification across clinical and real-world settings.

R5A-SPCH-13 POPULATION GRAPH MODEL TO PREDICT THE CLINICAL BENEFITS OF IMMUNOTHERAPY IN PATIENTS WITH NON-SMALL CELL LUNG CANCER

Jiangdian Song, PhD (*Presenter*)

PURPOSE

Image-based models have emerged as supplements to tissue biomarkers for predicting immunotherapy outcomes in non-small cell lung cancer (NSCLC). However, their high computational and operational demands limit the involvement of clinicians in their development, and methods to integrate baseline clinical data with computed tomography (CT) images for prognostic assessment remain unexplored.

METHODS AND MATERIALS

We developed and externally validated a clinician-operable population graph model for immunotherapy prognosis that operates on cost-effective processing hardware. Patients with NSCLC who underwent immunotherapy at six hospitals between January 1, 2014, and June 30, 2023, were enrolled. A pairwise association encoder (PAE) was introduced to convert the patients' baseline clinical characteristics into graphical edges to quantify the similarities between them. We then created a DeepHypergraph for NSCLC (DHGN) that incorporated pre-treatment CT imaging features as node attributes to enhance survival outcome predictions. Our approach was evaluated by ten clinicians for accuracy and clinical deployment potential.

RESULTS

The training dataset included 1,049 patients from two centers in China. External validation was performed on two datasets comprising 194 patients from three Chinese hospitals and 136 patients from the Memorial Sloan-Kettering Cancer Center. The DHGN achieved C-indexes (with 95% CI) in the training and two external test datasets of 0.70 (0.68-0.71), 0.71 (0.67-0.75), and 0.67 (0.61-0.72), respectively, for predicting progression-free survival (PFS). Compared with the patients with PD-L1 expression level of >49% (28.9%), those identified as the top 28.9% most likely to benefit from immunotherapy by DHGN had significantly higher median PFS (13.5 vs 9.4 months, p=0.003). Similarly, compared with the patients with tumor mutation burden of >10 (40.3%), those predicted to fall within the top 40.3% most likely to benefit from immunotherapy by DHGN had higher median PFS (12.8 vs 8.3 months, p<0.0001). Based on the ten clinicians' evaluation, DHGN significantly reducing the operational complexity and computational requirements (p<0.01) for clinical deployment.

CONCLUSION

Our population graph model provided enhanced prognostic assessments of the potential benefits of immunotherapy in patients with NSCLC, facilitating the future development of deep learning-based biomarkers using cost-effective hardware in clinical settings.

CLINICAL RELEVANCE/APPLICATION

The clinician-inspired, two-step prognostic model based on the sequential evaluation of baseline clinical data followed by CT image assessment can more accurately identify which patients with NSCLC are most likely to benefit from immunotherapy.

R5A-SPER-1 PATTERNS OF THORACIC INJURY IN BOMB BLAST VICTIMS: A RETROSPECTIVE RADIOLOGICAL REVIEW

Uffan Zafar, MD (*Presenter*)
Zohaib Mallick, MBBS (*Abstract Co-Author*)
Muhammad Abdullah (*Abstract Co-Author*)
Muhammad N. Ahmad, MBBS (*Abstract Co-Author*)

PURPOSE

To characterize the spectrum of thoracic injuries in bomb blast victims using a retrospective radiological review, aiming to improve diagnostic and management strategies in mass casualty events.

METHODS AND MATERIALS

Retrospective analysis of 130 bomb blast patients treated at Aga Khan University Hospital (January 2004 - October 2024). Data included demographics, injury mechanisms (primary, secondary, tertiary, quaternary), symptoms, and initial and follow-up radiological findings (chest radiography and CT). Frequencies, percentages, medians, and interquartile ranges were used for analysis.

RESULTS

The cohort was predominantly male (94.6%, n=123), median age 32 years (IQR: 26-43.5). Initial chest radiography (85.4%) revealed common findings of foreign bodies (22.8%), emphysema (10.4%), and atelectasis (10.4%). In subsequent imaging, these findings persisted, with increased CT utilization. Primary blast injuries were most frequent (68.4%-78.8%). A significant portion (48.5%) required no third imaging.

CONCLUSION

Thoracic injuries, particularly primary blast injuries, are prevalent in bomb blast victims. Chest radiography is crucial for initial rapid assessment, with CT reserved for complex cases. A tiered imaging approach optimizes diagnostic accuracy and resource utilization in resource-limited settings.

CLINICAL RELEVANCE/APPLICATION

Understanding the patterns of thoracic injury in bomb blast victims, as revealed by radiological review, can inform the development of efficient triage and imaging protocols, ultimately improving the timeliness and effectiveness of care in mass casualty incidents.

R5A-SPER-2 ECG-LESS CORONARY CT ANGIOGRAPHY WITH SSF2: A RAPID, RELIABLE TOOL FOR EMERGENCY CHEST PAIN EVALUATION

Cheng Zhao (*Presenter*)
Zhongying Wang, MD (*Abstract Co-Author*)
Jinfu Bu (*Abstract Co-Author*)
Chong Zheng (*Abstract Co-Author*)
Xiaomeng Shi (*Abstract Co-Author*)
Jie Lu, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate the diagnostic performance and feasibility of electrocardiogram (ECG)-less coronary computed tomography angiography (CCTA) using advanced motion correction (Snapshot Freeze 2, SSF2) for rapid assessment of acute chest pain in the emergency department (ED).

METHODS AND MATERIALS

Seventy consecutive ED patients underwent non-ECG-gated CCTA on a wide detector CT (Revolution Apex Expert, GE Healthcare). Datasets were reconstructed using standard filtered back-projection (STD), first-generation motion correction (SSF1), and SSF2. Image interpretability (per-segment/vessel/patient), diagnostic accuracy for significant stenosis (>50%), objective (noise, SNR, CNR) and subjective image quality (5-point Likert scale, 2 readers, kappa), and total examination times were compared.

RESULTS

The kappa value between two radiologists on STD, SSF1 and SSF2 images was 0.78, 0.83 and 0.87. SSF2 reconstructions achieved significantly higher patient-level interpretability (100%) compared to SSF1 (92.9%) and STD (51.4%; $p<0.001$ vs STD). Visualization of distal coronary segments were significantly improved with SSF2 (97.2% interpretable) versus SSF1 (89.4%; $p<0.05$). Subjective image quality ratings were significantly superior for SSF2 (median score: 5.0 [IQR: 4.8,5.0]) compared to SSF1 and STD ($p<0.001$). SSF2 demonstrated the highest diagnostic accuracy (84.3%) compare with the final interpretation by senior radiologist for stenosis assessment regarding to SSF1 (77.14%) and STD (68.57%). Objective analyses confirmed significantly reduced image noise and improved SNR/CNR with SSF2 compared to both alternative reconstructions (all $p<0.05$), facilitating definitive interpretation without reliance on ECG synchronization. Additionally, the examination time between ECG-less and conventional CCTA examination was significantly different (50.45±9.49 vs. 117.90 ±14.06).

CONCLUSION

The application of SSF2 motion correction enables high-diagnostic-quality, ECG-less CCTA with excellent interpretability, even in challenging distal segments. This technique significantly enhances diagnostic confidence and image quality compared to standard and earlier motion correction algorithms, offering a robust and efficient pathway for coronary artery evaluation during acute chest pain triage in the emergency department, potentially streamlining patient workflow.

CLINICAL RELEVANCE/APPLICATION

SSF2 motion correction enables rapid, ECG-less coronary CT angiography with diagnostic-quality imaging, particularly valuable for emergency chest pain evaluation. This innovation streamlines acute coronary syndrome assessment while reducing reliance on ECG gating and beta-blocker administration in time-sensitive settings.

R5A-SPER-3 REDUCTION OF REPEATED PULMONARY EMBOLISM CT WITH AN OPTIMIZED ACQUISITION PROTOCOL FOR PHOTON-COUNTING CT SCANNERS IN COMPARISON WITH ENERGY-INTEGRATING DETECTOR CT

Fides Schwartz, MD (*Presenter*)
Bryan Czajkowski, RT, ARRT (*Abstract Co-Author*)
Oliver Kenney, BS (*Abstract Co-Author*)
Aaron D. Sodickson, MD, PhD (*Abstract Co-Author*)

PURPOSE

To compare repeat injection rates for CT pulmonary angiograms (CTPA) between conventional energy-integrating detector (EID) CT scanners and an optimized photon-counting CT (PCCT) protocol.

METHODS AND MATERIALS

This HIPAA-compliant, IRB-approved retrospective study included all patients who received CTPA on 14 CT scanners from three vendors across two hospitals from 06/2024-03/2025. The standard CTPA protocol on EID CTs was: 50mL contrast (350mg/mL) + saline chaser using bolus tracking at a flow rate of 4.0-4.5 mL/sec, with acquisition at 100 kVp, using highest available pitch (up to 3.2 in flash mode where available), without dual-energy. The optimized PCCT protocol was performed with 50mL of contrast (350 mg/mL) diluted with 50mL of saline (total 100mL bolus) + saline chaser at a flow rate of 2.5 mL/sec and automated scan trigger at the end of bolus injection, acquired at 140 kVp, gantry rotation 0.25, pitch 3.2, and virtual monoenergetic reconstructions at 40 keV. Repeated CT scans were identified when injector data showed a second contrast injection (that was not due to extravasation or pressure limits). Statistical comparisons were made using two-tailed t-tests with unequal variance and ANOVA with post-hoc Tukey tests.

RESULTS

9,286 scans were included (4,424 males, mean age 62.2±19.1 years) from five scanner types (Siemens: NAEOTOM Alpha: 1,060 patients, SOMATOM Edge: 975, Force: 3615; Philips: IQon: 52; GE: Discovery CT HD750: 3584). Repeat scan rates were significantly lower on the PCCT scanner protocol (1/1060; 0.09%) than on EID CT scanners (1.4%-3.8%; $p<0.01$ for each PCCT-EID pair). The average repeat rate on PCCT was 54-fold to 76-fold lower than on the EID scanners.

CONCLUSION

Optimizing PCCT protocols to capitalize on spectral capabilities for low keV reconstructions can significantly reduce the number of repeat scans in CTPA over prior-generation CT scanners.

CLINICAL RELEVANCE/APPLICATION

An optimized PCCT contrast infusion and scanner protocol including low keV reconstructions can greatly reduce the number of repeat CTPA scans, thus avoiding the need for additional contrast material and radiation dose, and minimizing workflow inefficiency.

R5A-SPGI-2 NONINVASIVE DIFFERENTIATION BETWEEN PANCREATIC NEURO ENDOCRINE TUMOR (NET) AND INTRAPANCREATIC ECTOPIC SPLEEN (IPES) USING SPIO-ENHANCED MRI

Paolo Maria Sbeghen, MD (*Presenter*)
Priska Summer, MD, PhD (*Abstract Co-Author*)
Sarah Poetter-Lang (*Abstract Co-Author*)
Nina Bastati, MD (*Abstract Co-Author*)
Ahmed Ba-Ssalamah, MD (*Abstract Co-Author*)
Ulrike I. Attenberger, MD (*Abstract Co-Author*)

PURPOSE

To compare the diagnostic efficacy of extracellular contrast media-enhanced MRI (ECCM-MRI) and superparamagnetic iron oxide enhanced MRI (SPIO-MRI) to differentiate between neuroendocrine tumor (NET) and intra pancreatic ectopic spleen (IPES).

METHODS AND MATERIALS

We evaluated 23 patients (15 men, mean age of 59.3 ± 13.6 years), 10 with histopathologically-proven NET and 13 with presumptive IPES by long-term follow-up, who underwent ECCM-MRI and then SPIO-MRI simultaneously.Two radiologists independently assessed MR images for the location and size of each lesion and compared its signal intensity (SI) on MRI before and after administration of ECCM-MRI and SPIO-MRI, with those of the adjacent pancreas and spleen. For quantitative analysis, both radiologists calculated the mean lesional, pancreatic, and splenic SIs on unenhanced and ECCM-MRI and SPIO-MRI in each patient by placing regions of interests (ROIs). For statistical analysis, the independent samples T-Test or Mann-Whitney U test for continuous variables and Chi-Square Test or Fisher's Exact Test for categorical variables were used as appropriate.

RESULTS

Apart from one NET which was in the pancreatic body, all other lesions were located in the pancreatic tail. The average lesion measured 1.5±0.5 cm. On unenhanced and dynamic ECCM-enhanced T1 imaging, the SIs in NET and IPES were similar ($p>0.05$). Likewise, T2-weighted images demonstrated similar SI between NET and IPES (246 ±144.2 vs. 238.8±134.3, $p>0.05$). However, on SPIO-enhanced images, the T2-weighted SI of NETs remained unchanged pre-and post-contrast (246.5 ± 144.2vs. 236.5±118.8) while there was significant SI loss noted in all IPES lesions (236.7± 118.8 vs. 121.5 ± 92.6) $p<0.001$. Quantitively and qualitatively, using dynamic ECCM-enhanced T1 imaging, neither reader could confidently differentiate between IPES and NET ($p> 0.5$). However, with SPIO-MRI, they found that the degree of SI loss in all IPES was similar to that of the spleen, allowing both readers to correctly diagnose all 13 ESs and 10 NETs ($p<0.001$).

CONCLUSION

SPIO-enhanced MRI allows a confident non-invasive differentiation between IPES and NET

CLINICAL RELEVANCE/APPLICATION

Accurate differentiation between NET and IPES is of high clinical relevance, as the diagnosis directly influences patient management strategies and impacts the prognosis.

R5A-SPGI-3 DEVELOPMENT OF A NOVEL DIAGNOSTIC METHOD FOR DIFFERENTIATING BENIGN AND MALIGNANT COLORECTAL ELEVATED LESIONS USING TEXTURE ANALYSIS

Toru Tochigi, MD, PhD (*Presenter*)
MIURA RYOTA, MD (*Abstract Co-Author*)
Gaku Ohira (*Abstract Co-Author*)
Koichi Hayano, MD, PhD (*Abstract Co-Author*)
Atsushi Hirata (*Abstract Co-Author*)
Yoshihiro Kurata (*Abstract Co-Author*)
Ayano Kakimoto (*Abstract Co-Author*)

PURPOSE

To evaluate the diagnostic performance of radiomic texture features extracted from CT colonography (CTC) for differentiating benign and malignant colorectal polypoid lesions using machine learning techniques.

METHODS AND MATERIALS

From 613 patients who underwent CTC between April 2021 and September 2024, a total of 214 colorectal polypoid lesions (=30 mm) from 82 patients were retrospectively analyzed. All lesions were histologically confirmed via surgical or endoscopic resection. A total of 484 radiomic features were extracted from manually segmented 3D volumes using Pixspace (Japan). Least Absolute Shrinkage and Selection Operator (LASSO) regression identified features most strongly associated with lesion malignancy, selecting 51 features for non-contrast CTC and 32 for contrast-enhanced CTC. Logistic regression (LR) and support vector machine (SVM) classifiers were trained with an 80:20 split and evaluated by AUC, accuracy, sensitivity, and specificity.

RESULTS

In non-contrast CTC, AUCs were 0.913 (LR) and 0.879 (SVM); accuracies were 87.5% and 84.4%, respectively. In contrast-enhanced CTC, AUCs were 0.942 (LR) and 0.910 (SVM); accuracies were 88.0% and 92.0%. The contrast-enhanced SVM model achieved 100% specificity and 84.6% sensitivity.

CONCLUSION

Radiomic analysis of CTC allows accurate, non-invasive discrimination of colorectal polypoid lesions. This technique may support more effective colorectal cancer screening and diagnosis.

CLINICAL RELEVANCE/APPLICATION

Radiomic texture analysis of CT colonography (CTC) images offers a promising, non-invasive tool for differentiating benign from malignant colorectal polypoid lesions. This approach can augment existing screening programs by reducing the need for invasive procedures in low-risk cases and improving early detection of colorectal cancer through advanced machine learning models. The superior diagnostic performance of contrast-enhanced CTC radiomics particularly suggests its practical utility in clinical settings for risk stratification and treatment planning.

R5A-SPGI-4 PROGNOSTIC VALUE OF CT-BASED BODY COMPOSITION CHANGES IN PANCREATIC CANCER PATIENTS UNDERGOING NEOADJUVANT THERAPY

Bang Bin Chen, MD (*Presenter*)

PURPOSE

To evaluate the prognostic impact of CT-based body composition changes, particularly subcutaneous adipose tissue (SAT) loss on overall survival in pancreatic cancer patients treated with neoadjuvant therapy.

METHODS AND MATERIALS

This retrospective single-center study included 127 patients with histologically confirmed pancreatic cancer who received neoadjuvant therapy between January 2018 and December 2023. The study was conducted at a tertiary referral hospital, with follow-up completed on April 30, 2025. The median age was 63 years (IQR: 52-71), and 59% were male. Body composition parameters were extracted from contrast-enhanced CT scans at the L3 vertebral level. Skeletal muscle volume (SM), skeletal muscle density, subcutaneous adipose tissue (SAT), and visceral adipose tissue (VAT) were automatically calculated using TotalSegmentator, an open-source AI-based segmentation tool. Relative changes between pre- and post-treatment values were computed as (Post - Pre) / Pre. Demographic data, tumor markers, staging information, and conversion surgery status were collected. Overall survival (OS) was measured from diagnosis to death or last follow-up. A multivariable Cox proportional hazards model was constructed using stepwise AIC-based selection to predict OS.

RESULTS

The median follow-up duration was 668 days (IQR: 252-1136). In the final Cox model, conversion surgery (HR 0.117, 95% CI 0.065-0.211, $p < 0.001$) and SAT relative change (HR 0.483, 95% CI 0.235-0.993, $p = 0.048$) were independently associated with overall survival after adjustment for other variables. Each 10% greater loss in SAT was associated with an increased risk of death. The model's concordance index was 0.736.

CONCLUSION

Subcutaneous fat loss during neoadjuvant therapy is an independent adverse prognostic factor in pancreatic cancer, potentially reflecting underlying treatment-related cachexia. Alongside conversion surgery, SAT change should be considered as a radiologic biomarker of treatment tolerance and long-term outcomes.

CLINICAL RELEVANCE/APPLICATION

These findings support the integration of quantitative body composition metrics in preoperative imaging assessments.

R5A-SPGI-5 CYSTIC NEUROENDOCRINE TUMORS OF THE PANCREAS: IMAGING FEATURES AND NATURAL EVOLUTION

Federica Omboni, MD (*Presenter*)
Giulia A. Zamboni, MD (*Abstract Co-Author*)
Paolo Maria Sbeghen, MD (*Abstract Co-Author*)
Matteo Bonatti, MD (*Abstract Co-Author*)
Giancarlo Mansueto, MD (*Abstract Co-Author*)

PURPOSE

To study a population of resected or followed-up cystic pNETs to determine specific imaging features and their natural evolution, to evaluate possible management of these rare lesions.

METHODS AND MATERIALS

This retrospective study from an IRB-approved registry (PAD-R registry, n1101CESC) included 62 patients (26 F, 36 M, mean age 60 yrs) with 68 cystic pNETs (5 had multiple lesions). Diagnosis was obtained with FNA or pathology (53 lesions):when biopsy was not feasible, the diagnosis was confirmed by positivity at DOTATOC-PET-CT (15 lesions). All lesions were non-functioning. At pathology, all lesions had a Ki-67<3% except for one patient (focal 4%). For each patient, the initial, preoperative and last available MRI were reviewed.

RESULTS

Lesions were located predominantly in the pancreatic tail (40/68) with a mean diameter of 22 mm (8-70 mm) and a mean wall thickness of 2,5 mm. 45 pNETs were associated with other pancreatic lesions. 37 lesions had thin or thick septa; 3 demonstrated a fluid-fluid level. Enhancement was seen in all lesions, in the arterial phase but also as constant or late enhancement. None of the 68 lesions showed macroscopic lymphatic or metastatic spread at any exam. 22 lesions were resected, with mean diameter of 32,5 mm. 10 lesions were resected after a follow-up >6 months: 2/10 were resected for size increase (final diameter 27 mm and 12 mm), 1/10 were disseminated at peri-pancreatic lymph nodes (lesion diameter of 44 mm). Of the total lesions resected, 3 lesions with an initial diameter >40 mm (44, 52, 70 mm), demonstrated peri-pancreatic lymph node spread. None of these showed signs of recurrence or metastatic spread.46 lesions underwent only follow-up, 38 for >6 months (mean 38.5 months). Mean lesion diameter was 17,6 mm, with 8 lesions >20 mm, 7/8 of which remained stable. Of the 38 patients that underwent follow-up for longer than 6 months, only 3 showed clinical or radiological signs of progression (2 with diameter <20 mm and 1 with diameter >20 mm) (progression was not statistically associated with the cut-off diameter of 20 mm). No difference was observed in terms of progression/recurrence between patients who underwent follow-up or surgery (p=0.54).

CONCLUSION

In our series, no significant difference was observed in terms of behaviour in cystic PNETs below 20 mm and below 40 mm. If results are confirmed by larger studies, follow-up could be safe also for larger lesions.

CLINICAL RELEVANCE/APPLICATION

Cystic pNETS are classically seen as a less aggressive form of neuroendocrine tumor from their solid counterpart. Follow-up could be considered a feasible option also for completely cystic pNET larger than 20 mm (below <40 mm in diameter) if no signs of progression are seen, but further multicentric studies are required.

R5A-SPGI-6 DEVELOPMENT AND VALIDATION OF A CT/PET RADIOMIC BIOMARKER PANEL FOR NON-INVASIVE ASSESSMENT OF IMMUNE CHECKPOINT INHIBITOR RESPONSE IN LOCALLY ADVANCED ESOPHAGEAL SQUAMOUS CELL CARCINOMA

Qin Peng (*Presenter*)
Jing Gong, PhD (*Abstract Co-Author*)

PURPOSE

To address the challenges posed by tumor spatial heterogeneity, we developed a radiomics-based intratumoral heterogeneity (ITH) model integrating PET-CT metabolic features and CT morphological characteristics in locally advanced esophageal squamous cell carcinoma (ESCC).

METHODS AND MATERIALS

A retrospective cohort of 179 patients receiving neoadjuvant immunotherapy followed by surgery was analyzed. Radiomic features were extracted by manual delineation for precise tumor segmentation and PyRadiomics for feature extraction. A prospective single-cell transcriptomic analysis of 10 treatment-naive surgical specimens validated the model's biological relevance, revealing key immune subsets and stromal interactions linked to ITH.

RESULTS

The multi-omics model demonstrated robust predictive accuracy for major pathological response (MPR) (AUC = 0.81), significantly surpassing conventional biomarkers. Single-cell RNA sequencing of 101,839 cells from 10 prospectively collected tumors revealed ITH-high tumors were enriched with immunosuppressive subsets and tumor-associated macrophages (CCL18+, IDO1+), alongside reduced memory/naïve T cells.

CONCLUSION

This study presents a radiomics-based framework integrating tumor heterogeneity and single-cell transcriptomics enables precision immunotherapy in ESCC.

CLINICAL RELEVANCE/APPLICATION

By linking imaging features to molecular dynamics, this approach enhances mechanistic understanding and refines clinical decision-making for patient stratification.

R5A-SPGI-7 TUMOR MUTATION BURDEN IN PANCREATIC DUCTAL ADENOCARCINOMA CORRELATES WITH PROGNOSIS AND CAN BE PREDICTED BY DUAL-LAYER SPECTRAL DETECTOR CT

Siya Shi (*Presenter*)
Jiawei Liu (*Abstract Co-Author*)
Yanji Luo (*Abstract Co-Author*)
Shi-Ting Feng (*Abstract Co-Author*)

PURPOSE

The aim of this study was to explore the relationship between tumor mutation burden (TMB) and prognosis of patients with pancreatic ductal adenocarcinoma (PDAC) and to explore the role of dual-layer spectral detector CT in predicting TMB.

METHODS AND MATERIALS

This retrospective study included patients with pathologically performed PDAC who underwent dual-layer spectral detector CT from June 1, 2019 to December 31, 2023. The relationship between TMB and progression-free survival (PFS) was analyzed using a survival function and the best cut-off value was calculated, and the patients were divided into high/low TMB groups accordingly. The Kaplan-Meier survival curves were used to compare the PFS between both groups. The least absolute shrinkage and selection operator (LASSO) regression was using to select for independent predictors. The evaluation performance of the models constructed with independent predictors were analyzed using the receiver operator characteristic (ROC) curve and the precision-recall (PR) curve.

RESULTS

There were 75 patients with PDAC (mean age 60.40 ± 11.24 years, 41 males) were enrolled. The optimal cutoff value was 5.03 mut/Mb according to the relationship between TMB and PFS. For the convenience of clinical application, an integer 5 around the optimal cutoff value was taken as the threshold, and PFS was worse in the low TMB group than in the high TMB group (median PFS: 5 months vs. 7 months, P = 0.02). Among 52 patients receiving combination immunotherapy, there were 9 patients in the high TMB group with better PFS (median PFS: 7 months vs. 4 months, P = 0.02). According to LASSO regression, only normalized iodine density in the pancreatic phase (nICa) was independent predictor (area under the curve [AUC] of ROC = 0.901, cut-off value: 0.089, accuracy: 0.893, sensitivity: 0.818, specificity: 0.906). The nICa model had the best efficacy in predicting TMB using ROC analysis, outperforming conventional CT quantitative parameter (nCTa, AUC = 0.834), radiological features (pancreatic tumor infiltration [PTI], AUC = 0.679) and the combined model (nCTa+PTI, AUC = 0.864). The PR curve analysis also showed that the nICa model had the best efficacy. The PFS of the TMB-positive prediction was better than that of the TMB-negative prediction (median PFS: 7 months vs. 5 months, P = 0.04).

CONCLUSION

Poor PFS were observed in patients with low TMB. nICa was an independent relevant factor of TMB in PDAC with superior predictive efficacy than conventional CT quantitative parameter and radiological features.

CLINICAL RELEVANCE/APPLICATION

nICa derived from dual-layer detector CT allows for non-invasive prediction of TMB and prognosis which aids in preoperative clinical decisions for patients with PDAC.

R5A-SPGI-9 DEEP LEARNING CT SIGNATURE FOR PREDICTING OCCULT LIVER METASTASES AND NEOADJUVANT THERAPY BENEFIT IN PANCREATIC DUCTAL ADENOCARCINOMA: A MULTICENTER RETROSPECTIVE STUDY

Ben Zhao (*Presenter*)
Shenghong Ju, MD, PhD (*Abstract Co-Author*)

PURPOSE

To develop a deep learning (DL) framework integrating tumor and liver imaging features to predict occult liver metastases (OLM) in pancreatic ductal adenocarcinoma (PDAC), thereby guiding personalized neoadjuvant therapy (NAT).

METHODS AND MATERIALS

In this multicenter retrospective study (2015-2022), 1,063 patients were included: a training cohort (n = 450), internal validation cohort (n = 113), external validation cohort (n = 342), and an NAT cohort (n = 158). We developed a Mamba-based model that integrates multi-phase imaging features from both primary tumors and liver regions. Its performance was evaluated using the area under the receiver operating characteristic curves (AUCs). To assess clinical utility, survival outcomes were compared between NAT followed by surgery and upfront surgery groups based on model-defined risk stratification. Finally, radiotranscriptomics analysis was employed to elucidate its biological insights.

RESULTS

The Mamba-based model demonstrated robust performance for predicting the OLM, with the AUCs of 0.890 (training), 0.820 (internal validation), and 0.806 (external validation), respectively. Model-defined high-risk patients had significantly shorter progression-free survival (PFS: HR = 1.95, P < .001) and overall survival (OS: HR = 1.96, P < .001), independent of clinicopathological factors. Notably, NAT conferred significant OS benefits exclusively in model-defined high-risk patients (17.43 vs. 34.10 months; P < .001), even after propensity score matching (P = .003), while low-risk patients showed no survival benefit. Furthermore, radiotranscriptomics also revealed the relative biological aggressiveness of high-risk patients.

CONCLUSION

The proposed Mamba framework enabled accurate prediction of OLM and may serve as a clinically actionable tool for identifying PDAC patients most likely to benefit from NAT.

CLINICAL RELEVANCE/APPLICATION

The proposed Mamba-based model can identify patients at high risk of OLM who may benefit from NAT and demonstrate significant value of prognosis stratification, showing its potential to optimize personalized management for PDAC.

R5A-SPGI-11 VALUE ADDITION OF SUBSPECIALTY TRAINED RADIOLOGISTS IN MULTIDISCIPLINARY TUMOR BOARDS FOR PANCREATIC ADENOCARCINOMA: A META-ANALYSIS & SYSTEMATIC REVIEW

Adam Caulfield, MD (*Presenter*)
Ankush Jajodia, MD, MBBS (*Abstract Co-Author*)
Mila Ferri Latinovich (*Abstract Co-Author*)
Kartik Gupta, MD (*Abstract Co-Author*)
Khaled Y. Elbanna, FRCR (*Abstract Co-Author*)
Michael N. Patlas, MD, FRCPC (*Abstract Co-Author*)

PURPOSE

Background : Pancreatic adenocarcinoma (PAC) has high morbidity and mortality, with a five-year survival of only 15-20% post-curative treatment. Management typically involves surgery, radiotherapy, and chemotherapy, coordinated through multidisciplinary team (MDT) reviews. Accurate determination of tumor resectability can enhance survival. Retrospective studies demonstrate MDT input, including imaging review, significantly alters management in up to 37% of cases. However, radiology's precise role in PAC MDT decision-making remains unclear. Purpose We aim to perform a meta-analysis reviewing the role of radiology in a pancreatic adenocarcinoma multidisciplinary team (MDT) evaluation and the impact on patient outcomes.

METHODS AND MATERIALS

A search of literature was conducted using Ovid MEDLINE, Ovid Epub, Cochrane Central, Embase, and Scopus to find original research from articles published before August 31, 2023, related to the study question. Two reviewers independently assessed the risk of bias (QUADAS-2). Random-effects meta-analysis was performed.

RESULTS

Ten studies (4 retrospective, 6 prospective, and 4 multicenter vs. 6 single center), including 2,067 patients, met inclusion criteria in a pool of 12,969 studies. Three studies with 977 patients showed that there were clear changes in how patients were managed (average estimate 0.53 (95% CI, 0.50-0.56)) after a radiology review at the MDT. A random-effects meta-analysis of these studies shows that, on average, about 44% of patients had their treatment plans changed after a meeting at the MDT that included a dedicated radiologist, but there is a large range of uncertainty (18%-74%) due to differences in the studies' groups, what they considered a "change," and local practices. Two studies highlighted an important nuance: while MDT input is valuable, the interpretations can vary between teams or even within the same team over time, reflecting the complex nature of PAC. None of the studies showed a statistically significant survival boost solely from MDT involvement, likely because overall survival depends on many downstream factors.

CONCLUSION

The presence of radiology review in the setting of multidisciplinary team meetings provides crucial information, leading to management changes. Future studies could explore imaging modalities such as MRI and PET and establish the impact of intra/inter-observer variability within the multidisciplinary team.

CLINICAL RELEVANCE/APPLICATION

This data supports the ongoing involvement of skilled abdominal radiologists in the multidisciplinary team for PAC, and it significantly influences clinical decisions. Applicability concerns exist due to a potential lack of resources for robust MDT initiatives outside of tertiary centers.

R5A-SPGI-13 FROM CLINICAL SCORES TO CT: RADIOMICS AS A NOVEL TOOL FOR SURVIVAL PREDICTION IN COLORECTAL LIVER METASTASES

Angela Ammirabile, MD (*Presenter*)
Gilda Matteucci (*Abstract Co-Author*)
Francesco Fiz (*Abstract Co-Author*)
Guido Costa (*Abstract Co-Author*)
Ezio Lanza, MD (*Abstract Co-Author*)
Marco Francone, MD, PhD (*Abstract Co-Author*)
Guido Torzilli, MD (*Abstract Co-Author*)
Francesca Ieva, MD (*Abstract Co-Author*)
Luca Vigano (*Abstract Co-Author*)

PURPOSE

Surgery with perioperative chemotherapy is the standard treatment for colorectal liver metastases (CRLM), yet a subset of resectable patients does not benefit from surgery. Patient selection should rely on survival prediction: available prognostic factors have limited reliability, and most biomarkers can only be assessed on surgical specimens. This study investigated the potential of pre-operative CT-based radiomics for survival prediction in CRLM patients, focusing on its performance by the CT-surgery interval and comparison with clinical scores.

METHODS AND MATERIALS

This single-center retrospective study included all consecutive patients undergoing liver resection for CRLM (2010-2020). The main inclusion criterion was the availability of a high-quality CT scan (=60 days before surgery) with a detectable CRLM =10 mm. Manual tumor segmentation (Tumor-VOI) and automatic 5-mm peritumoral ring (Margin-VOI) were performed on the portal phase of CT scans. From each VOI, 110 IBSI-compliant features were extracted with LIFEx. Predictive models (Clinical, Clinical+Tumor-radiomics, Clinical+Tumor/Margin-radiomics) were built to predict overall survival (OS) by a two-step approach: feature selection via Boruta algorithm and random forest with 10-fold cross-validation. Performance was assessed in the whole cohort and in a = 30-day CT-surgery subgroup. A per-lesion analysis (up to five lesions) was conducted for inter-tumour heterogeneity. Tree-Edit Distance and Hierarchical Clustering were applied to stratify patients, and the resulting clusters were integrated into survival models.

RESULTS

306 patients were included (mean age 63 years) with five-year OS=40.9% (mean follow-up 34 months). At internal validation, the clinical model had C-index=0.629. While in the entire cohort radiomics lead to a minor improvement of model performance, in the 212 patients with a CT-surgery interval =30 days, the Tumor-VOI model reached C-index=0.691 and combining Tumor+Margin-VOIs increased it to 0.717. The full clinical-radiomic model outperformed standard prognostic scores (c-indices Fong/GAME/c-MS=0.502-0.593). Indices reflecting tumor heterogeneity did not improve survival prediction.

CONCLUSION

Radiomic features of CRLM and peritumoral tissue from preoperative CT scans enhance survival prediction beyond standard clinical scores, with better performance observed at shorter CT-surgery intervals.

CLINICAL RELEVANCE/APPLICATION

By offering a more precise evaluation, the combined clinical-radiomic model can refine CRLM treatment strategies, acting as a pre-operative filter to exclude resectable patients unlikely to achieve long-term survival and identify those most likely to benefit from surgery.

R5A-SPGI-14 REVERSE PANCREAS DIVISUM: AN ANATOMICAL VARIANT ASSOCIATED WITH PARADUODENAL PANCREATITIS

Zeynep Nur Akyol Sari, MD (*Presenter*)
Abraham Fourie Bezuidenhout, MD (*Abstract Co-Author*)

PURPOSE

As lifestyle factors compounded by inherent abnormal pancreatic drainage at the minor papilla at a microscopic level are considered predisposing factors to developing paraduodenal pancreatitis, we aimed to investigate pancreatic duct anatomy at MRCP as a potential imaging biomarker for patients at risk of developing paraduodenal pancreatitis.

METHODS AND MATERIALS

A retrospective analysis of consecutive patients presenting with paraduodenal pancreatitis that undergone MRCP from 2014-2024 were included. The main pancreatic duct (MPD) anatomy were classified into 5 types based on their drainage patterns.The frequency of MPD variants in our cohort was compared to that of the general population. The association between common MPD variants in our study and the involvement of specific pancreatic segments in paraduodenal pancreatitis was analyzed.

RESULTS

The prevalence of MPD types 1, 2 ,3, 4 and 5 were 18%, 6%, 0%, 27%, 39% respectively versus 29.5%, 1.9%, 5.5%, 2.2%, 54.5%. The most common MPD variant in our study was Type 5(MPD as the only duct), observed in 13/33 (39%) patients. This variant was frequently associated with the pure subtype of paraduodenal pancreatitis involving the antero-superior pancreatic head 11/13(%85). Type 4 (Reverse pancreas divisum (RPD))—where the main pancreatic duct drains into the major papilla and the accessory pancreatic duct drains into the minor papilla without interconnection—was identified in 9/33 (27%) patients with paraduodenal pancreatitis, making it the second most common MPD variant. This represents a 12-fold increased frequency compared to the general population. A strong association was observed between RPD and the segmental subtype of paraduodenal pancreatitis, with antero-inferior pancreatic head involvement seen in all 9 (100%) RPD patients.

CONCLUSION

The two most common MPD variants in our study of patients with paraduodenal pancreatitis were Type 5 and Type 4. As Type 5 is the most common MPD morphology seen in the general population, it would make sense that this would be the most common MPD morphology in our study population. However RPD was seen as the second most common MPD morphology with a 12 fold increase as compared to the general population, suggesting that it may play a role in impaired pancreatic drainage at the minor papilla.

CLINICAL RELEVANCE/APPLICATION

MRI readily detects RPD, facilitating patient counseling to potentially prevent paraduodenal pancreatitis development and associated suffering. Our findings emphasize the importance of recognizing pancreatic ductal variations when evaluating these patients. RPD and other MPD variants may require specialized interventions, such as endoscopic sphincterotomy or stenting, to improve drainage and relieve symptoms.

R5A-SPGI-15 CHARACTERIZATION OF SUSPECTED PANCREATIC INTRADUCTAL PAPILLARY MUCINOUS NEOPLASM ON SINGLE PHASE HIGH RESOLUTION PHOTON-COUNTING CT

Khanin Khanungwanitkul, MD (*Presenter*)
Fides Schwartz, MD (*Abstract Co-Author*)
Jennifer W. Uyeda, MD (*Abstract Co-Author*)
Abhishek R. Keraliya, MD (*Abstract Co-Author*)
Hei Shun Yu, MD (*Abstract Co-Author*)
Daniel I. Glazer, MD (*Abstract Co-Author*)
Olga Sliwicka, MD, PhD (*Abstract Co-Author*)
Aaron D. Sodickson, MD, PhD (*Abstract Co-Author*)

PURPOSE

Pancreatic intraductal papillary mucinous neoplasms (IPMN) are common incidental findings on portal venous phase CT and frequently require subsequent MRI for definitive characterization. The purpose of this study is to assess the utility of high-resolution thin-slice photon-counting CT (PCCT) to characterize such lesions as IPMN and reduce the need for MRI.

METHODS AND MATERIALS

All patients who received portal venous phase abdominal PCCT between 07/11/2023 - 03/272024 with hypoattenuating pancreatic lesions were retrospectively included. Exclusion criteria included absence of high-resolution PCCT images, no reference standard imaging (upper abdominal MRI or MRCP), and patients with active pancreatitis. All lesions were reviewed on 3 mm, 1.6 mm and 0.4 mm axial PCCT image series by three experienced Emergency Radiologists (Figs A, B). The readers assessed each image series for communication between the cyst and the pancreatic duct on a Likert scale: 1= no communication visualized; 2 = probable communication; 3 = definite communication. 0.4-mm iodine overlay images were used to assess enhancement. Comparison was made with reference standard MRI.

RESULTS

Within the 2,780 abdomen/pelvis PCCT scans, 78 patients with incidental hypoattenuating pancreatic lesions were identified, of which 46 were excluded. Within the included 32 patients, 34-47 pancreatic lesions (varying between readers) were identified by PCCT, ranging in size between 0.3 - 4.0 cm. Reader confidence in detecting duct communication (Fig C) was highest on 0.4 mm images (Friedman p-value = 0.001). By dichotomizing the Likert scale using 2-3 to indicate duct communication and 1 as none, communications were identified at 3.0 mm, 1.6 mm and 0.4 mm thickness respectively in 48.9%, 66.6% and 72.3% by reader 1; 23.5%, 32.4%, and 44.1% by reader 2; and 19.1%, 38.1%, and 54.8% by reader 3 (Chi-square $p<0.05$ between all slice thicknesses except between 1.6 and 3.0 mm for one reader). Agreement between CT and reference standard MRI was highest at 0.4 mm (Cochran's Q test p-value = 0.001) (Fig D).

CONCLUSION

High-resolution thin slice PCCT images show promise to characterize incidental IPMNs on single-phase scans. By revealing pancreatic duct communication and absent iodine uptake, thin slice PCCT may definitively characterize more IPMNs than at larger slice thickness.

CLINICAL RELEVANCE/APPLICATION

Characterization of IPMN by high resolution PCCT may reduce the need for follow-up MRI assessment.

R5A-SPGI-16 PREVALENCE AND IMAGING CHARACTERISTICS OF CHRONIC CALCIFIC PANCREATITIS IN PATIENTS WITH NEWLY DIAGNOSED PANCREATIC DUCTAL ADENOCARCINOMA

Rubab F. Malik, BA (*Presenter*)
Zahra Yousefli (*Abstract Co-Author*)
Mahya Faghih, MD (*Abstract Co-Author*)
Vikesh Singh, MD (*Abstract Co-Author*)
Atif Zaheer, MD (*Abstract Co-Author*)

PURPOSE

Chronic pancreatitis (CP) is a risk factor for pancreatic ductal adenocarcinoma (PDAC), with a cumulative risk of approximately 4% over 20 years. Most prior studies have evaluated the risk of PDAC among patients with CP. Given the lack of data on CP frequency in patients with newly diagnosed PDAC and the associated clinical or imaging characteristics, our research addresses this knowledge gap.

METHODS AND MATERIALS

A retrospective review of the clinical history and staging CT scans of patients diagnosed with resectable or borderline resectable/locally advanced PDAC at a high-volume center between 2011-2022 was conducted. CP and ductal dilatation were defined by the presence of pancreatic calcifications and a maximal pancreatic ductal diameter > 5 mm on CT, respectively. Two attending abdominal radiologists independently reviewed the CT imaging to evaluate imaging features on all available phases according to a published consensus on CP imaging findings and discrepancies were adjudicated by a third radiologist.

RESULTS

Among 1008 patients with PDAC, CP was found in 34 (3.4%), with a mean age of 69.9±8 years, 50% men, 91% white, and 59% with a history of smoking with 26.95±18.5 pack-years. Only 7 (21%) patients had a documented history of chronic abdominal pain before PDAC diagnosis. Abdominal pain was the most common presenting symptom for PDAC in our cohort, though painless CP prior to PDAC diagnosis (79%) was more than three times as common as painful CP (21%). The presence of ductal dilation, pseudocysts, or pancreatic atrophy was observed in nearly 40%, 10%, and 40% of patients, respectively, and 7 (21%) showed none of these features. Ductal dilation was associated with higher levels of CA19-9 (349.8 U/mL [IQR; 238.3, 455.0] vs 90.0 U/mL [IQR; 58.3, 162.2], p=0.003). Intratumoral and extratumoral-only calcifications were found in 14 (41%) and 20 (59%) patients, respectively.

CONCLUSION

CP is found in approximately 3% of patients who present with PDAC and most have primary painless disease. While many patients in our cohort showed at least one predictive imaging feature of PDAC (PD dilation, atrophy, or pseudocyst), more than half lacked ductal dilation, and one-fifth showed none of these imaging features. It is important not to overlook the possibility of PDAC in CP patients without these imaging findings. Further studies are required to determine optimal PDAC screening and surveillance in patients with primary painless CP.

CLINICAL RELEVANCE/APPLICATION

A high index of suspicion for PDAC should be maintained for calcified and non-calcified areas of the pancreas in patients with CP as calcifications can obscure small tumors and many with CP and PDAC lacked imaging signs predictive of PDAC.

R5A-SPGU-1 DIAGNOSTIC PERFORMANCE AND INTER-READER AGREEMENT OF THE TORONTO MRI SCORING SYSTEM FOR DETECTION OF RECURRENT PROSTATE CANCER AFTER FOCAL THERAPY

Jorge A. Abreu Gomez, MD (*Presenter*)
Adriano Basso Dias, MD, MSc (*Abstract Co-Author*)
Katherine Lajkosz (*Abstract Co-Author*)
Harini Thevarajah (*Abstract Co-Author*)
Kateri Corr (*Abstract Co-Author*)
Sangeet Ghai, MD (*Abstract Co-Author*)

PURPOSE

Evaluate the diagnostic performance of a locally developed Toronto MRI scoring system post-Focal Therapy (FT) and compare with other published systems (PI-FAB and TARGET). Assess inter-reader agreement among three readers for Toronto, PI-FAB, and TARGET scores.

METHODS AND MATERIALS

This retrospective study included patients with intermediate-risk PCa treated with primary FT using US- or MR-guided high-frequency ultrasound or MR-guided focal laser ablation. Patients underwent 'protocol' or 'for cause' follow-up mpMRI and biopsy at 6-48 months after FT. Review of a training dataset of mpMRI scans after FT was used by three fellowship-trained radiologists (7,10,18 years of experience) to establish a set of 3-point imaging descriptors for T2-WI, DCE and DWI each. Thereafter, two separate 5-point scoring systems - one for the peripheral zone (PZ) and other for transition zone (TZ) were finalised. 148 mpMRI scans after FT were independently scored by the 3 radiologists using the Toronto, PI-FAB, and TARGET systems. Diagnostic performance metrics were calculated.

RESULTS

Results: 41/148 mpMRI scans (27.7%) had csPCa (=GG2 PCa). For the most experienced reader, the Toronto Score had an overall sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) of 75.6%, 68.2%, 47.7% and 88% respectively. When using PI-FAB, the values were 61.0%, 77.6%, 51.0%, and 83.8%; and for TARGET, the values were 63.4%, 72.9%, 47.3% and 83.9% respectively. For baseline tumors in TZ, the sensitivity, specificity, PPV and NPV for the Toronto score was 71.4%, 71.4%, 38.5% and 91.9% compared to 28.6%, 92.9%, 50.0% and 83.9% for PI-FAB and 28.6%, 85.7%, 33.3%, 82.8% for TARGET. For tumors in the PZ, the sensitivity, specificity, PPV, and NPV for the Toronto score were 76.5%, 67.1%, 50%, and 86.9%; for PI-FAB score were 67.6%, 72.2%, 51.1%, and 83.8%, and for TARGET was 70.6%, 68.4%, 49%, and 84.4% respectively.Inter-reader agreement among the three readers showed a GWET's AC2 value as follows: Toronto score 0.782 (95% CI: 0.716-0.849; PI-FAB 0.789 (95% CI: 0.708-0.870) and TARGET 0.787 (95% CI: 0.714-0.860), p <0.001

CONCLUSION

Results suggest that a separate assessment of the PZ and TZ, as performed in Toronto score, may improve the mpMRI diagnostic performance after FT compared to PI-FAB and TARGET. Specifically, the Toronto score showed higher sensitivity for TZ tumors while maintaining a high NPV.

CLINICAL RELEVANCE/APPLICATION

The Toronto scoring system offers improved detection of PCa recurrence after FT, potentially providing a high sensitivity for detecting recurrent PCa while reducing the need for repeated biopsies after FT.

R5A-SPGU-3 99MTC-SESTAMIBI SPECT/CT DIFFERENTIATES RENAL ONCOCYTOMAS AND HYBRID TUMORS FROM MALIGNANT MIMICS

Ali Sheikhy, MD (*Presenter*)
Aryan Zahergivar, MD (*Abstract Co-Author*)
Mahshid Golagha, MD (*Abstract Co-Author*)
Negin Jarrah, MD (*Abstract Co-Author*)
Evrim B. Turkbey, MD (*Abstract Co-Author*)
Ashkan A. Malayeri, MD (*Abstract Co-Author*)

PURPOSE

To determine the diagnostic performance of 99mTc-sestamibi single-photon emission CT/CT (SPECT/CT) in distinguishing benign renal oncocytomas and hybrid oncocytic-chromophobe tumors (HOCTs) from malignant renal masses.

METHODS AND MATERIALS

A retrospective study included 20 patients (71 renal masses) who underwent 99mTc-sestamibi SPECT/CT at the NIH Clinical Center. Radiotracer uptake was categorized as hot (suggesting oncocytoma/HOCT) or cold (suggesting other renal cell carcinoma subtypes). Two blinded abdominal radiologists interpreted scans independently; disagreements were resolved by consensus. Histopathology served as the reference standard. Diagnostic metrics (sensitivity, specificity, accuracy) and inter-reader agreement (?) were calculated.

RESULTS

Among the 71 renal masses evaluated, histopathology identified 31 oncocytomas (43.6 %), 24 hybrid oncocytic-chromophobe tumors (HOCTs; 33.8 %), 13 chromophobe or papillary renal cell carcinomas (RCCs; 18.6 %), and 3 clear-cell RCCs (4.2 %). 99mTc-sestamibi SPECT/CT correctly classified lesions with an overall accuracy of 91.5 %, achieving a sensitivity of 100 % for detecting oncocytomas and HOCTs but a specificity of 62.5 % for excluding malignant masses. Inter-reader agreement between the two radiologists was moderate (? = 0.465). Notably, unexpected radiotracer uptake ("hot" appearance) occurred in 66.7 % of chromophobe and papillary RCCs, contributing to false-positive findings and highlighting areas for potential refinement in image interpretation.

CONCLUSION

Our study confirms that 99mTc-sestamibi SPECT/CT is a highly sensitive tool for identifying mitochondria-rich benign renal masses, correctly classifying all oncocytomas and HOCTs and yielding an overall accuracy of 91.5 %. Specificity, however, remained moderate because substantial radiotracer uptake was also observed in chromophobe, papillary type 1 RCCs, and clear-cell RCCs. These false-positive findings, together with only moderate inter-reader agreement, highlight the need for standardized interpretation criteria, incorporation of quantitative uptake metrics, and consensus or double-reading to optimize diagnostic confidence.

CLINICAL RELEVANCE/APPLICATION

Implementing 99mTc-sestamibi SPECT/CT could substantially reduce unnecessary nephrectomies and overtreatment of benign renal masses, supporting more patient-tailored management while highlighting the need for strategies that improve specificity.

R5A-SPGU-4 QUANTITATIVE FLOW PARAMETERS DIFFERENTIATING ONCOCYTOMA AND PAPILLARY RENAL CANCER FROM CLEAR CELL RENAL CANCER WITH PERFUSION CT

Alex Chung, MD (*Presenter*)
Sara Babapour, MD (*Abstract Co-Author*)
James W. Sayre, PhD,MS (*Abstract Co-Author*)
Steven S. Raman, MD (*Abstract Co-Author*)

PURPOSE

To evaluate quantitative differences in perfusion CT (pCT) parameters for differentiation of clear cell renal cell carcinoma (ccRCC) from papillary RCC (pRCC) and oncocytoma (Onc)

METHODS AND MATERIALS

With IRB approval & HIPAA compliance, we derived a study cohort of 76 consecutive patients who underwent pCT (Force, Siemens Healthineers (SH), Erlangen, Germany) for a known or suspected indeterminate solid renal mass. Virtual reconstructions of the noncontrast, corticomedullary, & nephrographic phases were generated using Syngo Via (SH, Malvern, PA). Volumes of interest were drawn on the most enhancing portion of the mass as well as normal ipsilateral & contralateral renal cortex during the corticomedullary phase. Perfusion parameters of blood flow (BF), blood volume (BV), mean transit time (MTT), flow extraction (FE), time to peak (TTP), absolute peak Hounsfield Units (pHU) values were generated from the perfusion curves & normalized to the ipsilateral cortex (IpCx) except for pHU. Perfusion parameters were compared by ANOVA between tumors grouped by their pathology results & by two-tailed paired sample t test between tumors & ipsilateral cortex.

RESULTS

Of 76 patients who underwent pCT, 46, 13 & 17 were ccRCC, pRCC & Onc, respectively. Significant differences were as follows: Between ccRCC & pRCC in BF, BV, FE, pHU and TTP (all $p=0.01$); between ccRCC & Onc in BV ($p=0.01$), pHU ($p=0.04$) and TTP ($p=0.03$); between pRCC & Onc in BF, BV, FE and pHU (all $p<0.01$). MTT was similar among groups ($p>0.05$). Significant differences were as follows versus IpCx: For ccRCC in MTT ($p=0.02$), FE ($p=0.04$) and TTP ($p<0.01$); for pRCC in BF, BV, FE, pHU and TTP (all $p<0.01$); For Onc in BV ($p<0.01$) and pHU ($p=0.01$).

CONCLUSION

Significant differences were demonstrated in BF, BV, FE, pHU and TTP between ccRCC & pRCC, in BV, pHU and TTP between ccRCC and in BF, BV, FE & pHU between pRCC & onc. Relative enhancement parameters of ccRCC, pRCC & Onc compared to IpCx demonstrated significant differences in certain parameters.

CLINICAL RELEVANCE/APPLICATION

Relative CT perfusion parameters differ by renal mass histological subtype and may help characterize common solid renal lesions if validated.

R5A-SPGU-5 EVALUATING EXTRAPROSTATIC EXTENSION OF PROSTATE CANCER: PRAGMATIC INTEGRATION OF MRI AND PSMA-PET/CT

Sungmin Woo, MD, PhD (*Presenter*)
Daniel Freedman, MD (*Abstract Co-Author*)
Anton S. Becker, MD, PhD (*Abstract Co-Author*)
Doris Leithner, MD (*Abstract Co-Author*)
Charlotte Charbel, MD (*Abstract Co-Author*)
Marius E. Mayerhoefer, MD, PhD (*Abstract Co-Author*)
Kent P. Friedman, MD (*Abstract Co-Author*)
Angela Tong, MD (*Abstract Co-Author*)
Samir S. Taneja, MD (*Abstract Co-Author*)
Michael J. Zelefsky, MD (*Abstract Co-Author*)
Hebert Alberto Vargas, MD (*Abstract Co-Author*)

PURPOSE

To explore pragmatic approaches integrating MRI and PSMA-PET/CT for evaluating extraprostatic extension (EPE) of prostate cancer (PCa).

METHODS AND MATERIALS

Consecutive patients with newly-diagnosed PCa that underwent multiparametric MRI and PSMA-PET/CT, followed by prostatectomy in 2021-2024 were included. Imaging parameters assessed on both modalities were: size, length of capsular contact (LCC), Likert scales (MRI EPE grade, PSMA Likert scale), PI-RADS/PRIMARY scores, and SUV max . Three pragmatic integrated approaches were tested: (1) Integration of Likert scales (positive if either or both MRI and PSMA-PET/CT were positive); (2) P score (framework combining PI-RADS+PRIMARY); and (3) combining MRI morphological information (LCC) with PSMA-PET/CT functional information (upgrading suspicion of lesions with LCC below cutoff if SUV max >12). Diagnostic performance was tested with receiver ROC curves and compared using DeLong and McNemar tests.

RESULTS

67 men (median age, 66 years) with EPE in 76.1% (51/67) were included. Area under ROC curves (AUC) were 0.61-0.82; MRI-based yielded the highest AUC 0.82 (0.71-0.92) with cutoff of =1.7 cm. Integrated Likert scale (MRI EPE grade/PSMA Likert scale) showed sensitivity of 80.4% (41/51) and specificity of 31.3% (5/16). P score (PI-RADS/PRIMARY) demonstrated sensitivity of 31.3% (16/51) and specificity of 87.5% (14/16). Combining morphological MRI information with functional PSMA-PET/CT yielded sensitivity and specificity of 80.4% (41/51) and 81.2% (13/16), respectively, which demonstrated significantly higher sensitivity but non-significantly different specificity compared with MRI-based LCC alone (66.7% [34/51, $p=0.02$] and 87.5% [14/16, $p>0.99$]). This approach upgraded suspicion in 8 patients with LCC<1.7 cm due to SUV max >12 among which 87.5% (7/8) were corrected upgraded and had pathological EPE.

CONCLUSION

Several pragmatic approaches were explored for integrating MRI and PSMA-PET/CT to assess EPE in PCa. Combining morphological information from MRI and PSMA expression on PET/CT demonstrated good diagnostic performance and may be a simple pragmatic integrated method that can be used.

CLINICAL RELEVANCE/APPLICATION

Accurate assessment of EPE at the time of PCa diagnosis is important for patient management. While prostate MRI is currently the recommended imaging modality for locoregional staging of PCa, there is also growing interest in using PSMA-PET/CT for primary tumor evaluation. However, it has not been well established how to

integrate information from both modalities. The results of this study show that combining morphological information from MRI and PSMA expression on PET/CT can be a simple and pragmatic solution for performing integrated EPE assessment.

R5A-SPHN-1 DEEP LEARNING AND RADIOMICS-BASED ANALYSIS OF THE POSITIONAL RELATIONSHIP BETWEEN THE FIRST MOLAR AND THE MAXILLARY SINUS FLOOR

Aritrick Chatterjee, PhD (*Presenter*)
Bowen Liu (*Abstract Co-Author*)
Dianning He (*Abstract Co-Author*)
Nan Lei (*Abstract Co-Author*)
Guantian Huang (*Abstract Co-Author*)
Shouliang Qi (*Abstract Co-Author*)
Wei Qian (*Abstract Co-Author*)
Ting Liu (*Abstract Co-Author*)
Xin Shi (*Abstract Co-Author*)

PURPOSE

The spatial relationship between the maxillary first molar and the maxillary sinus floor is crucial for clinical diagnosis and sinus floor elevation procedures. However, current assessment methods largely rely on clinicians' subjective judgment. Therefore, this study aims to objectively classify and evaluate this anatomical relationship using deep learning and radiomics approaches based on CBCT and panoramic radiographic images.

METHODS AND MATERIALS

A total of 132 CBCT scans and 152 panoramic radiographs were collected from patients at the Stomatological Hospital of China Medical University. For CBCT data, the key lesion slice of each patient was selected, and the regions containing the maxillary sinus floor and the roots of the first molar were cropped separately for the left and right sides. For panoramic radiographs, the regions of interest (ROIs) containing the first molar roots and the maxillary sinus floor were also cropped bilaterally. Two analytical approaches were applied:The first method is that deep learning uses the ResNet18_CBAM model for classification. This model is based on the ResNet18 backbone network, integrates the Convolutional Block Attention Module (CBAM) and Dropout regularization, and finally outputs the classification results through the sigmoid function. The second method uses PyRadiomics to extract radiomics features, and then combines Support Vector Machine (SVM) and cross-validation for classification.

RESULTS

In CBCT image classification using the deep learning approach, the highest accuracy on the left validation set was 77%. For the right side, the highest accuracy on the right validation set was 86%.Using the machine learning approach, the average ACC and AUC were 74.24% and 0.73 for the left side, and 73.44% and 0.68 for the right side, respectively. For panoramic radiographs, in the deep learning classification, the highest validation accuracy was 80% on the left side and 74% on the right side. Using the machine learning approach, the average ACC and AUC were 72.43% and 0.68 for the left side, and 63.81% and 0.62 for the right side.

CONCLUSION

This study proposes a classification framework based on deep learning and radiomics to effectively identify the positional relationship between the maxillary first molar and the sinus floor. This framework is applicable to both volumetric imaging (CBCT) and projection imaging (panoramic radiographs), offering an objective diagnostic tool for clinical dentistry.

CLINICAL RELEVANCE/APPLICATION

T his study supports dental professionals in preoperative risk assessment and treatment planning, reducing surgical complications and improving patient outcomes.

R5A-SPHN-2 DIFIUSION-WEIGHTED IMAGING COMBINED WITH AMIDE PROTON TRANSFER WEIGHTED IMAGING WAS USED TO DIFFERENTIATE BENIGN AND MALIGNANT PAROTID GLAND TUMORSDIFIUSION-WEIGHTED IMAGING COMBINED WITH AMIDE PROTON TRANSFER WEIGHTED IMAGING WAS USED TO DIFFERENTIATE PLEOMORPHIC ADENOMA OF THE PAROTID GLAND FROM WARTHIN TUMOR

Feng Yu (*Presenter*)
Lijun Wang (*Abstract Co-Author*)

PURPOSE

To investigate the value of diffusion-weighted imaging (DWI) combined with amide proton transfer weighted imaging (APTw) sequences to identify pleomorphic adenoma of the parotid gland and Warthin tumor.

METHODS AND MATERIALS

We retrospectively analyzed the data of 38 patients with pleomorphic adenoma of the parotid gland and 24 patients with Warthin's tumor who underwent 3.0 TMRI and were pathologically confirmed at our hospital. The scanning sequences included TIWI, T2WI, DWI and APT sequences. Two observers measured the ADC values and APT values of the lesions in the two groups. Differences in ADC and APT values between the two groups of cases were analyzed using the independent samples t-test or Mann-Whitney U-test.Logistic regression was used to analyze parameters with statistically significant differences and their diagnostic models in conjunction with baseline information. Receiver operatingcharacteristic curves were used to assess the diagnostic efficacy of the differentiated parameters and the combined model. The DeLong test was used to compare the differences in the area under the ROC curves. Spearman's correlation coefficient was used to analyze the correlation between ADC values and T2 values.

RESULTS

The agreement between the measurements of the two observers was good (ICC>0.75). ADC values were higher in the pleomorphic adenoma group than in the Warthin tumor group, and APT values were lower than in the Warthin tumor group, and the differences were statistically significant (P<0.01).The ADC values, APT values, and

the AUC values of the two combined to differentiate pleomorphic adenomas from Warthin tumors were 0.878, 0.679, and 0.882, respectively.DeLong's test showed that the ADC values and the AUC for the combined differential diagnosis of pleomorphic adenoma of the parotid gland and Warthin tumor were greater than the APT values (Z=2.153, P=0.031; Z=2.315, ,P=0.021) ,and the difference between the ADC values and the AUC for the combination of the two was not statistically significant (Z=0.313, P=0.754).There was no correlation between the ADC values and the APT values (r=- 0.133, P=0.303).

CONCLUSION

DWI and APT sequences have good value in differentiating pleomorphic adenoma of the parotid gland from Warthin tumor, and the diagnostic efficacy of the two is improved when they are combined, which can provide good guidance for the non-invasive clinical diagnosis of pleomorphic adenoma and Warthin tumor.

CLINICAL RELEVANCE/APPLICATION

DWI and APT sequences have good value in differentiating pleomorphic adenoma of the parotid gland from Warthin tumor, and the diagnostic efficacy of the two is improved when they are combined, which can provide good guidance for the non-invasive clinical diagnosis of pleomorphic adenoma and Warthin tumor.

R5A-SPHN-7 EVALUATION OF BENIGN AND MALIGNANT CERVICAL LYMPHADENOPATHY: A COMPARATIVE STUDY OF SHEAR WAVE ELASTOGRAPHY AND GRAYSCALE ULTRASOUND

Gaurav Gaurav, MD, MBBS (*Presenter*)

PURPOSE

To evaluate role of shear wave elastography (SWE) using a novel methodology for differentiation of benign and malignant cervical lymph nodes.

METHODS AND MATERIALS

SWE was performed on 38 patients who presented with cervical lymphadenopathy. Color-coded elasticity maps were obtained, from which the stiffest region of interest (ROI) with a diameter of 2mm was chosen. Maximum and mean Young’s modulus values (Kpa) were calculated in selected 2-mm ROI. Finally, the results were correlated with the fine needle aspiration cytology findings in all patients to assess the diagnostic accuracy, sensitivity, and specificity at a defined cutoff value for distinguishing between benign and malignant lymphadenopathies.

RESULTS

There were 20 malignant cervical lymph nodes and 18 benign cervical lymphnodes. Malignant nodes showed significantly higher mean Young’s modulus value (154.2+-46.19 kPa) compared with benign nodes (70.39+-30.76 kPa), with a p-value of less than 0.0001. Our findings indicate that the mean Young modulus value within a standardized 2-mm ROI outperformed grayscale ultrasound in terms of diagnostic accuracy (92.1 vs. 78.9%), sensitivity (100 vs. 80%), and specificity (83.3 vs. 77.7%), with the established cutoff values for high diagnostic accuracy indicating malignancy as greater than 92 for mean Young’s modulus with an area under the curve of 0.964.

CONCLUSION

SWE using a standardized 2-mm ROI provides improved sensitivity anddiagnostic accuracy for differentiation of benign and malignant lymph node lesions.

CLINICAL RELEVANCE/APPLICATION

SWE can aid in the evaluation of lymph nodes and when integrated with clinical and imaging data, has the potential to reduce reliance on invasive procedures in selected cases.

R5A-SPIN-1 AN EFFICIENT AND INTERPRETABLE BERT-BASED EVALUATION METRIC FOR FINE-GRAINED ASSESSMENT OF GENERATED RADIOLOGY REPORTS

Gihun Cho, BS (*Presenter*)
Seunghyun Jang, MEng (*Abstract Co-Author*)
Hanbin Ko (*Abstract Co-Author*)
Inhyeok Baek (*Abstract Co-Author*)
Chang Min Park, MD, PhD (*Abstract Co-Author*)

PURPOSE

Current evaluation metrics for radiology report generation (RRG) often lack interpretability or rely on computationally intensive large language models (LLMs). We introduce a novel BERT-based multi-target regression model for efficient quantification of error categories in generated radiology reports, aiming for high correlation with expert radiologist assessments.

METHODS AND MATERIALS

We developed a multi-target regression model using a pre-trained BERT model (PubMedBERT). The model features six regression heads, each predicting the count of each error category: 1. False prediction, 2. Omission of finding, 3. Incorrect location, 4. Incorrect severity of finding, 5. Erroneous comparison mentioned, and 6. Omission of comparison. The training dataset comprised 32,000 pairs of MIMIC-CXR reports and candidate reports generated by an RRG model (CheXagent). Error counts for these pairs, serving as labels for the six categories, were annotated by an LLM (gemini-2.5-pro-preview-03-25) using a structured prompting strategy. Evaluation was performed on the ReXVal dataset, comparing predicted total error counts against the average total error counts from six board-certified radiologists using Kendall's Tau coefficient.

RESULTS

Our model achieved a Kendall's Tau coefficient of 0.767 (95% CI: [0.724, 0.803]) when correlating its predicted total error counts with expert radiologist assessments on the ReXVal dataset. For reference, an LLM-based approach using gemini-2.5-pro-preview-03-25 for direct error counting (GREEN error count) on the same dataset yielded a Kendall's Tau of 0.756 (95% CI: [0.703, 0.803]). Our model demonstrated a significantly faster inference speed of approximately 20 ms per sample on a single GPU. Furthermore, the model provides a granular breakdown of error counts across the six predefined categories.

CONCLUSION

A BERT-based multi-target regression model can accurately and efficiently quantify fine-grained errors in generated radiology reports, showing strong correlation with expert radiologists. This approach offers substantial advantages in inference speed and computational efficiency compared to direct LLM-based evaluations, while providing interpretable, category-specific error counts.

CLINICAL RELEVANCE/APPLICATION

Our method provides a practical, efficient tool for the crucial task of evaluating AI-generated radiology reports. It enables rapid quality assessment and specific error identification, accelerating RRG system refinement for research and supporting quality assurance for clinical translation, ultimately aiming to improve diagnostic accuracy and workflow.

R5A-SPIN-2 MRI DEEP LEARNING RECONSTRUCTION IMPROVES RADIOMIC FEATURE STABILITY

Achraf Kanan, MD (*Presenter*)
Gabriel Ballout, MD (*Abstract Co-Author*)
Bruno Pereira (*Abstract Co-Author*)
Lucie Cassagnes, PhD (*Abstract Co-Author*)
Pascal Chabrot, MD, PhD (*Abstract Co-Author*)
Benoit Magnin, MD,MSc (*Abstract Co-Author*)

PURPOSE

Radiomic analysis is impacted by the parameters used in image acquisition and reconstruction. Deep Learning (DL) reconstruction methods are increasingly used in MRI to effectively reduce noise, leading to enhanced image quality. However, their impact on radiomic features, particularly regarding stability, has not yet been explored. To compare the reproducibility and repeatability of MRI radiomic features between conventional and DL reconstructions.

METHODS AND MATERIALS

An MRI protocol comprising seven sequences was conducted on a 1.5T GE Healthcare™ MRI scanner using 12 pieces of fruits as phantom models. Each sequence was acquired with four distinct protocols, repeated four times. Images were reconstructed using both conventional (non-DL) and DL techniques (AIR Recon DL, GE Healthcare™). After semi-automated segmentation, 107 radiomic features were extracted. Features were defined as reproducible if the intraclass correlation coefficient (ICC(3,1)) exceeded 0.9 and repeatable if the overall concordance correlation coefficient (OCCC) was above 0.9. Additional statistical criteria and a 0.75 threshold were also tested.

RESULTS

DL reconstruction yielded 53.27% reproducible features, compared to 43.52% with conventional reconstruction, i.e. a 9.75% improvement. Among the feature types, DL improved reproducibility by 7.94% for first-order features and by 12.00% for higher-order features. The difference in repeatability between reconstructions was 0.4% in favor of DL reconstruction. The use of other statistical criteria and threshold showed the same trend.

CONCLUSION

DL reconstruction improves the reproducibility of radiomic features relative to conventional methods, supporting the use of DL-based reconstruction in MRI radiomic studies.

CLINICAL RELEVANCE/APPLICATION

DL reconstruction improves the reproducibility of radiomic features relative to conventional methods, supporting the use of DL-based reconstruction in MRI radiomic studies.

R5A-SPIN-3 IMPROVING CT DETECTION OF SUBCENTIMETER LIVER METASTASES: AI-AUGMENTED CONTRAST BOOSTING ENHANCES SENSITIVITY AND CONSPICUITY IN CHOROIDAL MELANOMA

Fiona Mankertz, MD (*Presenter*)
Josephine Berger (*Abstract Co-Author*)
Nour Maalouf, MD (*Abstract Co-Author*)
Andreas Brendlin, MD, PhD (*Abstract Co-Author*)
Saif Afat, MD (*Abstract Co-Author*)

PURPOSE

To evaluate whether AI-based contrast boosting of single-phase CT improves the detection and visual conspicuity of subcentimetre liver metastases from choroidal melanoma, using liver MRI as the reference standard.

METHODS AND MATERIALS

This retrospective single-centre study included 68 patients (mean age, 69.6 years ± 11.2 [SD]; 46% men) with histologically confirmed choroidal melanoma and suspicion of liver metastases, included between January 2019 and July 2022. All patients underwent portal venous phase contrast-enhanced whole-body CT, as well as dedicated liver MRI. CT data was post-processed using a commercial AI-based contrast boosting algorithm (ClariACE, ClariPi, Seoul, South Korea). Liver metastases were identified on MRI and served as the reference standard. Lesions were stratified by size (<5 mm, 5-10 mm, >10 mm). Two radiologists independently evaluated each MRI-confirmed lesion for visibility on both standard and AI-boosted CT, recording binary detection (present/absent) and conspicuity on a five-point Likert scale. McNemar's test was used to compare paired detection rates between standard and boosted CT. Conspicuity scores were compared using the Wilcoxon signed-rank test. Inter-reader agreement was assessed using Cohen's kappa for detection and intraclass correlation coefficient (ICC) for conspicuity.

RESULTS

A total of 104 liver metastases were identified on MRI, including 58 <5 mm, 28 between 5-10 mm, and 18 >10 mm. Among these MRI-confirmed lesions, AI-boosted CT significantly improved detection sensitivity for sub-5 mm lesions, from 57% to 81% ($p < 0.001$, McNemar's test). A modest but non-significant increase was observed for 5-10 mm lesions (82% to 89%, $p = 0.09$), while detection of lesions >10 mm remained unchanged (100%). Median conspicuity scores for sub-5 mm lesions increased from 3.0 to 4.3 ($p < 0.001$, Wilcoxon test). Inter-reader agreement was excellent for both detection (? = 0.84) and conspicuity (ICC = 0.87). An increase in conspicuity was associated with improved detection for small lesions.

CONCLUSION

Contrast enhancement using an AI-based post-processing tool improved both sensitivity and conspicuity for detecting subcentimetre liver metastases from choroidal melanoma on CT. The largest benefit was observed in lesions smaller than 5 mm. While MRI remains the gold standard for liver lesions, added visibility without additional patient risk may support earlier recognition of metastatic disease on routine CT.

CLINICAL RELEVANCE/APPLICATION

Improved detection of small hepatic metastases by means of AI-augmented contrast post-processing may aid earlier staging and treatment planning in patients with choroidal melanoma and allow for earlier detection of incidental metastasis.

R5A-SPIN-4 CT-BASED RADIOMICS AND CLINICAL-SEMANTIC RISK PREDICTORS FOR SPREAD THOUGH AIR SPACES IN SOLID-PREDOMINANT STAGE I LUNG ADENOCARCINOMA: A MULTICENTER STUDY

Xiao-Ling Ma (*Presenter*)

PURPOSE

Spread though air spaces (STAS) is an independent prognosticator for lung adenocarcinoma, signifying a higher risk of relapse and a worse outcome. We aim to investigate the value of CT-based radiomics and clinical-semantic risk predictors for identifying STAS in solid-predominant stage I lung adenocarcinoma.

METHODS AND MATERIALS

This retrospective study enrolled 409 patients pathologically-confirmed stage I lung adenocarcinoma with consolidation-to-tumor ratio greater than 0.5 from three independent institutions. The CT-based radiomics signature predictive of STAS was developed to extract radiomics features from solid components of tumors in training cohort (n=237), and verified in independent validation cohort (n=102) and external test cohort (n=70). Patients' clinical characteristics and CT semantic features were documented. Clinical-semantic (CS) risk predictors were incorporated to construct a CS model and a clinical-semantic-radiomics (CSR) model along with radiomics signature using univariate and multivariate logistic regression analysis. Model performance was evaluated by AUC, sensitivity, specificity, calibration curve, and decision curve analysis. The comparisons of AUC were conducted by the DeLong test.

RESULTS

The radiomics signature achieved the AUC of 0.817 (95% CI: 0.762, 0.864) in training cohort, 0.803 (95% CI: 0.713, 0.875) in independent validation cohort and 0.716 (95% CI: 0.596, 0.818) in external test cohort. The AUC for CS model was 0.786 (95% CI: 0.728, 0.836), 0.788 (95% CI: 0.696, 0.863) and 0.727 (95% CI: 0.608, 0.827) across the respective cohorts, inferior to those of radiomics signature. Encouragingly, the combined CSR model achieved the highest AUC of 0.837 (95% CI: 0.783, 0.881), 0.829 (95% CI: 0.741, 0.896) and 0.748 (95% CI: 0.630, 0.844) across all three cohorts, indicating the incorporation of radiomics signature provided an incremental benefit over CS model. The calibration curves and decision curve analysis further verified the clinical utility of CSR model.

CONCLUSION

The CSR model based on clinical-semantic risk predictors and radiomics signature offers a promising predictive performance in predicting STAS, offering a valuable complement to individual CS model.

CLINICAL RELEVANCE/APPLICATION

The proposed model combining clinical-semantic risk predictors and radiomics signature holds significant potential as a noninvasive tool for preoperative assessment of STAS, which might serve as a helpful tool in directing surgical strategy and informing therapeutic decision-making.

R5A-SPIN-5 TRENDS IN THE UTILIZATION OF PERCUTANEOUS VERTEBROPLASTY AND KYPHOPLASTY AMONG MEDICARE PART B BENEFICIARIES FROM 2001-2022

Arsalan Nadeem, MBBS (*Presenter*)
Talha Iqbal, MBBS (*Abstract Co-Author*)

PURPOSE

To find and explain the trends in the utilization of percutaneous vertebroplasty and percutaneous kyphoplasty among Medicare Part B beneficiaries.

METHODS AND MATERIALS

Publicly available Centers for Medicare & Medicaid (CMS) Part B national summary data files from 2001 to 2022 were used for this study. For the 2001 to 2014 summary files, Current Procedural Terminology (CPT) codes 22520 and 22521 were used to identify vertebroplasty data. Codes 22510 and 22511 were used for the summary files from 2015 to 2022. CPT codes 22523 and 22524 were used to identify kyphoplasty data in the summary files from 2006 to 2014. Codes 22513 and 22514 were used for the summary files from 2015 to 2022. The annual count of the total Medicare Part B beneficiaries for these codes were extracted from the summary files. The total counts were converted to count per 10,000,000 of the total Medicare Part B beneficiaries for the respective year. This was done in order to make the counts comparable across different years. The data for the annual number of total Medicare Part B beneficiaries used for this conversion was obtained from the Harvey L. Neiman Health Policy Institute website. Joinpoint regression was used to identify the inflection points in the utilization of the two procedures. Significance level for the Annual Percent Changes (APCs) to be significantly different from 0 was set at 0.05.

RESULTS

The highest annual number of vertebroplasty beneficiaries per 10,000,000 were in 2008 (9512.45) and the lowest in 2022 (1664.80). For kyphoplasty, this value was the highest in 2009 (15897.62) and the lowest in 2006 (13016.90). Joinpoint regression identified three jointpoints at 2003, 2009 and 2012 for the vertebroplasty beneficiaries per 10,000,000 from 2001 to 2022. APCs obtained for 2001-2003, 2003-2009, 2009-2012 and 2012-2022 were 31.17 (P = 0.01), 3.80 (P = 0.08), -21.46 (P = 0.01) and -10.27 (P > 0.001) respectively. No joinpoint was identified for the kyphoplasty beneficiaries per 10,000,000 from 2006 to 2022 (APC = -0.18, P = 0.62).

CONCLUSION

Vertebroplasty beneficiaries peaked in 2008, with a notable inflection point in 2009 and significant decline afterwards.This was probably due to the publication of randomized controlled trials in 2009 that questioned vertebroplasty's efficacy and the subsequent 2010 American Academy of Orthopedic Surgeons (AAOS) guidelines advising against its routine use. In contrast, kyphoplasty utilization remained relatively stable, with only a modest decline during the COVID-19 pandemic years.

CLINICAL RELEVANCE/APPLICATION

The sustained use of kyphoplasty, despite the declining use of vertebroplasty, emphasizes its superiority in pain relief, better safety profile and vertebral height restoration.

R5A-SPIN-6 TRUST: A NOVEL FIVE-POINT SCALE FOR ASSESSMENT OF RELIABILITY AND REFERENCING INTEGRITY IN AI AGENT GENERATED RADIOLOGY REPORTS

Suvrankar Datta, MD, MBBS (*Presenter*)
Antarjot Kaur Rekhi (*Abstract Co-Author*)
Yasin Patangiyawala, MBBS (*Abstract Co-Author*)
FURQUAN AHMAD (*Abstract Co-Author*)
Sukriti Chaudhri, MD (*Abstract Co-Author*)
Satyam . (*Abstract Co-Author*)
Kartik Vuthoo (*Abstract Co-Author*)
Devansh Lalwani (*Abstract Co-Author*)
Bhavya Ratan Maroo, MBBS (*Abstract Co-Author*)
Sharwon Pius (*Abstract Co-Author*)
Abhiraj Baratam (*Abstract Co-Author*)

PURPOSE

Reference hallucination represents a critical patient safety concern in AI-generated radiology reports that existing quality metrics fail to address. While general draft quality assessments exist, no standardized metric specifically evaluates citation reliability. We introduce TRUST, a five-point Likert-type scale (Terrible, Risky, Usable, Supported, and Traceable), designed to objectively evaluate the reference integrity of grounded AI-generated drafts. Additionally, we analyze the reliability of distinct LLM augmented agentic pipelines to determine the robustness and reproducibility of agentic radiology workflows.

METHODS AND MATERIALS

Eighty preliminary drafts were generated using the novel RadNexus agentic pipeline (which generates references) utilising four popular and lightweight LLMs (GPT-4o, GPT-4o-mini, GPT-4.1-mini and GPT-4.1-nano), each applied to 20 unique multi-organ prompts. Four blinded radiologists independently rated each draft using the TRUST scale (1 to 5), focusing specifically on reference accuracy, completeness, and traceability. Score distributions across models were compared using the Friedman test. Inter-reader agreement was quantified for the two reader-pairs reviewing identical prompts (quadratic-weighted ?). Criterion validity was assessed through manual audit of citation errors in reports across TRUST score levels by a board certified radiologist.

RESULTS

Median TRUST scores varied descriptively (gpt-4.1-mini and gpt-4o-mini = 5; gpt-4.1-nano = 5; gpt-4o = 4), with differences approaching statistical significance (Friedman $?^2$ = 7.47, df = 3, p = 0.058). Inter-reader agreement showed improvement over general quality assessments: Pair A (Doctors 1 & 3): ? = -0.26 (poor); Pair B (Doctors 2 & 4): ? = 0.24 (fair). Manual audit confirmed strong correlation between TRUST ratings and actual citation error rates (? = -0.67, p < 0.001), validating the scale's specific focus on reference integrity.

CONCLUSION

TRUST provides a specialized, reproducible framework for evaluating citation integrity in AI-generated reports, a safety dimension not captured by existing NLP metrics. The scale successfully differentiates between reports with reliable references and those containing hallucinated citations. Reader calibration remains essential to strengthen inter-observer consistency.

CLINICAL RELEVANCE/APPLICATION

Reference hallucination represents a significant safety risk in AI-augmented reporting workflows, as we move towards semi-autonomous reporting. TRUST enables radiologists to efficiently evaluate citation reliability of grounded agentic workflows, supporting safer implementation of reporting systems while protecting against false or incomplete reference errors.

R5A-SPIN-7 VALIDATION OF RADAR AND TRUST METRICS: ANALYZING INTER-READER AGREEMENT AND DRAFT VARIABILITY IN AGENTIC RADIOLOGY REPORTING

Bhavya Ratan Maroo, MBBS (*Presenter*)
Devansh Lalwani (*Abstract Co-Author*)
Abhiraj Baratam (*Abstract Co-Author*)
Antarjot Kaur Rekhi (*Abstract Co-Author*)
Yasin Patangiyawala, MBBS (*Abstract Co-Author*)
Kartik Vuthoo (*Abstract Co-Author*)
FURQUAN AHMAD (*Abstract Co-Author*)
Satyam . (*Abstract Co-Author*)
Sukriti Chaudhri, MD (*Abstract Co-Author*)

Suvrankar Datta, MD, MBBS (*Abstract Co-Author*)
Sharwon Pius (*Abstract Co-Author*)

PURPOSE

Reliable interpretation of drafts from agentic radiology systems is crucial for workflow integration. Current evaluation frameworks lack systematic assessment of inter-reader agreement on standardized quality and reliability metrics, and model-specific output variability. This study introduces two new metrics: RADAR, which rates the quality and readiness of drafts on a 5-point scale, and TRUST, which evaluates draft reliability and reference integrity on a similar scale. It also analyzes lexical and factual variability across agents to assess the robustness and reproducibility of agentic radiology workflows.

METHODS AND MATERIALS

Eighty preliminary radiology drafts were generated using the RadNexus agentic pipeline across four lightweight LLMs (GPT-4o, GPT-4o-mini, GPT-4.1-mini and GPT-4.1-nano). Two independent reader pairs (1 & 3; 2 & 4) scored drafts using 5-point RADAR and TRUST scales. Inter-reader agreement was assessed using Cohen's kappa. To evaluate model reproducibility, each input was processed twice, and absolute differences in BLEU, ROUGE-L, and RaTEScore were computed. Dispersion was compared across models using Friedman and Wilcoxon tests.

RESULTS

Inter-reader agreement was poor for RADAR (? = -0.23, -0.04) and variable for TRUST (? = -0.18, 0.07). GPT-4.1-nano showed the highest output consistency (BLEU ? = 0.06, ROUGE-L ? ˜ 0.02, RATE ? = 0.14), whereas the other models displayed markedly larger spreads. No significant differences were detected in RaTEScore dispersion (Levene p = 0.43); by contrast, dispersion in BLEU and ROUGE-L was significant before multiple-comparison correction (both $p < 0.001$) and would be attenuated, though still the lowest for gpt-4.1-nano, after a strict adjustment.

CONCLUSION

RADAR and TRUST enable structured evaluation of agentic outputs, but inter-reader variability limits standalone reliability. While intra-model variability was comparable across architectures, GPT-4.1-nano demonstrated superior reproducibility across repeated runs. These results highlight the need to assess both report quality and reproducibility using both radiologist evals and automated metrics when benchmarking agentic systems.

CLINICAL RELEVANCE/APPLICATION

We present a dual-metric benchmarking framework combining human and automated assessments to evaluate agentic report quality and stability, critical for safe and scalable clinical deployment.

R5A-SPIN-8 THE DIAGNOSTIC ACCURACY OF ARTIFICIAL INTELLIGENCE MODELS IN DETECTING LYMPH NODE METASTASES IN LUNG CANCER USING ENDOBRONCHIAL ULTRASOUND (EBUS) IMAGES: A BIVARIATE DIAGNOSTIC META-ANALYSIS

Bruno Ishizuka (*Presenter*)
Victor Arthur Ohannesian (*Abstract Co-Author*)
Luciano Falcao (*Abstract Co-Author*)
Isabelle Menezes (*Abstract Co-Author*)
Ricardo Suruagy-Motta (*Abstract Co-Author*)
Miriana E. Mariussi, MD (*Abstract Co-Author*)
Joao Marcelo Baptista (*Abstract Co-Author*)
Atul K. Taneja, MD,PhD (*Abstract Co-Author*)
Mariana Leticia De Bastos Maximiano (*Abstract Co-Author*)
Miguel J. Francisco Neto, MD, PhD (*Abstract Co-Author*)
Rodrigo G. Garcia, MD, PhD (*Abstract Co-Author*)
Marcia Jacomelli (*Abstract Co-Author*)
Marcelo R. Silva, MD (*Abstract Co-Author*)
Marcos R. Queiroz, MD, MBA (*Abstract Co-Author*)

PURPOSE

To systematically evaluate the diagnostic accuracy of artificial intelligence (AI) models in detecting lymph node metastases in lung cancer using endobronchial ultrasound (EBUS) images. The objective was to estimate pooled sensitivity, specificity, likelihood ratios, diagnostic odds ratio (DOR), and area under the curve (AUC) across distinct AI architectures.

METHODS AND MATERIALS

A systematic review was conducted following PRISMA-DTA guidelines and registered in PROSPERO (CRD42025635581). Searches were performed in PubMed, Embase, Scopus, and Web of Science. Eligible studies applied AI models to classify metastatic lymph nodes using cytologic or histologic confirmation as the reference standard. Extracted outcomes included sensitivity, specificity, TP, TN, FP, FN, AUC, DOR, and likelihood ratios (LR+/LR-). AI models were categorized into four classes: CNN-A (Convolutional Neural Networks), BASM (Biomedical Application-Specific Models), AFP (Automated Frameworks and Platforms), and G-DDN (Generic Deep Neural Networks). A bivariate random-effects meta-analysis was conducted to pool estimates. Subgroup and sensitivity analyses were performed to assess heterogeneity.

RESULTS

Twenty-two studies were included. Pooled sensitivity was 87% (95% CI: 68-95%), specificity 90% (95% CI: 83-94%), and AUC 0.94 (95% CI: 0.92-0.96). The pooled DOR was 56 (95% CI: 17-182). CNN-A models showed the highest performance (AUC 0.97, DOR 182), while AFP models had the lowest (sensitivity 5.8%, DOR 5.1). Pooled likelihood ratios were LR+ 8.39 (95% CI: 4.93-14.28) and LR- 0.15 (95% CI: 0.06-0.39). Assuming a pre-test probability of 25%, this corresponds to post-test probabilities of 74% for a positive result and 5% for a negative result. Subgroup analyses revealed performance variation across architectures and study conditions.

CONCLUSION

AI models, especially CNN-A architectures, exhibit high diagnostic accuracy for detecting lymph node metastases via EBUS. However, performance heterogeneity suggests that clinical application requires model-specific validation and context-aware integration.

CLINICAL RELEVANCE/APPLICATION

Given their high sensitivity (87%) and specificity (90%), AI models—especially CNNs—can assist in biopsy decisions for lymph nodes with indeterminate sonographic features, support lung cancer staging in nodes <1 cm, necrotic, or with inconclusive PET-CT, and serve as alternatives when ROSE is unavailable. CNNs reduce operator dependency and diagnostic variability, enabling standardized interpretation. Clinical implementation should occur in expert centers with validated models, structured data pipelines, and integration into imaging workflows.

R5A-SPIN-9 MEDICAL IMAGING 2.0 - A NEW LOOK AT PHYSICAL MEASUREMENTS OF IN VIVO BIOLOGICAL SYSTEMS FOR EARLY CANCER DETECTION

Jerome Z. Liang, PhD (*Presenter*)
Shaojie Chang, PhD (*Abstract Co-Author*)
Weiguo Cao (*Abstract Co-Author*)
Yongfeng Gao (*Abstract Co-Author*)
Marc Pomeroy (*Abstract Co-Author*)
Li Cheng Kuo, MS (*Abstract Co-Author*)

Lihong Li (*Abstract Co-Author*)
Perry J. Pickhardt, MD (*Abstract Co-Author*)

PURPOSE

Expert interpretation of medical images for diagnosis of lesions may not always reflect the underlying in vivo tissue pathology, particularly those categorized as indeterminate lesions (IDLs) by the experts, and thus cannot be considered a definitive truth for malignancy or benignity. This discrepancy poses a major barrier to effective low dose computed tomography (LdCT) screening for the malignant lesions or cancers at early stages of development, where unnecessary follow-ups can be costly and risky. This study aims to address this diagnostic bottleneck.

METHODS AND MATERIALS

We hypothesize that the limitation arises from the static nature of image representations, which fail to capture the dynamic biological behavior of living or in vivo tissues. Current imaging technologies lack the spatial, temporal, and spectral/energy resolutions to resolve this gap. To test this, we treat physical measurements of in vivo biological systems as dynamic tissue responses to X-ray flux across a broad energy spectrum. These interactions of in vivo tissues with X-ray energy produce intrinsic image contrast (relative to water) for each tissue type (e.g. muscle, fat, lung and bone) and energy level, encoding tissue biological information into the contrast variations across the lesion space. We reconstruct multispectral image contrasts across lesion space, assuming each tissue type has a reproducible response pattern across energies from 5 to 50 keV (in 5 keV intervals). For lesion diagnosis task, the goal is to find tissue pathological characteristics from the reconstructed multispectral image contrast variations. An example of pathological characteristic merits is tissue elasticity. A machine intelligence (MI) model is developed to extract elastic characteristic features (ECFs) from these multispectral contrast variations and integrate them using an adaptive classifier to predict lesion malignancy. Experiments were performed using LdCT screening scans, including two sets of pulmonary nodules and three sets of small, large and mass colorectal polyps. All the lesions were categorized as IDLs, thus tissue biopsy was performed. Their pathological reports were used as the ground truth for malignancy or benignity.

RESULTS

Experimental outcomes show an area under the receiver operating characteristic curve (AUC) of 0.89 for small polyps and 0.97-0.99 for the other four sets of lesions.

CONCLUSION

The presented MI model significantly outperforms current state-of-the-art references, which typically yield AUCs between 0.60 and 0.95 for the same tasks.

CLINICAL RELEVANCE/APPLICATION

MI architecture that models the underlying tissue dynamics and extract task-relevant tissue biological features can substantially enhance diagnostic accuracy in medical imaging.

R5A-SPIN-10 OPTIMAL SAMPLE SIZES FOR INTERCHANGEABILITY STUDIES IN DIAGNOSTIC IMAGING: A SIMULATION-BASED STUDY

Kyunghwa Han, PhD (*Presenter*)
Ahram Kim (*Abstract Co-Author*)
Inkyung Jung (*Abstract Co-Author*)
Jiwoo Park, MD, PhD (*Abstract Co-Author*)
Young Han Lee, MD (*Abstract Co-Author*)

PURPOSE

Testing the interchangeability of new diagnostic tests with existing ones—such as comparing radiologists to medical artificial intelligence or standard to new imaging techniques—has become increasingly important, particularly when a valid reference standard is unavailable or unnecessary. Interchangeability is established when the 95% confidence interval (CI) of the individual equivalence index (IEI)—the difference in agreement between the new and existing methods versus within the existing methods—falls within a pre-specified interchangeability equivalence criterion (IEC). The statistical significance of interchangeability depends on both the IEC and the sample size. This study aimed to determine the optimal sample size required to yield reliable results in interchangeability testing under varying conditions (e.g., agreement level, number of readers, IEC) using simulation-based approaches.

METHODS AND MATERIALS

Monte Carlo simulations were conducted to evaluate type I error and statistical power. Test results were generated from a multivariate normal distribution with pairwise correlations (both between and within diagnostic methods) set to 0.6, 0.8, or 0.9 to reflect varying agreement levels. The number of readers was set to 2, 4, or 10, and total patient counts were set to 100 or 200.

RESULTS

When the IEC was set to 0.01 or 0.025, the statistical power was effectively zero. As sample size increased—through more patients or more readers—the power to detect interchangeability improved. For 2 readers, a power of 80 percent or greater was achieved when the IEC was equal to or greater than 0.1, except when the correlation was 0.6. With 4 readers and 100 patients, 80 percent power was reached when the correlation was 0.8. With 4 readers and 200 patients, 80 percent or greater power was observed when the IEC was equal to or greater than 0.05. A motivating example from a prospective lumbar spine MRI study involving 4 radiologists and 70 patients illustrated how the 95 percent CI of the IEI is influenced by the level of agreement.

CONCLUSION

Interchangeability testing depends on the number of readers and patients, the level of agreement among raters or methods, and the chosen IEC. Careful pre-specification of the IEC and adequate sample size planning are essential to ensure valid hypothesis testing.

CLINICAL RELEVANCE/APPLICATION

This study provides practical guidance for determining the necessary sample sizes of both readers and patients when designing studies to assess the interchangeability of new versus existing diagnostic tests.

R5A-SPIN-11 EVALUATING THE RELATIONSHIP BETWEEN AI-ESTIMATED PULMONARY ARTERY OBSTRUCTION INDEX AND PULMONARY EMBOLISM DISTRIBUTION ON ROUTINE CHEST CT AND CT PULMONARY ANGIOGRAM

Javier Contreras Yametti, MD (*Presenter*)
Anushree M. Burade, MBBS (*Abstract Co-Author*)
Subba R. Digumarthy, MD (*Abstract Co-Author*)
Arun Innanje (*Abstract Co-Author*)
Terrence Chen (*Abstract Co-Author*)
Keith J. Dreyer, DO, PhD (*Abstract Co-Author*)
Bernardo C. Bizzo, MD, PhD (*Abstract Co-Author*)

PURPOSE

Although quantification of pulmonary embolism (PE) burden helps predict outcome and treatment options, it is time-consuming and cumbersome, and thus, rarely reported. We performed external validation of an AI model that detects, localizes, and segments PE to estimate pulmonary artery obstruction index (PAOI), a semiquantitative measure of PE burden based on the previously Qanadli scoring system.

METHODS AND MATERIALS

Our IRB-approved study included 754 adult patients (mean age: 61±17 years; 314 males, 440 females) who underwent chest CT pulmonary angiography (CTPA) or contrast-enhanced chest CT at one of the seven hospitals. We processed the deidentified 1-1.25mm images with the AI model (UII, United Imaging Intelligence) to obtain outputs on the presence/absence and the location of the PE and PAOI. Radiology reports and an additional review from a thoracic radiologist established the ground truth. All discrepant AI and ground truth cases were reviewed by a thoracic radiologist. In addition to Student t-test s to estimate differences between the AI-generated PAOI and PE presence, and ROC AUC for assessing PE detection statistics, we performed stratified analyses for assessing PAOI with central vs. peripheral PE, and with main/lobar/segmental/subsegmental PE.

RESULTS

The AUC ROC of the model for detecting PE was 0.89 (95% CI: 0.84 - 0.94). There were 706 PE-negative CT (93.6%) and 48 CT exams (6.4%) with PE. The AI algorithm provided PAOI values for each case. The PAOI was significantly higher in PE-positive CT (mean±SD: 23±18) compared to PE-negative CT (mean±SD: 1.2±4.8) ($p < 0.001$). There was a large difference between the mean PAOI scores for central (mean±SD: 24.3±17.2) and peripheral PE (mean±SD: 7.08±8.8). The mean PAOI scores for the main-vessel, segmental, and subsegmental PE were 35.23±18.39, 19.85±15.48, and 8.5±9.1, respectively.

CONCLUSION

AI-derived PAOI can provide an estimate of PE burden in patients with central vs. peripheral PE, and main vs. segmental/subsegmental PE locations.

CLINICAL RELEVANCE/APPLICATION

Automating pulmonary embolism burden estimation with AI can augment PE reporting and decrease radiologists' effort in describing all PE locations.

R5A-SPIN-12 "OUT-OF-THE-BOX BUT NOT OUT-OF-THE-WOODS": EVALUATING PERFORMANCE OF SMALL MULTIMODAL GENERATIVE AI FOR CHEST X-RAY INTERPRETATION

Sreyes Venkatesh (*Presenter*)
Syed Muhammad Awais Bukhari, MD (*Abstract Co-Author*)
Charit R. Tippareddy, MD (*Abstract Co-Author*)
Komal M. Awan, MD (*Abstract Co-Author*)
Amit Gupta, MD, MBBS (*Abstract Co-Author*)

PURPOSE

Small multimodal large language models (LLMs), such as LLaVA-Rad, hold promise for automated radiological report generation, offering resource efficiency for local clinical deployment. Recent works demonstrate robust performance on controlled biomedical benchmarks, positioning it as a candidate for chest X-ray (CXR) interpretation in resource-constrained settings. However, vendor-reported metrics from controlled environments may not translate to real-world clinical scenarios. This study evaluates the out-of-the-box performance of LLaVA-Rad on diverse CXR datasets to assess its generalizability and clinical readiness.

METHODS AND MATERIALS

We evaluated LLaVA-Rad on two open-access CXR datasets: the Indiana University dataset (IU: 6,469 CXRs; 3,200 patients) and the ReXGradient dataset (ReX: 273,004 CXRs; 160,000 studies; 109,487 patients). LLaVA-Rad uses a pre-trained vision encoder and a multilayer perceptron adapter to align image and text modalities. Generated reports are compared against radiologist reports using automated metrics: ROUGE-L (RL: lexical similarity); RadGraph-F1 (RF1: factual accuracy); CheXprompt (cXp: error rate via GPT comparison). Results for ReX are pending and will be updated upon completion.

RESULTS

Result for the IU dataset: RL score of 0.241 (vs. 0.306 in controlled settings); RF1 score of 0.248 (vs. 0.294); cXp error-free rate of 28.2% (vs. 26.0%), the higher error-free rate due to alignment with templated educational reports. Preliminary results for the ReX dataset: RL score of 0.231; RF1 score of 0.244; cXp error-free rate of 19.2%. Performance declined on the ReX dataset, which represents complex real-world clinical environments.

CONCLUSION

LLaVA-Rad's performance degrades as dataset complexity and variability increase. The discrepancy between GPT-based scoring and factual accuracy suggests that CheXprompt may overestimate quality in templated settings. The parallel decline in ROUGE-L and RadGraph-F1 suggests a link between lexical and factual robustness. These findings reinforce the need for domain-specific fine-tuning, careful selection of evaluation metrics, and broad dataset validation.

CLINICAL RELEVANCE/APPLICATION

This study highlights critical generalizability gaps in generative multimodal AI for radiology. Relying solely on published benchmarks or GPT-based metrics may obscure performance limitations. Clinical readiness requires testing across heterogeneous datasets and alignment with radiologist expectations. As generative AI enters deployment, out-of-the-box models must be thoroughly tested before integration into patient care workflows.

R5A-SPIR-1 HEMODYNAMICS BASED Q-DSA FOR NONINVASIVE EFFICACY ASSESSMENT IN PULMONARY VASCULAR INTERVENTIONS

Jiawei Long (*Presenter*)
Jielong Lin (*Abstract Co-Author*)
Cheng Hong (*Abstract Co-Author*)
Haowen Ye (*Abstract Co-Author*)
Xinye Xia (*Abstract Co-Author*)
Daibing Zhou (*Abstract Co-Author*)
Siyu He (*Abstract Co-Author*)
Yan XU (*Abstract Co-Author*)
Yuting Ling (*Abstract Co-Author*)
Xiaoyun Liang, PhD (*Abstract Co-Author*)

PURPOSE

In pulmonary vascular interventions, traditional pulmonary pressure assessment is invasive and increases procedural complexity and cost. Quantitative digital subtraction angiography (q-DSA), a hemodynamics-based extension of DSA, enables functional evaluation of pulmonary blood flow. This study aims to evaluate the diagnostic value of q-DSA parameters and their utility in assessing treatment efficacy.

METHODS AND MATERIALS

This retrospective study included patients who underwent balloon pulmonary angioplasty for chronic thromboembolic pulmonary hypertension or pulmonary artery stent implantation for fibrosing mediastinitis from July 2020 and April 2024. Sex, age, BMI, and mean and systolic pulmonary arterial pressures proximal and distal to the stenosis were collected. Pressure gradient (dPASP) was defined as proximal minus distal pulmonary arterial systolic pressures (PASP). Offline hemodynamic analysis used a research prototype software to extract time-density curves from pre- and post-treatment DSA images. Three regions of interest (ROI) were defined (Fig.1): stenosis (ROI1), proximal post-stenosis (ROI2), distal post-stenosis (ROI3). Parameters - time to peak (TTP), peak intensity (PEAK), area under the curve (AUC), mean transit time (MTT), first-pass intensity ratio (FIR), and full width at half maximum (FWHM) - were derived. Hemodynamic ratios (e.g., rTTP 21 = TTP ROI2 /TTP ROI1) and their correlations with dPASP changes were analyzed via Spearman.

RESULTS

Seventeen patients (mean age: 57.76 ± 12.76 years; 47.06% male; 88.2% with pulmonary hypertension), and 19 vessels were analyzed (Table 1). The dPASP decreased from 17.00 mmHg to 9.00 mmHg post-treatment ($p = 0.006$) (Table 2). Only the rTTP 21 changed significantly ($p = 0.015$) (Table 3); other ratios (rPEAK, rAUC, rMTT, rFIR, rFWHM) showed no significance (all $p > 0.05$) (Table 3). Relative changes in rTTP (rrTTP) correlated positively with the changes in pressure gradient (rdPASP) ($r = 0.486$, $p = 0.035$) before and after treatment (Fig. 2).

CONCLUSION

These findings suggest that angiography-derived TTP ratios reflect pressure gradient improvements and may serve as noninvasive markers of therapeutic efficacy.

CLINICAL RELEVANCE/APPLICATION

This study provides a noninvasive approach for the evaluation of pulmonary vascular pressure and interventional efficacy.

R5A-SPIR-2 DUCTS PRESERVED, TUMORS TARGETED: HISTOTRIPSY FOR CENTRALLY LOCATED LIVER LESIONS

Valerie Khaykin (*Presenter*)
Neehar Parikh, MD (*Abstract Co-Author*)
Nathan E. Loudon, MD (*Abstract Co-Author*)
Andrew Navarro, MD (*Abstract Co-Author*)
Aadithya Nalla, BS (*Abstract Co-Author*)
Man Zhang, MD, PhD (*Abstract Co-Author*)
Vaibhav Sahai, MBBS (*Abstract Co-Author*)
Elaine M. Caoili, MD, MS (*Abstract Co-Author*)
Mishal Mendiratta-Lala, MD (*Abstract Co-Author*)

PURPOSE

Patients with centrally located liver tumors often have limited treatment options due to proximity to major biliary structures. Locoregional therapies such as thermal ablation, SBRT, and embolization carry significant risks of bile duct injury, including ischemia, strictures, and biloma formation. Surgical resection is often not feasible due to involvement of critical biliary and vascular anatomy. Histotripsy, a non-invasive, non-thermal ultrasound-based ablation modality, has a unique property of tissue selectivity, resulting in sparing of critical structures such as bile ducts, thus offering a potentially safer treatment alternative for centrally located tumors. This study evaluates the safety of biliary structures and early outcomes after histotripsy for centrally located liver tumors.

METHODS AND MATERIALS

An IRB-approved HIPAA-compliant retrospective review was conducted on 14 patients treated with histotripsy for centrally located liver tumors between February 2024 and April 2025. Central tumors were defined as those adjacent to the common hepatic duct or first-order right/left biliary radicles. Histotripsy was performed as part of routine clinical care using the Edison system. Imaging was reviewed at immediate, 30-day, and 6-month post-treatment timepoints using contrast-enhanced CT or MRI to assess tumor response and biliary complications. Demographics, tumor histology, and ablation parameters were recorded.

RESULTS

14 patients (11 male, 3 female; mean age 61 years (range 45-85)) had 15 centrally located tumors treated with histotripsy, including tumor types: colorectal (n=4), cholangiocarcinoma (CCA) (n=3), neuroendocrine (NET) (n=2), ovarian (n=2), hepatocellular (HCC) (n=1), pancreas (n=1), breast (n=1), and esophagus (n=1). Average pretreatment tumor size was 24.3 mm (9-56 mm), and average post-treatment ablation zone size was 37 mm (19-67 mm). Of 15 central tumors, 12 (80%) were non-enhancing immediately post-treatment and 3 (20%) remained viable (1 CCA, 1 HCC, 1 NET). At 30-day follow-up, 10 tumors (67%) were non-viable and 5 (33%) were viable. 6-month outcome data was only available for 8 patients. Regardless of outcomes data, there were no instances of bile duct ischemia, strictures, bilomas, abscesses, or biliary ductal dilatation across all timepoints.

CONCLUSION

Our data suggest histotripsy is a safe, feasible option for centrally located liver tumors. Absence of biliary complications supports its potential as a bile duct-sparing therapy in anatomically complex cases.

CLINICAL RELEVANCE/APPLICATION

Centrally located liver tumors limit many locoregional therapy options due to risk of biliary injury and anatomic complexity. Histotripsy offers a bile duct-sparing alternative in this high-risk setting.

R5A-SPIR-4 SHIFTING PARADIGMS IN INFERIOR VENA CAVA FILTER MANAGEMENT: FIVE-YEAR MEDICARE ANALYSIS OF PROVIDER-SPECIFIC TRENDS

Zain Hussain, MD (*Presenter*)
Yusuf Zaidi (*Abstract Co-Author*)
Hamza Masood (*Abstract Co-Author*)

PURPOSE

To quantify 2017-2021 national trends in IVC-filter placement and retrieval among Medicare beneficiaries and to determine how provider specialty has reshaped market share in response to FDA safety advisories and evolving guidelines.

METHODS AND MATERIALS

Annual CMS Medicare Part B Public-Use-File data (2017-2021) were queried for CPT 37191 (placement) and CPT 37197 (retrieval). Volumes were stratified by billing specialty, Radiology, Surgery, Cardiology, Other, and by year. Univariate linear regression estimated annual rate-of-change (ß, 95% CI). Market share was expressed as each specialty's percentage of all retrievals per year. Analyses were performed in SPSS v29.

RESULTS

A total of 25,509 placements and 870 retrievals were billed during the study window. Placements fell 57.7% (7,979?3,376); retrievals declined 61.2% (263?102). Radiology performed 78.8% of placements (ß = -917 procedures/year; p<0.01) and 60.2% of retrievals (ß = -10.9 retrievals/year; p<0.01). Cardiology's retrieval share plummeted from 46.4% in 2017 to 0% in 2021 (ß = -19.1; p<0.01). Radiology's retrieval dominance surged from 43.7% to 81.4%, while Surgery's share rose modestly from 9.9% to 18.6% (ß = -2.3; NS). Overall retrieval-to-placement ratio remained low (3.4%) and did not improve over time.

CONCLUSION

Medicare data confirm a sharp contraction in IVC-filter utilization but no parallel improvement in retrieval rates. Radiologists now perform >80% of retrievals, whereas other specialties have virtually exited this space. Persistent under-retrieval highlights an unmet need for coordinated, specialty-agnostic follow-up pathways.

CLINICAL RELEVANCE/APPLICATION

As IVC-filter management consolidates under Radiology, radiologists must lead system-level solutions to close the retrieval gap and align real-world practice with the 2005 FDA advisory statement.

R5A-SPIR-5 EFFICACY OF HEPATIC VEIN OCCLUSION FOR HEPATOPULMONARY SHUNT REDUCTION IN ^{90}Y RADIOEMBOLIZATION: QUANTITATIVE ANALYSIS OF PRE-TREATMENT ^{99M}TC-MAA SPECT/CT AND POST-TREATMENT ^{90}Y PET/CT

Aakash Gupta, MD,BS (*Presenter*)
David S. Wang, MD (*Abstract Co-Author*)
Daniel Y. Sze, MD, PhD (*Abstract Co-Author*)
Lynne N. Martin, MD (*Abstract Co-Author*)
Andrew Kesselman, MD (*Abstract Co-Author*)
Jagruti Shah, MD, MBBS (*Abstract Co-Author*)
Erin E. Grady, MD (*Abstract Co-Author*)
Andrei Iagaru, MD (*Abstract Co-Author*)
Matthew Hung, MD (*Abstract Co-Author*)
Kip E. Guja, MD, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate the efficacy of hepatic vein occlusion (HVO) in reducing hepatopulmonary shunt fraction (HPSF) in patients undergoing radioembolization by comparing pre-treatment 99m Tc-macroaggregated albumin (MAA) SPECT/CT and post-treatment 90 Y PET/CT.

METHODS AND MATERIALS

A single-center, retrospective analysis of hepatic 90 Y radioembolization between 2004-2024 identified 22 patients undergoing 25 treatments with HVO for high HPSF. Inclusion criterion was availability of post-treatment 90 Y PET/CT with full lung coverage (6 patients). Hepatic venography was evaluated for tumor-in-vein and collateral flow. Temporary or permanent HVO was performed at the discretion of IR. 90 Y PET/CT was acquired on a digital scanner over 20 mins in 2 bed positions. HPSF was calculated on both pre-treatment 99m Tc-MAA SPECT/CT and post-treatment 90 Y PET/CT using [(lung activity) / (liver activity + lung activity)] in an established workflow (MIM Software Inc, Cleveland OH). Pre-HPSF on 99m Tc-MAA planar imaging was similarly calculated using geometric mean. Absolute HPSF and relative change percentages were recorded between 99m Tc-MAA SPECT/CT and 90 Y PET/CT. Paired statistical analysis was performed with Wilcoxon signed-rank test.

RESULTS

Six patients (50% male; median age 74 years) met the inclusion criterion and underwent radioembolization treatments for primary hepatic malignancies (N=4, 67%) and metastases (N=2, 33%). Radioembolization (glass N=4 vs. resin N=2; lobar N=3 vs. segmental N=3) was performed in a median of 9 days after 99m Tc-MAA. HVO was performed with temporary balloon occlusion (N=5, 83%) and permanent vascular plugs (N=1, 17%). Median balloon occlusion time was 30 min (range, 5-60 min). Median pre-HPSF by 99m Tc-MAA planar imaging and SPECT/CT were 22.0% (range, 13.1% to 32.0%) and 11.1% (range, 6.2% to 18.4%) respectively. Post-HPSF by 90 Y PET/CT was 3.4% (range, 1.0% to 15.6%) (p=0.063). One patient with tumor in vein and large hepatic venous collaterals had increased HPSF 11.7% to 15.6%. All remaining 5 patients without large collaterals or tumor in vein had a reduction in HPSF: median relative change of -66.7% (range, -83.9% to -52.2%) and median absolute change of -6.9% (range, -9.6% to -4.4%) when comparing 99m Tc-MAA SPECT/CT to 90 Y PET/CT.

CONCLUSION

Hepatopulmonary shunting may be reduced with HVO during radioembolization in patients with high HPSF and without large hepatic venous collaterals or tumor in vein.

CLINICAL RELEVANCE/APPLICATION

Quantitative analysis of HPSF on pre-treatment 99m Tc-MAA SPECT/CT and post-treatment 90 Y PET/CT demonstrates reduction in HPSF by HVO during radioembolization. This technique may expand availability of radioembolization and allow higher treatment doses in patients with elevated HPSF.

R5A-SPMK-3 DYNAMIC BLOOD POOL IODINE CORRECTION IMPROVES FULLY AUTOMATED OPPORTUNISTIC BONE MARROW DENSITY ASSESSMENT ON CONTRAST-ENHANCED DUAL-ENERGY CT

Nedim Beste, MD (*Presenter*)
Simon Lennartz, MD (*Abstract Co-Author*)
Thorsten Persigehl, MD (*Abstract Co-Author*)
Philipp C. Fervers, MD (*Abstract Co-Author*)

PURPOSE

Opportunistic bone mineral density (BMD) assessment on contrast-enhanced CT may reduce underdiagnosis of osteoporosis in oncologic patients. However, these measurements are biased by sampling variability and intravenous contrast. We aimed to evaluate an automated tool for thoracic CT-based BMD screening and propose dynamic adjustment based on iodine blood pool intensity.

METHODS AND MATERIALS

Patients without metastatic or primary bone disease undergoing contrast-enhanced dual-energy CT were retrospectively included. The thoracic spine was segmented using a pre-trained neural network. Mean attenuation of the cancellous bone was extracted in Hounsfield units (HU) and mapped to age- and sex-specific BMD reference values. Four linear regression models were fitted: (1) uncorrected, (2) corrected for vertebral iodine uptake, (3) corrected for portal vein iodine concentration, and (4) corrected for age-adjusted iodine blood pool. Model performance was assessed by r^2 and 95% confidence interval (CI) width. Intraindividual consistency was evaluated by histogram overlap across scans.

RESULTS

645 CTs from 179 patients (87 female; mean age 61.4 ± 16.0 years) were analyzed. Iodine blood pool correction improved model fit, most pronounced with age adjustment (r^2 from 0.88 and 0.47 to 0.93 and 0.65; CI width from 57/123 to 45/99 mg/ml for females/males). Vertebral iodine correction had no benefit (Fig.1).

CONCLUSION

We present an AI-based, fully automated method for BMD assessment on contrast-enhanced CT. Dynamic iodine correction based on blood pool intensity significantly improved accuracy and consistency.

CLINICAL RELEVANCE/APPLICATION

Automated BMD assessment on contrast-enhanced CT with dynamic iodine correction may enable reliable opportunistic osteoporosis screening in oncologic patients. The proposed method improves accuracy and consistency, offering a practical approach for secondary fracture prevention without additional imaging.

R5A-SPMK-4 INJURY PATTERNS IN KNEE MRI: IS THERE A GENDER GAP?

Ali Ghasemi, MD (*Presenter*)
Jenifer Pitman, MD (*Abstract Co-Author*)
Shivani Ahlawat, MD (*Abstract Co-Author*)
Laura M. Fayad, MD (*Abstract Co-Author*)

PURPOSE

To investigate the differences in structural knee injuries between female and male of different age groups

METHODS AND MATERIALS

Single Center Retrospective Study?This study is done using mPower application and done solely on the MRI reports that are reported in 4 outpatient radiology facilities affiliated with Johns Hopkins Hospital.?13,549 reports of consecutive routine knee MRI studies from 1/1/2019-9/30/2024 were included.? Inclusion criteria:?Knee MRI Scans done on outpatient individuals?Knee pain reported as chief complaint? Exclusion criteria:?History of cancer?Presence of a chronic illnessPrior knee surgery? Demographic data including age and gender were recorded.?The presence or absence of the following features were extracted from the report:?Medial meniscal (MM) tear?Lateral meniscal (LM) tear?Anterior cruciate ligament (ACL) tear?Posterior cruciate ligament (PCL) tear?Medial collateral ligament (MCL) tear?Lateral collateral ligament complex (LCL) tear?Extensor mechanism tear?Patellofemoral dislocation

RESULTS

There were significant differences between males and females for:?ACL tear alone (males > females in all age groups except for "=60," p=0.001),?ACL tear with MM tear (males > females in all age groups except for "=60," p=0.014)?ACL tear with LM tear (males > females in all age groups except for "=60," p=0.001).? There were also significant differences for MM tears and LM tears alone:?Males > females in age groups "=20" and "21-40," and females >males for age groups "41-60" and "=60" (p<0.001 for MM and LM).?MCL tears alone were also more commonly seen in males "=20" and "21-40," and females "41-60" and "=60" (p=<0.001).? There were no significant sex differences for any age group for PCL, ACL + PCL, ACL + MCL, ACL + LCL, LCL, patellar tendon tears, or for patellofemoral dislocation. ?

CONCLUSION

Differences in injury patterns exist between males and females, particularly for ACL, MCL, and meniscal as well as ACL alongside either medial or lateral meniscal tears. Overall, in younger patients, tears were more commonly seen in males, while in older patients, tears were more commonly seen in females. Contrary to available literature, our results showed a significantly higher prevalence of ACL injuries in male patients in both age-stratified and non-age-stratified comparisons.

CLINICAL RELEVANCE/APPLICATION

Sex- and age-specific patterns of knee injuries can inform personalized approaches to diagnosis, prevention, and rehabilitation strategies. Recognizing that younger males are more prone to ACL and meniscal injuries, while older females exhibit higher rates of these injuries, may aid clinicians in tailoring imaging protocols, risk assessment, and early intervention strategies to optimize patient outcomes.

R5A-SPMK-5 FEASIBILITY STUDY OF T2MAPPING AND FACT IN THE EVALUATION OF THIGH QUADRICEPS AFTER EXERCISE TRAINING

JIE HU (*Presenter*)
Xianfeng Yang, MBBCh (*Abstract Co-Author*)

PURPOSE

To explore the feasibility of evaluating T2 value, proton density fat fraction (PDFF), and cross-sectional area (CSA) of quadriceps femoris after exercise training based on T2 mapping and Fat Analysis and Calculation Technique (FACT).

METHODS AND MATERIALS

Thirty-two healthy volunteers were recruited and underwent MRI examination of thigh muscles, including axial T2 mapping and FACT sequence. The T2 value, PDFF, and CSA of quadriceps femoris, adductor magnus, and gracilis were measured. The peak torque (PT) of the quadriceps femoris was measured using an isokinetic muscle strength system. The differences in T2 value, PDFF, and CSA before and after countermovement jump(CMJ) were compared, as well as the differences between genders.

RESULTS

The T2 value and CSA of quadriceps femoris and adductor magnus increased and PDFF decreased after CMJ ($p<0.01$). The PDFF of the gracilis was significantly higher than that of the vastus lateralis, and the vastus lateralis had a significantly higher PDFF than the other muscles ($p < 0.01$).PT was highly correlated with CSA of quadriceps femoris ($p < 0.001$, $r = 0.906$). CSA and PT of males were higher than those of females ($p < 0.001$).

CONCLUSION

T2 mapping and FACT can quantitatively evaluate the differences of T2 value, PDFF and CSA of different muscles after exercise training, which is an important evaluation method for competitive sports training and disease rehabilitation.

CLINICAL RELEVANCE/APPLICATION

Apply quantitative magnetic resonance imaging to competitive sports and rehabilitation assessment, which helps to achieve individualized precision training.

R5A-SPMK-6 FAST KILOVOLTAGE-SWITCHING DUAL-ENERGY COMPUTED TOMOGRAPHY WATER-CALCIUM DECOMPOSITION AND VIRTUAL LOW-KEV MONOENERGETIC TECHNIQUE FOR THE ASSESSMENT OF THE EXTREME LATERAL LUMBAR DISC HERNIATION

Yang Menghua (*Presenter*)
Xuee Zhu, MD (*Abstract Co-Author*)
Tongbo Yu (*Abstract Co-Author*)
Rong Yao (*Abstract Co-Author*)
Rui Zhang (*Abstract Co-Author*)
Hanxiao Yu (*Abstract Co-Author*)

PURPOSE

To assess the diagnostic performance of dual-energy CT (DECT) with reconstruction of water (calcium) images and virtual low-keV(50 keV) images for the detection of the extreme lateral lumbar disk herniation compared with conventional CT, with magnetic resonance imaging (MRI) serving as reference.

METHODS AND MATERIALS

A total of 25 consecutive patients with 125 intervertebral disks who underwent both DECT and MRI of the lumbar within 2 weeks from each other were retrospectively enrolled in our study. The patients were 34~90 years old, 11 males and 14 females. Three radiologists blindly and independently evaluated conventional grayscale CT series for the presence and type of lumbar disk herniation, and the focus was on the extreme lateral lumbar disc herniation. After the following 4 and 8 weeks, readers reevaluated examinations based on virtual 50-keV images and color-coded water (calcium) images, respectively. MR images were blindly assessed by an experienced ragiologist, serving as the reference standard. Sensitivity, specificity and accuracy were the primary metrics of diagnostic performance, which were compared by application of the Mc Nemar test.

RESULTS

Color-coded water (calcium) images showed higher sensitivity than virtual 50-keV and conventional CT images (75.68% vs 58.56% vs 56.75%) for detecting the extreme lateral lumbar disc herniation ($P = 0.001$). The sensitivity of virtual 50-keV images was similar to that of conventional CT($P>0.05$). The accuracy of virtual 50-keV images were higher than the other two (82.13% vs 81.07% vs 77.60%, $P< 0.001$).

CONCLUSION

Fast KV-switching DECT water (calcium) decomposition technique significantly improves the sensitivity of the extreme lateral lumbar disc herniation and reduces the rate of missed diagnosis. The virtual low-keV (50 keV) images significantly improve the diagnostic accuracy of the extreme lateral lumbar disc herniation.

CLINICAL RELEVANCE/APPLICATION

Extreme lateral lumbar disc herniation is a relatively rare clinical but may cause serious orthopedic symptoms. If not treated timely, quadriceps atrophy may even appear which seriously harm the quality of life of patients. However, due to the special location of the protrusion, it is often overlooked at conventional CT. Fast KV-switching DECT water (calcium) decomposition technique significantly reduces the rate of missed diagnosis for this type of lumbar disk herniation compared with conventional CT.

R5A-SPMS-1 DEEP LEARNING FOR POST-CONTRAST T1-WEIGHTED MRI SEQUENCE SYNTHESIS: A SYSTEMATIC REVIEW

Emmy Y. Hu, MD,BA (*Presenter*)
Siddhant Dogra, MD (*Abstract Co-Author*)

PURPOSE

Gadolinium-based contrast agents for MRI expose patients to nephrogenic and tissue-retention risks, increase exam time and cost, and may cause patient discomfort. Recently, deep-learning (DL) models synthesizing post-contrast T1-weighted images from pre-contrast sequences have gained popularity. This systematic review catalogues and appraises studies using DL for post-contrast T1 synthesis, highlighting applications, architectures, inputs, quantitative and reader-based metrics, and data transparency to guide future research.

METHODS AND MATERIALS

This study was performed as per PRISMA guidelines. 5 databases (PubMed, Embase, Cochrane Central, Scopus, Web of Science) were searched on 1/16/25. The search strategy used keywords and synonyms related to "MRI," "post-contrast," "deep learning," and "synthesis." 2 reviewers independently screened titles, abstracts, and full texts, extracting subspecialty/organ/pathology, MRI inputs, DL architectures, quantitative metrics, reader study details if performed, datasets, code availability, and data characteristics.

RESULTS

268 articles underwent title-abstract screening, resulting in 54 studies whose full-texts were screened, and ultimately 43 studies included.Neuroradiology accounted for the majority of papers (n=25; 21 brain and 4 nasopharyngeal studies), followed by breast imaging (n=8, all breast cancer) and body applications (n=6; 3 liver, 2 prostate, and 1 uterus). Fundamental DL architectures included generative adversarial networks (GANs, n=20), convolutional neural networks (CNNs, n=19), transformers (n=3), diffusion models (n=2), and novel hybrids (n=2).13 studies (30%) included a reader assessment (mean 4.6 readers, standard deviation 3.1). Quantitative metrics commonly reported were structural similarity index, peak signal-to-noise ratio, and mean absolute error.

CONCLUSION

DL synthesis of post-contrast T1 MRI has primarily targeted neuroradiology, predominantly utilizing GAN and CNN models. Diffusion and transformer architectures require further exploration. The field faces limitations from heterogeneous evaluations and limited reader studies.

CLINICAL RELEVANCE/APPLICATION

DL synthesis of post-contrast T1 MRI shows promise but requires more consistent prospective reader evaluations and standardized, clinically relevant metrics to see if these models could be suitable for clinical applications.

William Rooney, PhD (*Abstract Co-Author*)
Rochelle Fu (*Abstract Co-Author*)
Sadek Nehmeh (*Abstract Co-Author*)
Jana Ivanidze, MD, PhD (*Abstract Co-Author*)
Prakash Ambady (*Abstract Co-Author*)

PURPOSE

Hypoxia is a fundamental biological feature of Glioblastoma (GBM). 18F-fluoromisonidazole (FMISO) PET quantifies hypoxia, which portends a poor prognosis. MRI-based response assessment metrics lack diagnostic accuracy for definitively establishing therapeutic outcomes. This is especially true for immunotherapies that are likely to cause increased incidence of neuroinflammatory pseudoprogression (Psp). Therefore, we aimed to define the diagnostic utility of FMISO PET/MRI for differentiating Psp from therapy failure (Progression).

METHODS AND MATERIALS

A prospective clinical trial was undertaken in patients with newly diagnosed IDH-wildtype GBM or IDH-mutant astrocytoma grade 4 (NCT03649880). All patients received Stupp protocol temozolomide-based chemoradiotherapy following maximal safe resection. A subset of patients were concurrently enrolled in a phase II study (NCT03347617) of pembrolizumab immunotherapy (200 mg IV every 3 weeks) combined with Stupp protocol following maximal safe resection. FMISO PET/MRI (3.7 MBq/kg, 90 min uptake, 40-minute emission time) was performed at time of mRANO-presumed progression. Hypoxic volume (HV) was defined by voxels with FMISO uptake =1.2x that of the mean cerebellar white and grey matter uptake. MRI-Gd enhancing volume was segmented using a semi-automated approach. Hypoxic fraction (HF) was defined as the HV-to-MRI enhancing volume ratio. Disease progression or Psp was confirmed through surgery or follow-up MRI. T-test and receiver operator characteristic (ROC) analysis was performed. P< .05 denoted significance.

RESULTS

24 patients with IDH-wildtype GBM or IDH-mutant astrocytoma grade 4 (17 with pembrolizumab [12 Progression and 5 Psp] and 7 without pembrolizumab [5 Progression and 2 Psp]) provided evaluable disease. 3 patients had an IDH-mutation (1 progression and 2 Psp). HF for all patients (N= 24) and GBM (N= 21) was significantly elevated with progression compared to Psp (P< .01; Figure). HV was not different between progression and Psp (P> 0.09). No difference in HF or HV was observed based on therapy (P> 0.61). HF yielded an AUROC of .94 for all patients and .98 for patients with GBM with an optimal threshold cut-off of 0.88, to differentiate progression from Psp (Figure).

CONCLUSION

At time of mRANO presumed progression, HF with FMISO PET/MRI accurately distinguishes tumor progression from Psp irrespective of prior pembrolizumab immunotherapy.

CLINICAL RELEVANCE/APPLICATION

In this prospective clinical trial, HF served as a robust and noninvasive metric for treatment response assessment. The incorporation of FMISO PET/MRI in future therapeutic clinical trials is underway. If validated, HF is likely to improve upon current response assessment criteria for patients with GBM.

R5A-SPNMMI-2 DOES DOPAMINE D2/D3 RECEPTOR AVAILABILITY EXHIBIT SEASONAL VARIATIONS IN HEALTHY ADULTS? A [^{11}C]PHNO PET STUDY

Mahsa Mayeli, MD, MPH (*Presenter*)
Marc Potenza (*Abstract Co-Author*)
Kelly Cosgrove (*Abstract Co-Author*)
Richard E. Carson, MD, PhD (*Abstract Co-Author*)
David Matuskey (*Abstract Co-Author*)

PURPOSE

Dopamine is a neurotransmitter implicated in functions ranging from motor control to cognitive performance. In humans, dopaminergic markers have been associated with seasonal symptomatic fluctuations. Here, we investigated potential seasonal variations in dopamine D2/D3 receptor availability in healthy adults using [11 C]PHNO positron emission tomography (PET) imaging.

METHODS AND MATERIALS

Data were retrospectively extracted from a database at the Yale School of Medicine. All healthy participants with non-displaceable binding potential (BP ND) measurements from [11 C]PHNO over the past 20 years were included. Scan dates were used to group participants into spring, summer, fall, and winter, and daylight

hours and average daily temperatures on the scan date were extracted from appropriate sources. Mixed-effects models were used to investigate the predictive potential of daylight exposure and average daily temperatures for [11 C]PHNO BP ND .

RESULTS

Participants (n=124, 85 men; mean age = 34.77(9.52) years)-. demonstrated no significant differences in [11 C]PHNO BP ND levels between those scanned in different seasons. Additionally, mixed-effects analyses revealed no significant associations between daylight exposure and average daily temperatures and [11 C]PHNO BP ND after adjusting for age, sex, and body mass index as fixed effects and subject as a random effect.

CONCLUSION

Our findings do not provide strong evidence for significant seasonal variations in dopamine D2/D3 receptor availability in healthy individuals. However, variations in PET ligand, geographic latitude, and seasonal daylight exposure may affect findings. These factors should be carefully considered before including seasonal variation as a covariate in dopamine receptor imaging studies.

CLINICAL RELEVANCE/APPLICATION

Dopaminergic dysfunction is implicated in a range of neuropsychiatric conditions, including depression, schizophrenia, and seasonal affective disorder. Understanding whether dopamine receptor availability varies seasonally is important for the design and interpretation of PET imaging studies, particularly those assessing treatment effects or pathophysiological mechanisms in clinical populations. Our findings suggest that seasonal variation in dopamine D2/D3 receptor availability, as measured by [^{11}C]PHNO PET, may be less pronounced than previously reported with raclopride, underscoring the need to consider tracer sensitivity and geographic factors when using PET to investigate dopamine-related disorders.

R5A-SPNPM-1 DEMOCRATIZING LEADERSHIP: IMPLEMENTING A MERIT-BASED MODEL FOR RADIOLOGY CHIEF RESIDENT SELECTION:

Anam Khan, MBBS (*Presenter*)
Zainab Hussain, MBBS (*Abstract Co-Author*)
Shaista A. Saeed, MBBS (*Abstract Co-Author*)

PURPOSE

To develop and implement a structured, merit-based model for radiology chief resident selection. This model aims to enhance fairness, objectivity, and resident engagement, creating a transparent, standardized approach that identifies and appoints the most qualified residents, improving resident leadership and the educational experience.

METHODS AND MATERIALS

A five-step model was developed:1. Resident Voice: Gauging Awareness and Expectations Residents were surveyed to assess their awareness of the chief resident selection process and the leadership attributes they deemed important.2. Opening Doors: Formal Call for Applications Final-year residents were invited to formally submit applications for the chief resident position.3. 360° Feedback: Holistic Evaluation Across Stakeholders a) Resident Evaluation Peers rated candidates (scale 0-4) based on leadership, teaching participation, and professionalism.b) Staff Evaluation Allied health staff assessed candidates' communication, teamwork, and day-to-day clinical conduct.c) Faculty Assessment Faculty members evaluated academic performance, clinical competence, administrative skills, and research contributions.4. Leadership in Focus: Structured Candidate Interviews Candidates participated in interviews with program leadership (Program Director and Associate Program Director). 5. Objective Excellence: Scoring Grid and Final Selection A pre-defined evaluation grid assigned weighted scores (out of 100) across domains of academic achievements, leadership, professionalism, educational contributions, and research activities. A composite score combining feedback from all stakeholders determined the final selection.

RESULTS

The resident poll highlighted communication, leadership, and professionalism as key desired attributes. The multi-stakeholder feedback provided a nuanced evaluation of candidates. The final selection resulted in the appointment of two final-year residents for six-month chief tenures, demonstrating strong alignment with the merit-based criteria identified throughout the process.

CONCLUSION

This multi-step, merit-based model offers a transparent and comprehensive alternative to discretionary chief resident selection. By incorporating diverse perspectives and focusing on key competencies, it aims to foster leadership development and enhance resident engagement.

CLINICAL RELEVANCE/APPLICATION

This framework may serve as a scalable model for other radiology training programs seeking to optimize their leadership selection processes.

R5A-SPNPM-2 RELATIVE IMPORTANCE OF COMMUNITY FACTORS ON U.S. COUNTY-LEVEL CANCER SCREENING, PREVALENCE, AND MORTALITY

Elizabeth Y. Rula, PhD (*Presenter*)
Alexandra Drake (*Abstract Co-Author*)
Eric Christensen, PhD (*Abstract Co-Author*)
Jinel A. Scott, MD (*Abstract Co-Author*)
William Small JR, MD (*Abstract Co-Author*)

PURPOSE

This study assessed the relative importance of diverse community measures for explaining County-level variance in cancer outcomes—screening, prevalence, and mortality rates—for breast, colorectal, lung, and prostate cancers, and mapped regional patterns.

METHODS AND MATERIALS

Using random forest algorithms, we estimated the relative importance of 24 community measures - including health behaviors/lifestyle, socioeconomic, and environment factors - as explanatory factors for County-level cancer outcomes (screening, prevalence, and mortality rates) and for the four highest prevalence cancers in the U.S. (breast, colorectal, lung and prostate cancers). County-level cancer screening and prevalence rates were measured using the 5% sample of Medicare fee-for-service beneficiaries (2020) and 5-year (2016-2020) average mortality rates were from National Cancer Institute's State Cancer Profiles. County-level choropleth mapping of significant community-factor to outcome associations visualized geospatial patterns.

RESULTS

We found that the most important community factors for explaining outcomes varied by cancer type and by outcome measure. The strongest explanatory factors for mortality were smoking rate for lung and colorectal cancers, and the non-Hispanic Black population share for breast and prostate cancers. Poverty, severe housing problems, limited access to health foods, and insufficient sleep were the most important factors for breast, colorectal, lung, and prostate cancer prevalence, respectively. Hispanic population share, poverty, poor physical health, and air toxics cancer risk were the most important factors for screening rates, respectively, for each cancer. Broadly, across the outcome-cancer type combinations, smoking, poor physical health days, and poverty showed strong association with mortality, prevalence, and screening, respectively. The maps visually illustrate the association of community and outcome measures and how they are regionally concentrated throughout the U.S. The results provide evidence to inform population health initiatives tailored to community needs.

CONCLUSION

The relative explanatory importance of community measures on cancer screening, prevalence and mortality rate differed, both within and across cancers, and the rates of risk and outcome varied locally and regionally.

CLINICAL RELEVANCE/APPLICATION

The importance of community measures for population health cancer measures can better inform, prioritize, and target efforts to improve cancer outcomes, and drive prospective research on causal mechanisms and to test interventions. The choropleth maps help identify high-priority local and regional strategies to improve outcomes.

Lee Cooper (*Abstract Co-Author*)
Hyunsuk Shim, PhD (*Abstract Co-Author*)

PURPOSE

Glioblastoma (GBM) is the most aggressive brain cancer and demands precise radiotherapy (RT). Whole-brain 3D spectroscopic MRI (sMRI) noninvasively quantifies brain metabolites and serves as a precise biomarker for RT. However, spectral artifacts degrade metabolite maps. Effective artifact filtration ensures reliable maps for high-dose RT. Our prior convolutional neural network misclassified tumor spectra due to data imbalance with a high number of normal spectra. We introduce a deep learning (DL) model trained on T2-FLAIR hyperintense spectra to guide high-dose RT and enhance peritumoral artifact detection.

METHODS AND MATERIALS

Eighty-nine subjects from two trials were scanned on 3T Siemens systems using high-TE sMRI, T1-weighted, and T2-FLAIR sequences. Spectra were quantified with MIDAS and preprocessed via FLAIR segmentation. Eight experts labelled 5257 spectra as either "acceptable" or "unacceptable." We applied an 80/20 patient-level split, stratified by label, for training and testing. Our fusion ResNet1D model splits each spectrum into six tiles processed by shared ResNet1D blocks then passes the result through two dense layers to a sigmoid output. Test-set predictions were ensembled by averaging the outputs of the five-fold cross-validation models. Area under the ROC curve (AUC), average precision (AP), sensitivity and specificity at Youden-optimal threshold, and human-rater disagreement assessed model performance.

RESULTS

Reviewers reached unanimous agreement on 89% of spectra. Final model assessments were done with the four-channel model due to strong AUC (0.97), AP (0.93), sensitivity (92%), and specificity (90%). Model-human disagreement averaged 10%, ranging 6% to 24%, indicating strong inter-rater concordance. Our original model misclassified tumor spectra at a higher rate than the new model. For each representative patient, ~50 additional tumor spectra were recovered by the new model.

CONCLUSION

High inter-rater agreement and high AUC/AP indicate that the four-channel model reliably classifies tumor spectra. Providing the quantified spectra as channel inputs, fusion of multiple channels and ensemble averaging mitigated individual model biases and yielded performance gains over single-input configurations. We will apply active learning to our unlabeled spectral pool by soliciting annotations of spectra with high predictive uncertainty, further improving model generalization.

CLINICAL RELEVANCE/APPLICATION

DL artifact filtration delivers reliable peritumoral metabolite maps from sMRI, enabling more precise RT targeting and tighter margins in GBM patients. By improving accuracy, artifact filtration enhances treatment efficacy while minimizing normal-tissue toxicity.

R5A-SPNR-2 HYPOPERFUSION INTENSITY RATIO IS ASSOCIATED WITH FOLLOW-UP INFARCT VOLUME IN MEDIUM VESSEL OCCLUSIONS: A MULTICENTER MULTINATIONAL STUDY

Hamza A. Salim, MD (*Presenter*)
Dhairya Lakhani, MD (*Abstract Co-Author*)
Kambiz Nael, MD (*Abstract Co-Author*)
Gregory W. Albers, MD (*Abstract Co-Author*)
Jeremy J. Heit, MD, PhD (*Abstract Co-Author*)
Adrien Guenego, MD (*Abstract Co-Author*)
Adam A. Dmytriw, MD,FRCPC (*Abstract Co-Author*)
Max Wintermark, MD (*Abstract Co-Author*)
Vivek Yedavalli, MD, MS (*Abstract Co-Author*)

PURPOSE

Medium vessel occlusion (MeVO) accounts for a substantial proportion of acute ischemic strokes (AIS). The hypoperfusion intensity ratio (HIR), defined as the ratio of tissue volume with time-to-maximum (Tmax) >10 seconds to that with Tmax >6 seconds, serves as a surrogate of collateral circulation and has been associated with infarct progression in large-vessel occlusions. Its role in MeVO stroke remains unclear.

METHODS AND MATERIALS

This multicenter, multinational retrospective study evaluated consecutive patients with MeVO who underwent mechanical thrombectomy with or without intravenous thrombolysis. Inclusion required available follow-up imaging and pretreatment CT perfusion. Follow-up infarct volume (FIV) was measured on CT or MRI 12 to 36 hours post procedure. Univariable linear regression was used to identify predictors of FIV, with variables meeting a threshold of $p<0.1$ entering a multivariable model. HIR was the primary variable of interest.

RESULTS

Among 147 patients (median age, 75 years; 57% female), the M2 segment was the most common occlusion site (88%). The median National Institutes of Health Stroke Scale score was 11 (IQR, 7-16), baseline Alberta Stroke Program Early CT Score was 9 (IQR, 8-10), and median HIR was 0.32 (IQR, 0.20-0.57). Univariable analysis showed HIR to be associated with larger FIV (ß=80 mL; p<0.001). In multivariable analysis adjusting for age, sex, baseline NIHSS, and ASPECTS, HIR remained independently associated with FIV (ß=40 mL; p<0.001). Tmax >10 seconds showed the strongest correlation with final infarct volume (r=0.56; p<0.001).

CONCLUSION

In patients with MeVO, higher HIR correlates with larger final infarct volume, suggesting that compromised collateral flow plays a critical role in outcomes.

CLINICAL RELEVANCE/APPLICATION

This finding supports that HIR adds valuable information for prognostication and care for patients with distal occlusions.

R5A-SPNR-4 ALTERATIONS OF THE GLYMPHATIC SYSTEM IN ACUTE ISCHEMIC STROKE: A DIFFUSION KURTOSIS IMAGING STUDY

Feifei Zheng (*Presenter*)
Weiwei Cui (*Abstract Co-Author*)
Jun Liu, PhD (*Abstract Co-Author*)

PURPOSE

The DKI-ALPS (Diffusion Kurtosis Imaging along the Perivascular Space) method has been applied to assess glymphatic function in migraine patients. As a higher-order diffusion imaging technique, diffusion kurtosis imaging (DKI) employs a fourth-order statistical model to characterize water molecule diffusion, offering enhanced accuracy over conventional DTI-ALPS in resolving cross-fiber ambiguities. This study investigates glymphatic dysfunction in acute ischemic stroke (AIS) using DKI.

METHODS AND MATERIALS

This study enrolled a total of 29 patients with unilateral acute ischemic stroke (AIS) and 29 age- and sex-matched healthy controls. All participants underwent 3.0T MRI (MAGNETOM Prisma, Siemens Healthineers, Germany) with a 20-channel head/neck coil. Diffusion tensor and kurtosis tensor maps along the x-, y-, and z-axes were generated using PyDesigner. Regions of interest (ROIs) were placed within projection and association fiber tracts at the lateral ventricular body level using DSI Studio. Diffusion coefficients (Dxx, Dyy, Dzz) and kurtosis parameters (Kxxxx, Kyyyy, Kzzzz) were extracted to calculate DTI-ALPS and DKI-ALPS indices. Differences in ALPS indices between AIS patients and controls, as well as ipsilateral versus contralateral hemispheres in AIS patients, were statistically evaluated.

RESULTS

The DTI-ALPS index was significantly lower in AIS patients (1.243 ± 0.1101) compared to controls (1.438 ± 0.1371; p < 0.0001, 95% CI [0.1296-0.2604]). Similarly, DKI-ALPS indices were reduced in AIS (1.406 ± 0.2022 vs. 1.752 ± 0.2518 in controls; p < 0.0001, 95% CI [0.2253-0.4656]) . These findings suggest impaired glymphatic function in AIS. No significant differences were observed between ipsilateral (DTI-ALPS: 1.204 ± 0.1375; DKI-ALPS: 1.371 ± 0.3104) and contralateral hemispheres (DTI-ALPS: 1.282 ± 0.1567; DKI-ALPS: 1.442 ± 0.2837; p = 0.1017 and p = 0.6027, respectively) .

CONCLUSION

Reduced DKI-ALPS and DTI-ALPS indices in AIS suggest glymphatic dysfunction. The absence of hemispheric asymmetry implies global impairment of metabolic waste clearance during the acute phase of ischemic stroke, rather than unilateral deficits.

CLINICAL RELEVANCE/APPLICATION

The decreased DKI-ALPS and DTI-ALPS values in patients with acute ischemic stroke (AIS) suggest potential glymphatic system dysfunction, supporting clinical strategies targeting glymphatic restoration to improve patient outcomes.

R5A-SPNR-5 SIGNIFICANT IMPROVEMENT IN CHOROID PLEXUS SEGMENTATION ON PRE-CONTRAST 3D T1 MRI USING DEEP LEARNING

Woojin Jung, PhD (*Presenter*)
Seoyoung Lim, MS, BS (*Abstract Co-Author*)
Byungjun Kim, MD, PhD (*Abstract Co-Author*)
Sung-Hye You, MD (*Abstract Co-Author*)

PURPOSE

The choroid plexus (CP) is recognized as a key structure in the brain glymphatic system, involved in waste clearance and neurodegenerative disease. Thus, accurate CP segmentation on MRI is essential for investigating these processes. However, conventional methods (e.g., FreeSurfer) often show low accuracy due to algorithmic limitations and low contrast between CP and adjacent brain tissue. To address this challenge, we developed a deep learning-based algorithm that improves CP segmentation accuracy on 3D pre-contrast T1w MRI by leveraging paired pre- and post-contrast (CE-/CE+) scans during label generation.

METHODS AND MATERIALS

This retrospective study used paired CE-/CE+ 3D T1w MRI scans from 720 patients with cognitive decline, acquired on a 3T Siemens Prisma (MPRAGE: TR/TE/TI = 1800/2.52/904 ms, flip angle = 8°, and voxel size = 1×1×1 mm^3). Data from 100 patients were used for model development. Initial masks from FreeSurfer (FS) were refined using GMM-based segmentation on CE- images to generate labels for the pretraining phase. The output of the pretrained model was then intersected with an intensity-thresholded map from the CE+ images. Manual corrections were applied to selected cases, resulting in high-quality labels that were used to fine-tune the final model.For evaluation, both imaging and clinical validations were conducted. For imaging validation, expert-labeled maps on CE+ images from 20 subjects served as ground truth to compare FS and deep learning (DL) results via Dice coefficient and volume differences. For clinical validation, 574 subjects were grouped into SCI, early MCI, late MCI, and AD. Group-wise differences in CP volume were tested via ANOVA. Lastly, in a subset of 247 subjects with DTI scans, correlation between CP volume and ALPS index was assessed.

RESULTS

In imaging validation, DL model significantly outperformed FS in both Dice coefficient (0.8243 vs. 0.3671, P < 0.001) and absolute volume percentage errors (44.32% vs. 51.77%). Mean segmentation time was dramatically reduced (0.40 vs. 188.00 min, P < 0.001), highlighting its practical utility for large-scale or clinical applications. In clinical validation, CP volumes showed significant group-wise differences across cognitive stages for both FS (P = 0.0039) and DL (P = 0.0418). Lastly, CP volume was negatively correlated with ALPS index in the DTI subset for both methods (FS: ? = -0.4335; DL: ? = -0.3441; both P < 0.001).

CONCLUSION

Our deep learning-based algorithm enables fast and accurate CP segmentation on 3D T1w MRI, outperforming conventional methods and supporting clinical applicability.

CLINICAL RELEVANCE/APPLICATION

Accurate and efficient segmentation of the choroid plexus using 3D T1w MRI can enable large-scale studies on glymphatic dysfunction.

R5A-SPNR-6 SPATIALLY HETEROGENEOUS WHITE MATTER HYPERINTENSITY VOLUMES MEDIATE METABOLIC SYNDROME SEVERITY-COGNITION ASSOCIATIONS: A UK BIOBANK COHORT STUDY OF NEUROCOGNITIVE PATHWAYS

Xinxin Huo (*Presenter*)
Meng Li (*Abstract Co-Author*)

Boyao Chen (*Abstract Co-Author*)
Fushuai Zhang (*Abstract Co-Author*)
Xinyue Zhang (*Abstract Co-Author*)
Zhenyu Cheng (*Abstract Co-Author*)

Yuanyuan Wang (*Abstract Co-Author*)
Pengcheng Liang (*Abstract Co-Author*)
Yiwen Chen (*Abstract Co-Author*)
Changhu Liang, MD, PhD (*Abstract Co-Author*)
Lingfei Guo, MD (*Abstract Co-Author*)

PURPOSE

Our investigation aimed to explore the associations of different distribution of white matter hyperintensity (WMH) volumes with metabolic syndrome (MetS) severity, as well as their impact on multiple cognitive domains.

METHODS AND MATERIALS

A total of 5549 participants were incorporated into our study, comprising 2271 MetS patients and 2823 healthy controls (HCs). Two independent samples t tests and multivariate regression analysis, adjusted for age, sex, ethnicity, education, smoking status, and alcohol status, evaluated the relationship between MetS characteristics and WMH volume. We examined the mediating role of WMH volume between the Mets severity and multiple cognitive domains. All cognitive test were z-transformed, and finally integrated into a global cognition score, defined as mean z score of all domains. 652 participants underwent longitudinal analysis via generalized estimating equations (GEE).

RESULTS

Participants with MetS exhibited significant higher WMH volume than HCs did ($P < 0.001$), including deep white matter hyperintensities (DWMH) and periventricular hyperintensities (PVH). Increased DWMH correlated well with enlarged waist circumference (WC)[95% CI (0.07, 0.219), $P<0.001$], elevated triglyceride [95% CI (0.033, 0.182), $P =0.004$], and elevated hypertension [95% CI (0.188, 0.359), $P<0.001$]; increased PVH correlated well with enlarged WC [95% CI (0.051, 0.146), $P<0.001$], elevated Hemoglobin A1c [95% CI (0.004, 0.011), $P<0.001$], elevated hypertension [95% CI (0.145, 0.254), $P<0.001$] and decreased high-density lipoprotein (HDL) [95% CI (0.014, 0.113), $P=0.012$]. DWMH volume partially mediated the relationship between MetS score and global cognition, processing speed, and fluid intelligence with the mediating effect accounted for 4.4%, 7.9%, and 6.4% of the total effect respectively. PVH partially mediated the relationship between MetS score and global cognition, processing speed, memory, and fluid intelligence with the mediating effect accounted for 9.6%, 9.6%, 3.3% and 12.5% of the total effect respectively. DWMH was correlated with the severity of MetS ($P=0.005$) and PVH was correlated with the severity of metabolic syndrome ($P<0.001$) and the follow-up time ($P=0.006$). And global cognition was also associated with the severity of metabolic syndrome ($P=0.025$) in GEE.

CONCLUSION

Spatially heterogeneous WMH volumes could medicate MetS severity and cognitive performance, revealed underlying pathophysiological mechanisms of cognitive decline due to metabolic syndrome.

CLINICAL RELEVANCE/APPLICATION

Increased WMH also suffered from obesity, hyperglycemia and hyperlipidemia. It provides a new idea for clinical prevention and diagnosis of cognitive decline caused by metabolic syndrome.

R5A-SPNR-7 PROPOSAL OF NOVEL MRI GRADING SYSTEMS FOR LUMBAR NEURAL FORAMINAL STENOSIS: SUPERIOR CLINICAL RELEVANCE OVER EXISTING MODELS

Tom Mishael Jolly, MBBS, MD (*Presenter*)
Anitha Jasper, MD,DMRD,MBBS (*Abstract Co-Author*)
Harshad Vanjare, MD (*Abstract Co-Author*)
Bernice T S (*Abstract Co-Author*)
Jayavelu H Prasad (*Abstract Co-Author*)

PURPOSE

This study evaluates the inter-observer agreement and clinical correlation of two new grading systems (NGS1 and NGS2) for lumbar neural foraminal stenosis, comparing their performance with the Wildermuth and Lee grading systems.

METHODS AND MATERIALS

This retrospective study included 200 patients who underwent lumbar spine MRI in June and July 2024. Exclusion criteria were cauda equina compression, prior spine surgeries, or coexisting spinal pathologies. MRI was performed using a 1.5T scanner with sagittal and axial T1- and T2-weighted sequences. Two experienced radiologists graded foraminal stenosis at L2-L3 to L5-S1 using the Wildermuth, Lee, NGS1, and NGS2 systems. NGS1 has 4 grades. Grade 0: Normal neural foramen. Grade 1: Mild circumferential foraminal stenosis with obliteration of perineural fat in at least one but less than four directions. Grade 2: Moderate stenosis with obliteration in four directions (two opposing directions) without nerve root deformation. Grade 3: Severe stenosis with morphological changes in nerve root. NGS2 simplifies NGS1 into three grades, combining Grade 2 and 3 into a single category termed "marked stenosis". Inter-observer agreement was assessed using kappa (K) statistics. Clinical correlation was determined by neurological symptoms (paraesthesia, numbness, weakness, radicular pain) and signs (denervation on EMG, Lhermitte sign, Spurling sign, reduced deep tendon reflexes).

RESULTS

Inter-observer agreement (K value) was substantial for Wildermuth (0.703) and almost perfect for Lee (0.828). NGS1 and NGS2 outperformed both, with K values of 0.886 and 0.924, respectively ($p < 0.001$). Clinical correlation was highest for NGS2 (94.5%), followed by NGS1 (93.5%), Wildermuth (90%), and Lee (81.5%) ($p < 0.001$). NGS2's simplified structure enhanced reproducibility, while NGS1's detailed grading supported better quantitative assessments.

CONCLUSION

NGS1 and NGS2 demonstrated superior clinical correlation and inter-observer agreement compared to existing systems, with NGS2 excelling in simplicity and reproducibility. These systems improve diagnostic clarity and radiologist-clinician communication.

CLINICAL RELEVANCE/APPLICATION

The novel grading systems (NGS1 and NGS2) enhance diagnostic precision, demonstrate superior clinical correlation and inter-observer agreement, and improve communication between radiologists and clinicians, offering a valuable tool for better management of lumbar neural foraminal stenosis.

R5A-SPNR-8 MIDLIFE METABOLIC HEALTH AND BRAIN PERFUSION: VISCERAL FAT AND INSULIN RESISTANCE AS PREDICTORS OF CEREBRAL BLOOD FLOW

Joseph E. Ippolito, MD, PhD (*Abstract Co-Author*)
John C. Morris, MD (*Abstract Co-Author*)
Cyrus A. Raji, MD, PhD (*Abstract Co-Author*)

PURPOSE

Midlife obesity and adiposity, linked to Alzheimer's disease (AD) risk, may contribute to neurodegeneration via vascular dysfunction and reduced cerebral perfusion. This study examined associations between metabolic markers (BMI, VAT, SAT, waist circumference, lipids, insulin resistance, and HbA1C) and cerebral blood flow (CBF) in cognitively normal midlife adults.

METHODS AND MATERIALS

Eighty-seven cognitively normal, middle-aged adults (mean age: 49.97 years; 66.7% female; 55.2% obese; mean BMI: 31.65 kg/m²) underwent abdominal/brain MRI, brain PET, and metabolic assessments. Visceral and subcutaneous fat were segmented using MATLAB-based software. Insulin resistance was indexed using HOMA-IR. Cerebral blood flow (CBF) was measured via 3D pCASL and processed in SPM12 to produce absolute CBF (aCBF) maps, normalized and smoothed (6 mm FWHM). ROI masks (AAL3 atlas) targeted limbic and cortical regions. Multiple linear regressions examined associations between metabolic metrics (e.g., BMI, VAT, HOMA-IR) and whole-brain/regional aCBF. Mediation models tested HDL, triglycerides, and HOMA-IR as mediators of BMI-aCBF relationships. Voxel-wise analyses were FDR-corrected and adjusted for age.

RESULTS

The results showed significant negative associations between several metabolic markers and aCBF in both the whole brain and specific ROIs. Higher BMI, VAT, triglycerides, and HOMA-IR were associated with lower CBF across multiple regions, including the hippocampus, amygdala, calcarine cortex, middle temporal gyrus, and posterior cingulate. Conversely, higher HDL levels were positively associated with aCBF in these regions. SAT, waist circumference, and LDL were not significantly associated with aCBF. The mediation analysis revealed that the association between BMI and aCBF both in whole brain and ROIs is significantly mediated by TG, HDL, and HOMA.IR. Voxel-wise analyses revealed that higher BMI, waist circumference, VAT, Chol/HDL ratio, HbA1C, and HOMA-IR were significantly associated with lower aCBF, while higher HDL was associated with higher aCBF in clusters located in the temporal, occipital, and frontal lobes.

CONCLUSION

Obesity, particularly increased visceral fat, is associated with reduced cerebral blood flow (CBF) in both whole brain and AD-related regions, suggesting early midlife brain hypoperfusion. Findings indicate that insulin resistance and VAT—but not SAT—drive this reduction, with HDL potentially mediating the BMI-CBF link through atherosclerotic pathways.

CLINICAL RELEVANCE/APPLICATION

Targeting and reducing visceral obesity and insulin resistance may help enhance brain perfusion and potentially lower the risk of developing AD.

R5A-SPNR-9 AUTOMATED SWI-BASED LESION QUANTIFICATION IMPROVES PROGNOSTICATION IN DIFFUSE AXONAL INJURY PATIENTS

Hadiseh Kavandi, MD (*Presenter*)
David Gulisashvili, MD (*Abstract Co-Author*)
Lei Zhang (*Abstract Co-Author*)
Quincy Tran (*Abstract Co-Author*)
Samantha Camp (*Abstract Co-Author*)
Saad Pirzada (*Abstract Co-Author*)
Hasaan Syed (*Abstract Co-Author*)
Natalie Chao (*Abstract Co-Author*)
Miroslaw Janowski (*Abstract Co-Author*)
Elana B. Smith, MD (*Abstract Co-Author*)
David Dreizin, MD (*Abstract Co-Author*)

PURPOSE

Adams grading is a coarse, subjective measure of DAI severity, offering limited prognostic value. We automated 3D SWI-based quantitative lesion visualization, identified features with a) internal validity and b) predictive power for poor short-term outcomes, and compared the quantitative model's performance with blinded MRI-based Adams grading.

METHODS AND MATERIALS

Our cohort had 258 adults with DAI diagnosis and MRI performed w/in 30 days of admission (2008-2019). Two radiologists assigned Adams grades. DAI lesions in 7 regions— gray-white matter junction (GWJ), corpus callosum (CC), basal ganglia (BG), thalami (TH), parahippocampal gyri (PH), cerebellum (CB), and brain stem (BS) —were segmented manually from SWI-MRI and automated w/ nn-unet. Automated features w/ at least moderate correlation to manual were used to predict outcomes (coma/persistent vegetative state (PVS) or brain death (BD)) using bi- & multinomial regression. Association w/ GCS, AMPAC, and Los Ranchos scores was interrogated w/ F-statistics. Automated model and Adams grade AUCs were compared.

RESULTS

Poor short-term outcomes occurred in 59/258 (22.8%): coma/PVS in 38, BD in 21. Automated volumes had moderate to high correlation with manual for total lesion volume, GWJ, CC, TH, & BS (Pearson r: 0.7, 0.68, 0.44, 0.69, 0.72; ICC: 0.81, 0.79, 0.59, 0.79, 0.83; mean zero-adjusted volume similarity (ZAVS): 0.64, 0.61, 0.54, 0.74, 0.60, respectively). Logistic regression identified total and regional volumes (GWJ, CC, TH, BS), age, and arrival GCS as significant predictors. AUC for the quantitative total hemorrhage volume was 0.73 ($p<0.005$) vs. 0.65 for Adams grade 3 ($p<0.005$). In multinomial regression, risk of coma/PVS increased by 8%/mL for total lesion burden, 6%/mL for GWJ, 2.2×/mL for CC, 7.6×/mL for TH, and 9.9×/mL for BS. Total and regional hemorrhage burden (GWJ, CC, TH, BS) showed significant association with GCS at day 5 (highest/lowest) and at discharge ($p<0.05$). CC lesion volume showed significant association with Los Ranchos and AMPAC scores ($p<0.05$).

CONCLUSION

Manual-automated agreement in key regions supports using automated MRI metrics for precise and granular automated DAI prognostication. Lesion burden predicted catastrophic in-hospital outcomes and short-term functional outcome scores, supporting automated SWI-based quantitative visualization as an objective prognostic tool.

CLINICAL RELEVANCE/APPLICATION

Automated SWI lesion quantification improves DAI outcome prediction, outperforming subjective Adams grading. This pilot study initiates development of lesion burden metrics from admission and follow-up CT-based synthetic SWI (in progress) as an objective tool for evaluating early post-injury therapeutic trials.

R5A-SPNR-10 FROM CORE TO CORRIDOR: PERITUMORAL MRI METRICS DIFFERENTIATE TRUE PROGRESSION FROM TREATMENT EFFECT IN GLIOBLASTOMA

Ajay Kumar, MD, PhD (*Presenter*)
Laiz Godoy, MD (*Abstract Co-Author*)
Steven Brem, MD (*Abstract Co-Author*)
Stephen Bagley (*Abstract Co-Author*)
Suyash Mohan, MD (*Abstract Co-Author*)
Sanjeev Schawla (*Abstract Co-Author*)

PURPOSE

Distinguishing pseudoprogression (PsP) from true tumor progression (TP) in glioblastoma (GBM) during the early post-treatment period remains a formidable diagnostic challenge. We evaluated whether quantitative diffusion- and perfusion-weighted MRI metrics derived not only from the contrast-enhancing core but also from the immediate (IPR) and distal (DPR) peritumoral regions can improve discrimination of PsP versus TP after standard of care chemoradiotherapy.

METHODS AND MATERIALS

Seventy consecutive GBM patients with new or enlarging enhancing lesions within six months post-concurrent chemoradiotherapy underwent anatomical, diffusion, and perfusion MRI at 3T. Quantitative parameters—including mean diffusivity (MD), fractional anisotropy (FA), linear (CL), planar (CP) and spherical (CS) anisotropy coefficients, relative cerebral blood volume (rCBV), maximal rCBV (rCBV_max), and minimal MD—were extracted from three spatial domains: (i) the contrast-enhancing region (CER), (ii) a 4-mm annulus immediately beyond the enhancement (IPR), and (iii) the remaining abnormal FLAIR signal (DPR). Patients were categorized as TP (n=52) or PsP (n=18) based on histopathology (>25% vs. <25% malignant cells, respectively) or modified RANO (mRANO) criteria on follow-up imaging when histology was unavailable. Inter-group differences between TP and PsP were assessed with the Mann-Whitney U test. A multivariate logistic regression model with receiver operating characteristic (ROC) analysis was used to determine diagnostic performance.

RESULTS

Relative to PsP, TP demonstrated significantly higher rCBVmax (CER: 3.88±1.62 vs. 2.72±1.40, p=0.03; IPR: 3.32±1.24 vs. 2.54±0.81, p=0.01), FA (0.14±0.04 vs. 0.12±0.03, p=0.02), and CL (0.05±0.02 vs. 0.03±0.01, p=0.015) from CER. A trend toward higher rCBVmax in DPR was also observed in TP (2.55±1.12 vs. 1.95±0.52, p=0.06). The multivariate model combining rCBV_max (CER + IPR), FA, and CL yielded an AUC of 0.83, with 77 % sensitivity and 74 % specificity for identifying TP.

CONCLUSION

A novel multiparametric model that interrogates both enhancing tumor and its peritumoral milieu, significantly improves differentiation of true progression from pseudoprogression in GBM compared with CER-only analyses.

CLINICAL RELEVANCE/APPLICATION

Early, reliable discrimination between TP and PsP can reduce unnecessary interventions and enable timely therapeutic adaptation. Incorporating quantitative multiparametric metrics from IPR and DPR may therefore enhance personalized management of patients with GBM in this era of precision neuro-oncology.

R5A-SPNR-11 COMPOSITE ARTERIAL AND VENOUS COLLATERAL SCORE ON SINGLE-PHASE CTA PREDICTS 90-DAY OUTCOMES IN ANTERIOR CIRCULATION LARGE-VESSEL OCCLUSION STROKE

Hamza A. Salim, MD (*Presenter*)
Dhairya Lakhani, MD (*Abstract Co-Author*)
Kambiz Nael, MD (*Abstract Co-Author*)
Gegory Albers (*Abstract Co-Author*)
Tobias Faizy, MD (*Abstract Co-Author*)
Jeremy J. Heit, MD, PhD (*Abstract Co-Author*)
Max Wintermark, MD (*Abstract Co-Author*)
Vivek Yedavalli, MD, MS (*Abstract Co-Author*)

PURPOSE

Collateral circulation influences clinical outcomes in patients with acute ischemic stroke due to anterior circulation large-vessel occlusion (LVO). While both arterial and venous collateral assessments on single-phase CTA have prognostic value, they have traditionally been evaluated independently. We developed the CTA Collateral Impairment Score (CCIS), a composite measure incorporating arterial (Tan) and venous (COVES) scores, and investigated its association with 90-day functional outcomes.

METHODS AND MATERIALS

We conducted a retrospective cohort study including 1,080 patients with anterior circulation LVO stroke across four comprehensive stroke centers. Patients were assigned a CCIS of 0 (preserved), 1 (moderate impairment), or 2 (severe impairment) based on predefined thresholds for Tan and COVES scores.

RESULTS

Favorable outcomes (mRS 0-2) occurred in 66% of patients with CCIS 0, 32% with CCIS 1, and 17% with CCIS 2 ($p<0.001$). Mortality increased with higher CCIS (11%, 25%, and 36% for CCIS 0, 1, and 2 respectively; $p<0.001$). In multivariable models, CCIS 0 and 1 were independently associated with greater odds of favorable outcomes compared with CCIS 2 (adjusted OR 5.77 [95% CI, 3.78-8.82] and 1.72 [95% CI, 1.14-2.60], respectively). CCIS also predicted mortality (adjusted OR for CCIS 0 vs. 2: 0.39 [95% CI, 0.25-0.61]; $p<0.001$). The predictive performance of CCIS (AUC 0.73) exceeded that of ASPECTS and occlusion site and approximated NIHSS; inclusion of CCIS improved multivariable model discrimination (AUC 0.84).

CONCLUSION

CCIS, a composite arterial and venous collateral score derived from single-phase CTA, was strongly and independently associated with 90-day outcomes in anterior circulation LVO stroke.

CLINICAL RELEVANCE/APPLICATION

CCIS integration into acute stroke imaging assessment may improve risk stratification and guide therapeutic decisions.

R5A-SPNR-12 MICROSTRUCTURAL WHITE MATTER INJURY IN NON-ARTERITIC ANTERIOR ISCHEMIC OPTIC NEUROPATHY EVALUATED BY DIFFUSION TENSOR IMAGING

Lamei Zhao (*Presenter*)
Pengde Guo, MD (*Abstract Co-Author*)
Qiu Huan Zhang (*Abstract Co-Author*)
Weixin Wang (*Abstract Co-Author*)

PURPOSE

To assess the impairment of the microstructural white matter in NAION patients based on diffusion tensor image (DTI).

METHODS AND MATERIALS

The DTI data were acquired from a cohort consisting of 23 healthy control subjects (HCs) and 23 patients diagnosed with NAION. These data were preprocessed and analyzed to calculate the peak width of skeletonized mean diffusivity (PSMD) and skeletonized free water (FW) maps, which serve as measures of white matter microstructural injury. We compared the PSMD and skeletonized FW between the groups. We subsequently analyzed the correlations between PSMD and the DTI analysis along the perivascular space (DTI-ALPS) index, choroid plexus (CP) volume, Montreal Cognitive Assessment (MoCA) scores as well as clinical data within the NAION group.

RESULTS

In NAION patients, we observed significant increases in the right PSMD and skeletonized FW in the bilateral inferior longitudinal fasciculus, the bilateral inferior fronto-occipital fasciculus, and the right superior longitudinal fasciculus (temporal part). Within the NAION group, the PSMD was negatively correlated with the right retinal nerve fiber layer thickness. Furthermore, the PSDM was negatively correlated with the ALPS index, and positively correlated with the CP volume and MoCA score

CONCLUSION

This study reveals early subclinical white matter damage in patients with NAION, particularly in tracts associated with cognitive function. This injury may arise from impairment of the glymphatic system and disruptions in cerebrospinal fluid circulation, potentially contributing to subsequent cognitive dysfunction. Our findings suggest that NAION may represent a form of small vessel disease. Furthermore, PSMD shows promise as a potential biomarker for NAION in future studies.

CLINICAL RELEVANCE/APPLICATION

Non-arteritic anterior ischemic optic neuropathy (NAION) is the second most prevalent optic neuropathy that leads to visual impairment. There is presently no definitive and effective treatment or medication available. we identified that the microstructural white matter injury was existed in patients with NAION and associated with retinal nerve fiber layers. This study supports the theory that NAION may represent a form of small vessel disease and contribute to cognitive dysfunction.

R5A-SPNR-13 DEVELOPMENT OF A MULTIMODAL MRI-BASED PREDICTIVE MODEL FOR ASSESSING ISCHEMIC STROKE RISK IN INDIVIDUALS WITH INTRACRANIAL ATHEROSCLEROTIC DISEASE

Ming Ming Yang (*Presenter*)
Ling Li (*Abstract Co-Author*)

PURPOSE

This study aimed to construct a risk prediction model for ischemic stroke in patients with anterior circulation atherosclerosis based on high-resolution magnetic resonance imaging (HR-MRI) and arterial spin labeling (ASL)

METHODS AND MATERIALS

Patients with atherosclerosis with middle cerebral artery stenosis diagnosed by HR-MRI from September 2021 to December 2023 were retrospectively analyzed. According to clinical manifestations and diffusion weighted imaging (DWI), the patients were divided into stroke group and non-stroke group. Demographic data, atherosclerosis risk factors, and laboratory indicators were collected, plaque characteristics were extracted based on HRMRI, and the existence of 1.5 s-arterial transport artifacts (ATA) and 2.5 s-ATA was determined based on ASL images. Multivariate logistic regression analysis was used to screen the meaningful indicators, construct the prediction model, and establish the nomogram. The nomogram was evaluated for the degree of differentiation, calibration and clinical effectiveness.

RESULTS

128 cases were included in this study, including 68 in the stroke group and 60 in the non-stroke group. Multivariate analysis showed that age, hypertension, plaque enhancement rate, plaque length, positive remodeling, and the presence of 1.5s-ATA and 2.5s-ATA were important independent predictors of ischemic stroke in patients with intracranial atherosclerosis, and were used to establish predictive models. The area under the curve (AUC) was 0.936 (95%CI: 0.897-0.974), and the model showed good diagnostic performance. The calibration curves also show good agreement between the nomogram predictions and the observed curves. Decision curve analysis further showed that the nomogram had significantly higher clinical net benefit.

CONCLUSION

The nomogram constructed based on multi-modal MRI can accurately predict the risk of ischemic stroke, which is of great help to the risk stratification of stroke decision.

CLINICAL RELEVANCE/APPLICATION

This study developed a multimodal MRI-based nomogram integrating clinical, plaque, and ASL-derived arterial transit artifacts (ATA) features to effectively predict ischemic stroke risk in anterior circulation atherosclerosis, aiding personalized risk stratification and preventive decision-making.

R5A-SPNR-14 VALIDATION OF A DEEP LEARNING ALGORITHM IN DETECTING CERVICAL SPINE FRACTURES ON CT: PRELIMINARY RESULTS

Mohamed Hassan, MD (*Presenter*)

PURPOSE

Cervical spine fractures are devastating injuries that may result in permanent disability, and prompt diagnosis to direct treatment is essential to ensuring the best possible patient outcomes (1). Artificial intelligence (AI) algorithms are critical tools that can assist in triaging patients with specific acute findings to optimize worklist management and enhance patient care (2). This study analyzed the diagnostic accuracy and radiologist concordance with Aidoc cervical spine fracture tool, in detecting acute cervical spine fractures on computed tomography (CT).

METHODS AND MATERIALS

A retrospective review of CT cervical spine studies from multiple institutions performed on adult patients between November 2020 to March 2021 was performed. The interpretation of the Aidoc algorithm was compared to manual review of radiologist reports. For cases with discrepancies or any positive cases, a group of 3 radiologists reviewed the imaging to adjudicate the final diagnosis. Performance between AI and radiologist were compared

RESULTS

The study included 2653 CT spine studies 4.1% prevalence of acute cervical spine fractures. The Radiologist have a 95.4% sensitivity and 99.7% specificity, while the AI algorithm had sensitivity of 88.9% and specificity of 99.1%. The concordance between the radiologist report and the AI algorithm was 93.5%. Of 108 cervical spine fractures, AI correctly identified 96 fractures with 22 false-positive cases. Causes for AI false-positives included chronic spine fractures (6) and beam artifact (4).

CONCLUSION

Our study demonstrated moderate sensitivity and high specificity a commercial acute cervical spine fracture AI algorithm in identifying acute cervical spine fractures with a fracture detection rate comparable to attending radiologists in terms of specificity while radiologist performed better in terms of sensitivity.

CLINICAL RELEVANCE/APPLICATION

AI shows promise as a tool to detect acute cervical spine fractures on CT cervical spine exam.

R5A-SPNR-15 PREDICTION OF INDIVIDUAL TREMOR IMPROVEMENT AFTER MRGFUS THALAMOTOMY IN ESSENTIAL TREMOR VIA MACHINE LEARNING ON RESTING-STATE FMRI DATA

(*Presenter*)
Xiaoyu Wang (*Abstract Co-Author*)
Haoxuan Lu (*Abstract Co-Author*)
Yina Lan (*Abstract Co-Author*)
Xinyu Wang (*Abstract Co-Author*)
Xin Lou, MD, PhD (*Abstract Co-Author*)

PURPOSE

Magnetic resonance-guided focused ultrasound (MRgFUS) is an emerging non-invasive technique for the treatment of refractory essential tremor (ET). However, biomarkers that accurately predict a tremor response to MRgFUS have yet to be identified.This study was to develop a model for the prediction of the individual tremor improvement after MRgFUS from brain connectivity.

METHODS AND MATERIALS

In this cohort study, resting-state functional magnetic resonance imaging (rs-fMRI) data were collected using 3-T MRI and individual brain connectivity were calculated. Fifty-six patients with ET received unilateral MRgFUS thalamotomy and were followed up for 12 months. A support vector machine regressor (SVR) was used to predict tremor improvement at 12 months post-MRgFUS thalamotomy based on pretreatment brain connectivity. The nonparametric Spearman rank test was used to evaluate the relationship between the top-weighted preoperative FC and tremor improvement ratio.

RESULTS

Fifty-six patients (mean age 63.20 years, SD=9.99, 40 males) showed a 68% tremor improvement at 12 months after treatment. The application of SVR to brain connectivity matrices allowed prediction of tremor responses with statistically significant accuracy (r = 0.38, P-value = 0.03; mean sum of squares = 0.05, P-value = 0.02). The actual tremor improvement ratio was correlated with the top two weighted FCs (Top1: r =-0.39, P-value < 0.01; Top2: r =-0.41, P-value < 0.01). Compared to HCs, the FC with highest weight, decreased at baseline (T = -3.263, P-value = 0.002) and then elevated at 12 months post-operation (T = 3.09, P-value = 0.005) with reaching a normalized trend to HCs (T = -1.139, P-value = 0.257).

CONCLUSION

Preoperative intrinsic brain connectivity, as measured with rs-fMRI, can predict the individual therapeutic effectiveness of MRgFUS thalamotomy using a support vector machine method.

CLINICAL RELEVANCE/APPLICATION

In this cohort study of patients with essential tremor underwent MRgFUS thalamotomy, we achieved a successful prediction of tremor response, with a correlation of 0.38 and a mean sum of squares of 0.05. Furthermore, MRgFUS induced a massive increase in FC between left and right precentral gyrus, which was associated with the tremor responses. The prediction model based on preoperative functional connectivity has excellent predictive capability and holds promise for clinical use.

R5A-SPNR-16 RADIATION-INDUCED EXHAUSTED T CELL EVOLUTION: A CEST-BASED LONGITUDINAL PHENOTYPING STUDY IN GLIOBLASTOMA MOUSE MODELS

Ruili Wei (*Presenter*)
Jiaxin Lin (*Abstract Co-Author*)
Yongzhou Xu (*Abstract Co-Author*)
Ruimeng Yang, MD,PhD (*Abstract Co-Author*)

PURPOSE

Radiotherapy may potentiate the efficacy of immune checkpoint inhibitor (ICI) treatment. However, the optimal timing for this combination therapy remains to be established. Early-exhausted T cells can be reinvigorated by PD-1 blockade, whereas terminally exhausted T cells cannot. This study aimed to determine the optimal timing for combination therapy and developed a CEST radiomics approach to visualize the status of T cell exhaustion.

METHODS AND MATERIALS

GL261-Luc cells were orthotopically implanted into the right striatum of 84 female C57BL/6 mice. Mice underwent whole brain radiotherapy (10 Gy). MRI was performed in indicated timepoints (12 mice per group) on a 9.4 T small animal MRI-scanner. The imaging protocol was composed of conventional sequences and CEST. After MRI scan, mice were euthanized, brains were harvested for flow cytometric analysis using a BD LSRFortessa™ flow cytometer system, and the data were analyzed using FlowJo V10 software (TreeStar). Machine learning was employed to select robust radiomic features and predict T cell exhaustion.

RESULTS

The infiltration of CD8+ T cells increased from day 3 to 5 following radiation, with terminally exhausted T cells becoming predominant in the late phase. This indicates that the period from day 3 to day 5 post-irradiation may represent an optimal therapeutic window for ICI treatment. Longitudinal evaluation of CEST parameters could differentiate the status of T cell exhaustion, which demonstrated good applicability in both ICI and irradiation settings. Moreover, increased heterogeneity in CEST image textures was associated with more advanced T cell exhaustion.

CONCLUSION

We introduce a non-invasive imaging biomarker that precisely evaluates the heterogeneous status of T cell exhaustion associated with ICI treatment and irradiation, potentially offering a reliable method to promptly gauge the immune responsiveness of the tumor microenvironment and pinpoint the optimal timing for combination therapy.

CLINICAL RELEVANCE/APPLICATION

The optimal window of radiotherapy in combination with immune checkpoint inhibitor (ICI) depends on the dynamic monitoring of distinct exhausted subpopulations of CD8+ T cells during peri-irradiation period, which is unavailable via repeated biopsies in clinical practice. This study identified an optimal 3-5 day post-irradiation window for ICI treatment, targeting early-exhausted T cells responsive to PD-1 blockade. The CEST-based signatures offers a non-invasive imaging biomarker to monitor the tumor microenvironment, assess immune responsiveness, and guide personalized treatment timing. Future work may focus on validating these findings in patient cohorts and exploring broader applications in other cancers.

R5A-SPNR-18 RISK FACTORS ASSOCIATED WITH SUBSEQUENT VASCULAR EVENTS IN PATIENTS WITH ACUTE ISCHEMIC CEREBROVASCULAR DISEASE: A HR-VWI STUDY

Jiayuan Hu (*Presenter*)
Shu Wu (*Abstract Co-Author*)
Juan Huang, MMed (*Abstract Co-Author*)
Sheng Jiao, MD (*Abstract Co-Author*)
Yange Chang (*Abstract Co-Author*)
Yan Song, MD, PhD (*Abstract Co-Author*)

PURPOSE

Patients with acute ischemic cerebrovascular disease have a high long-term risk of recurrent vascular events. This study aimed to investigate the imaging characteristics of culprit plaques and clinical factors associated with one-year vascular events recurrence.

METHODS AND MATERIALS

Patients with acute ischemic stroke or TIA admitted to the Neurology Department of Beijing Hospital from January 2020 to August 2023 wereprospectively enrolled and underwent high-resolution vessel wall imaging (HR-VWI). Baseline plaque characteristics were measured, and clinical information was collected. Patients were followed up every three months to inquire about medication status, general conditions, worsening of original symptoms, new onset TIA or cerebral infarction symptoms, and myocardial ischemia or infarction. If any of the above conditions were present, head MRI and HR-VWI was performed. Based on the one-year follow-up results, patients were divided into recurrence and non-recurrence groups for comparison. Univariate and multivariate Cox regression analyses wereused to determine the risk factors for subsequent vascular event recurrence.

RESULTS

A total of 129 patients were recruited, with 97 males (75.19%) and 32 females (24.81%). The median follow-up time was 12.0 (9.95, 12.7) months. During the follow-up period, 29 patients (22.48%) experienced endpoint events. Compared with the non-recurrence group, the recurrence group had a higher proportion of females (41.38% vs. 20.00%, P=0.019), older age (67.38 ± 9.86 vs. 61.55 ± 11.23 years, P=0.013), higher prevalence of diabetes (68.97% vs. 43.00%, P=0.014), higher prevalence of coronary artery disease (31.03% vs. 12.00%, P=0.031), and higher NIHSS scores (4.00 [1.00, 6.00] vs. 1.50 [0.00, 3.00] , P=0.008). Multivariate Cox regression analysis showed that plaque length (HR 0.86, 95%CI 0.77-0.96), remodeling index (HR 7.50, 95%CI 2.15-26.15), intraplaque hemorrhage (HR 5.62, 95%CI 1.12-28.12), coronary artery disease (HR 3.26, 95%CI 1.31-8.11), and NIHSS scores (HR 1.22, 95%CI 1.07-1.39) were independent risk factors for one-year vascular event recurrence.

CONCLUSION

Plaque length, remodeling index, intraplaque hemorrhage, coronary artery disease, and NIHSS scores were independent risk factors for one-year vascular event recurrence in patients with acute ischemic cerebrovascular disease.

CLINICAL RELEVANCE/APPLICATION

Understanding these predictors may enhance patient management by informing personalized treatment strategies and improving long-term outcomes for individuals at high risk of future vascular events.

R5A-SPPD-1 FROM FIRST CASE TO REGIONAL PRACTICE: TEN YEARS OF HYDROSTATIC INTUSSUSCEPTION REDUCTION IN ETHIOPIA

Samuel S. Hailu, MD (*Presenter*)
Bethelhem B. Belachew, MD (*Abstract Co-Author*)
Eyasu K. Wakjira, MD (*Abstract Co-Author*)
Biniyam Beyene Tabor (*Abstract Co-Author*)
Abass Noor, MD (*Abstract Co-Author*)
Kassa Darge, MD, PhD (*Abstract Co-Author*)
Hansel J. Otero, MD (*Abstract Co-Author*)

PURPOSE

Hydrostatic reduction is an effective non-operative treatment for pediatric intussusception, yet its adoption in low-resource settings remains variable. In Ethiopia, hydrostatic intussusception reduction was introduced in 2014 through a collaborative effort with international partners. Our aim is to assess national trends in training, implementation, and sustained practice of pediatric imaged-guided hydrostatic intussusception reduction in Ethiopia.

METHODS AND MATERIALS

A nationwide cross-sectional survey was conducted targeting all radiology graduates in Ethiopia from 2015 to 2024. This cohort, comprising 365 individuals, represents the entire decade following the introduction of the procedure in the country. The questionnaire assessed multiple aspects of hydrostatic reduction practice: exposure during residency, post-graduation practice, current availability at their institutions, perceived obstacles, personal confidence, and beliefs regarding the effectiveness of the technique.

RESULTS

Of 365 potential participants, 184 responded (response rate = 50.4%); 178 respondents from 75 different facilities provided complete data. Most respondents (150, 84.3%) had hydrostatic reduction training during residency, and nearly half (87, 48.9%) reported performing the procedure in routine clinical practice. Of 75 facilities represented, hydrostatic reduction was performed in 46, yielding an institutional adoption rate of 61.3%. Confidence was high, with (133, 75%) graduates expressing readiness to independently perform the procedure. Of the 19 radiologists (18%) who discontinued performing hydrostatic reduction, institutional and system-related factors were the leading causes, such as limited staffing, lack of surgical backup, and referral of cases to advanced care facilities. Eight respondents reported working outside of Ethiopia in 7 different countries, 5 of whom had successfully started and were still performing hydrostatic reduction in their institutions, demonstrating cross-border expansion of skills to Angola, Lesotho, Liberia, Namibia, and Tanzania.

CONCLUSION

A decade after its introduction, hydrostatic reduction has become a widely taught and increasingly practiced procedure among Ethiopian radiologists. Our findings highlight strong individual readiness and measurable clinical benefits yet underline the need for systemic improvements.

CLINICAL RELEVANCE/APPLICATION

This study demonstrates how hydrostatic reduction has been adopted and expanded nationally and regionally, offering a non-operative solution for intussusception in resource-limited settings.

R5A-SPPD-2 ULTRASOUND-GUIDED ATTENUATION PARAMETER FOR ASSESSMENT OF STEATOSIS WITH REFERENCE TO MRI-PDFF IN PEDIATRIC METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE

Jake Weeks, BS (*Presenter*)
Lael Ceriani (*Abstract Co-Author*)
Tanya Wolfson, MS (*Abstract Co-Author*)
Yesenia Covarrubias, MS (*Abstract Co-Author*)
Walter Henderson (*Abstract Co-Author*)
Michael P. Andre, PhD (*Abstract Co-Author*)
Susan Lynch (*Abstract Co-Author*)

Michael S. Middleton, MD, PhD (*Abstract Co-Author*)
Patricia Ugalde Nicalo (*Abstract Co-Author*)
Andrew Wang (*Abstract Co-Author*)
Jeffrey B. Schwimmer, MD (*Abstract Co-Author*)
Claude B. Sirlin, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the correlation, repeatability, and diagnostic accuracy of Ultrasound-Guided Attenuation Parameter (UGAP) for steatosis, with MRI proton density fat fraction (PDFF) as reference, in children with known or suspected metabolic dysfunction-associated steatotic liver disease (MASLD).

METHODS AND MATERIALS

Prospectively enrolled children with known or suspected MASLD underwent MRI (GE Discovery MR750 3.0T) and up to 2 ultrasound exams (GE LOGIQ E10) on the same day. In each ultrasound exam, a study-trained sonographer acquired at least 6 valid UGAP values in a homogeneous region of the right lobe via an intercostal approach; the median and interquartile range (IQR) values were recorded. The median value was considered reliable if the IQR/median < 0.30. Each MRI exam included a PDFF sequence. Study-trained MRI readers placed a region of interest in each right-lobe segment; the mean right-lobe PDFF value was recorded. The relationship between median right-lobe UGAP and mean right-lobe PDFF values were assessed by Spearman rank correlation rho, its p-value, and 95% confidence interval (CIs). Repeatability

was assessed by Bland-Altman analysis with calculation of 95% limits of agreement (LOA), repeatability coefficient (RC), and intraclass correlation coefficient (ICC). For classifying steatosis (defined as PDFF = 5%), area under the receiver operating characteristic curve (AUC) and performance at the Youden index were calculated.

RESULTS

34 children (11 female; age range, 8-18 years) were enrolled. 3 children could not tolerate MRI and were excluded. All median UGAP values were reliable. Median per-child right-lobe UGAP values ranged from 0.51 to 0.88 dB/cm/MHz (mean, 0.70). Mean per-child right-lobe PDFF values ranged from 1.4% to 41.2% (mean, 16.8%). Median right-lobe UGAP correlated positively and significantly with mean right-lobe PDFF (rho = 0.79, $p < 0.001$, 95% CI: 0.60, 0.89). 29 children had a second UGAP exam and were included in the repeatability study. Inter-exam LOA, RC, and ICC were -0.08 to 0.11, 0.1, and 0.889 (95% CI: 0.78 to 0.95), respectively. The diagnostic accuracy of UGAP was excellent (AUC = 0.95). Sensitivity and specificity at the Youden-based cutoff (0.62) were 0.89 and 0.70, respectively.

CONCLUSION

Right-lobe UGAP and MRI were significantly correlated in this pilot study in children with known or suspected MASLD, with high repeatability and diagnostic accuracy. The correlation is of similar strength to that reported previously for adults, but our sample size is small. Future studies with larger cohorts will be necessary to validate these findings.

CLINICAL RELEVANCE/APPLICATION

UGAP shows promising preliminary performance for assessing hepatic steatosis in children.

R5A-SPPH-2 METAL ARTIFACTS REDUCTION USING TILT HELICAL SCAN TECHNIQUE IN CT EXAMINATION (METAL ARTIFACTS CAN BE REDUCED WITH RADIOGRAPHER'S INGENUITY)

Katsumi Tsujioka, RT (*Presenter*)

PURPOSE

In clinical CT examinations, metal artifacts caused by screw bolts fixed to the posterior lumbar interbody region are a problem. The occurrence of metal artifacts may prevent accurate diagnosis. In this case, the long axis of the bolt and the scan plane are often parallel. In this case, the long axis of the bolt and the scan plane are often parallel. In this report, we describe the reduction of metal artifacts by tilting the gantry during CT scanning.

METHODS AND MATERIALS

The phantom has brass rods of 8 mm diameter and different lengths, and an acrylic surface is placed on the tip of the brass rod. The gap between the brass rod and the acrylic surface can be changed to 0 mm and 2 mm. Scans of a homemade phantom were performed at tilt angles of 0 degrees and 30 degrees. Two image reconstruction techniques were used: conventional reconstruction and metal artifact reduction. Metal artifacts were visually evaluated on the MPR display, and the gap between the brass rod and the acrylic surface was measured.

RESULTS

Compared to conventional reconstruction, metal artifact reduction reduced artifacts from metal rods. However, when the direction of the metal rod was performed in the direction of the object, the artifacts were not completely eliminated. Therefore, it was not possible to accurately measure the gap between objects. By tilting the gantry and scanning, metal artifacts are reduced and it is now possible to accurately measure the gap between objects.

CONCLUSION

Metal artifacts are caused by beam hardening. By tilting the CT, metal artifacts can be reduced. Being able to accurately measure the gap at the tip of a metal rod is clinically useful.

CLINICAL RELEVANCE/APPLICATION

Recent CT scans are equipped with software such as metal artifact reduction (MAR). However, these are not perfect technologies. Tilting the gantry during CT scans is technically simple, but it is possible to greatly reduce metal artifacts. We can achieve better examinations by combining MAR and scanning technology. CT has made progress in terms of equipment, but it is also important to innovate in the imaging technique.

R5A-SPPH-3 IMPACT OF A PROTOTYPE, DEDICATED AI-BASED SPECTRAL IMAGE RECONSTRUCTION ALGORITHM ON THE QUALITY OF LOW-KEV MONOENERGETIC VIRTUAL IMAGES: A PHANTOM STUDY

Djamel Dabli (*Presenter*)
Joel Greffier, PhD (*Abstract Co-Author*)
Jean-Paul Beregi, MD, PhD (*Abstract Co-Author*)
Stephan Skornitzke (*Abstract Co-Author*)
Philippe Coulon, PhD (*Abstract Co-Author*)

PURPOSE

To assess the impact of a prototype, dedicated Spectral AI Recon (SAIR) reconstruction algorithm (DLR; Philips Healthcare) on image quality and dose reduction compared with a Hybrid Iterative Reconstruction (HIR) algorithm (Spectral, Philips Healthcare) on low-keV virtual monoenergetic images (VMIs).

METHODS AND MATERIALS

A Multi-Energy CT phantom (Sun Nuclear) was scanned on the dual-layer spectral CT system (Spectral CT 7500) at 120 kVp for three dose levels (3/6/12 mGy). VMIs at 40/50/60/70 keV were generated using the level 4 of HIR algorithm and the levels Standard, Smooth and Smoother of SAIR algorithm. Noise power spectrum (NPS) was computed to assess noise magnitude and noise texture (f av). Task-based transfer function (TTF) was calculated to assess spatial resolution (f 50) on blood-mimicking material plus iodine at 2 mg/mL insert. A detectability index (d') was computed to model the detection task of one contrast-enhanced lesion as function of keV.

RESULTS

For all dose and SAIR levels, noise magnitude was lower with SAIR than HIR and the difference increases from Standard (-13.8 ± 3.3%) to Smoother (-69.2 ± 2.8%) levels. Regarding noise texture, f av values decreased as the dose and energy levels decreased and from Standard to Smoother. For all dose and energy levels, f av values were higher with Standard (4.5 ± 5.4%) than HIR but lower with Smooth (-3.4 ± 5.0%) and Smoother (-24.0 ± 12.7%) levels. Regarding spatial resolution, f 50 values decreased as the dose and energy levels decreased and from Standard to Smoother. For all dose and energy levels f 50 values were higher with Standard level than HIR and were in the same range with Smooth level. For Smoother level, f 50 values were lower than HIR for all dose and energy levels, except at 40 keV and 6 mGy and at 70 keV at 12 mGy. For all dose levels and all keV, d' values were higher with SAIR levels than HIR and this difference increased from Standard (34.8 ± 5.2%) to Smoother (302.6 ± 37.0%).

CONCLUSION

Compared to HIR algorithm used in clinical practice for low-keV VMIs, the three levels of SAIR reduced image noise and improved the detectability for contrast-enhanced lesions. The impact on noise texture and spatial resolution depends on the SAIR level used.

CLINICAL RELEVANCE/APPLICATION

Compared to HIR algorithm used in clinical practice for low-keV VMIs, the three levels of SAIR reduced image noise and improved the detectability for contrast-enhanced lesions. The impact on noise texture and spatial resolution depends on the SAIR level used.

R5A-SPPH-4 EVALUATION OF RECONSTRUCTION KERNELS AND RESOLUTION TECHNIQUES FOR VOLUMETRIC ACCURACY OF GROUND-GLASS OPACITY NODULES IN LOW-DOSE PHOTON-COUNTING CT

Elsa Pimenta, MSc, MSc (*Presenter*)
Gisell Ruiz Boiset (*Abstract Co-Author*)
Alessandra Tomal, PhD (*Abstract Co-Author*)
Luuk J. Oostveen, DIPLPHYS (*Abstract Co-Author*)
Ioannis Sechopoulos, PhD (*Abstract Co-Author*)
Paulo Costa, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate the impact of reconstruction kernel and resolution techniques with a photon-counting computed tomography (PCCT) system on the volumetric accuracy of ground-glass opacity (GGO) nodule.

METHODS AND MATERIALS

A PCCT (photon-counting computed tomography) system (Canon Medical Systems Corporation) was used for image acquisition of the patient-based anthropomorphic lung phantom. Image acquisition protocols were performed at six CTDI vol (Computed Tomography Dose Index volume) dose levels from 0.3 to 2.7 mGy. The reconstruction techniques used included hybrid iterative reconstruction (HIR) methods (AIDR 3D, Canon Medical Systems Corporation) in combination with specific reconstruction kernels, such as FC52 and FC51 with normal resolution (NR; pixel size = 0.782 mm^2) and high resolution (HR; pixel size = 0.390 mm^2) settings, using a focal spot size of 0.4/0.5 mm. Ten acquisitions were performed for each protocol. The volume of the GGO-type synthetic nodule was measured based on CT images using 3D Slicer (version 5.6.2, Slicer Community) and compared with its ground truth (142 mm^3) determined by the µCT system (U-SPECT6CThr, MILabs B.V., Netherlands).

RESULTS

The FC51/HR protocol showed the most accurate performance, with median relative errors (RE%) below 5% and narrow interquartile ranges (IQRs), at low doses (0.3 and 0.5 mGy). The FC51/NR protocol had higher variability, with RE% over 10% at 0.3 mGy and doubling at 0.5 mGy. The FC52/HR had RE% of 5.8% (IQR: 2.8%) at 0.3 mGy, while the FC52/NR protocol had the highest RE%, surpassing 25% at 0.3 mGy and 30% at 0.5 mGy. As dose increased accuracy improved for all protocols. The FC51/HR protocol had RE% levels below 4% and the FC51/NR protocol reduced to around 5-7%. At 1.1 mGy, RE% for the FC52/HR protocol was close to 3%, while for the FC52/NR protocol, RE% ranged from approximately 6-8%. At 1.4 and 2.7 mGy, protocols became less distinguishable. The FC51/NR and FC52/HR protocols had similar performance at 1.4 mGy, while the FC51/NR protocol remained stable and the FC52/NR approached 10%, with reduced variability.

CONCLUSION

FC51/HR protocol exhibited consistent superior volumetric accuracy across all dose levels, particularly under low-dose conditions where precise measurements are most challenging. The differences among all protocols became less pronounced at higher dose levels. This finding underscores the benefits of high-resolution reconstruction in preserving measurement precision while minimizing radiation exposure.

CLINICAL RELEVANCE/APPLICATION

This study underscores the clinical significance of selecting suitable reconstruction protocols for precise volumetric evaluation of GGO-type nodules at low-dose CT.

R5A-SPPH-5 A DIRECT COMPARISON OF TWO ULTRASOUND CONTRAST AGENT'S PERFORMANCE IN SUBHARMONIC-AIDED PRESSURE ESTIMATION (SHAPE) FOR NONINVASIVE EVALUATION OF PORTAL HYPERTENSION

Hailee Mayer, BS (*Presenter*)
Priscilla Machado, MD (*Abstract Co-Author*)
Trang Vu (*Abstract Co-Author*)
Michael C. Soulen, MD (*Abstract Co-Author*)
Susan M. Schultz, BA (*Abstract Co-Author*)
Antonina Antonenko (*Abstract Co-Author*)
Jaime Bosch, MD (*Abstract Co-Author*)
Annalisa Berzigotti (*Abstract Co-Author*)
Kirk Wallace, PhD (*Abstract Co-Author*)
Flemming Forsberg, PhD (*Abstract Co-Author*)

PURPOSE

Portal hypertension (PH) is the most common consequence of chronic liver disease and is marked by increased pressures in the portal venous system. Current invasive clinical standard to assess the degree of portal hypertension involves hepatic vein catheterization with a balloon-tip catheter to measure the wedged and free hepatic vein pressures after inflating and releasing the balloon. The difference between the two represents the hepatic venous pressure gradient (HVPG, in mmHg). HVPG measurement cannot be repeated frequently and thus limits real-time assessment of a patient's disease. Subharmonic-aided pressure estimation (SHAPE) is a novel ultrasound-based technique for non-invasive pressure estimation. SHAPE uses the subharmonic responses of ultrasound contrast agents (UCA's) to estimate changes in hydrostatic pressure. The objective of this study is to compare the ability of SHAPE to assess PH in patients undergoing hepatic vein catheterization, using both Sonazoid (GE HealthCare) and Definity (Lantheus Medical Imaging). The hypothesis is that Definity is not inferior to Sonazoid for SHAPE-based HVPG estimation.

METHODS AND MATERIALS

26 subjects undergoing hepatic vein catheterization have been enrolled in this ongoing, multi-center, IRB-approved study and had their data analyzed. Sonazoid and Definity were administered in random order, with a 30-minute washout period in between the two exams. SHAPE was performed using a LOGIQ E10 (GE HealthCare) with a C1-6 probe (tx: 2.5 MHz, rx: 1.25 MHz) in the commercially available subharmonic imaging mode. A calibration algorithm was used to allow for optimization of acoustic pressures on an individual subject basis, then 3-5 five second cine clips were obtained with the portal and hepatic vein at similar depths. Offline, an ROI was placed in both veins to acquire the subharmonic amplitude of each, and the SHAPE gradient was calculated as the difference in subharmonic signal between the two veins and was compared to the HVPG using linear regression. The slope of the linear models indicated that agent's SHAPE sensitivity for estimating HVPG. Analysis of covariance was performed to test for inferiority between the two agents.

RESULTS

Linear regression analysis resulted in a sensitivity of 0.43 dB/mmHg for both Sonazoid and Definity. ANCOVA revealed that there was no significant difference between the linear models for Sonazoid and Definity ($p = 0.98$).

CONCLUSION

These preliminary results suggest both Sonazoid and Definity are suitable for PH evaluation with SHAPE and that Definity is not inferior to Sonazoid in this application.

CLINICAL RELEVANCE/APPLICATION

SHAPE may be used as a reliable tool to estimate portal pressures, allowing for noninvasive evaluation as opposed to hepatic vein catheterization.

R5A-SPPH-7 LOW-DOSE HIGH RESOLUTION IMAGING IN MOBILE PHOTON-COUNTING DETECTOR CT: A VALIDATION STUDY FOR PEDIATRIC PROTOCOLS

Junyoung Park (*Presenter*)
Su-Jin Park (*Abstract Co-Author*)
Kwanhee Han (*Abstract Co-Author*)
Sukanya Iyer (*Abstract Co-Author*)
Raeef Istfan (*Abstract Co-Author*)
Yuechen Qian, PhD (*Abstract Co-Author*)
Jinwook Jung (*Abstract Co-Author*)

PURPOSE

The purpose of this study is to validate low-dose high resolution imaging using mobile photon-counting detector CT (PCD-CT) for pediatric protocols.

METHODS AND MATERIALS

To validate the performance of mobile PCD-CT, we conducted a comparative analysis with mobile EID-CT in pediatric imaging protocols. Using the OmniTom Elite with PCD and OmniTom Elite with EID, we acquired pediatric brain and lung scans at a tube voltage of 80 kV across various radiation dose levels. A 5-year-old phantom (CIRS Model 715) was used for this purpose. Quantitative parameters, including CNR and SNR, were measured and compared. Additionally, two radiologists qualitatively assessed the sharpness, overall image quality, and visibility of small anatomical structures. Radiation dose was compared by measuring CTDI vol for both PCD-CT and EID-CT. Furthermore, patient images from ICU were analyzed to evaluate the performance of both systems in clinical settings.

RESULTS

Quantitative analysis of the head scan revealed that PCD-CT achieved higher CNR (87.01 vs. 70.51) and SNR (139.86 vs. 102.07) than EID-CT at the same radiation dose (14.96 mGy) in pediatric protocols. To achieve equivalent CNR, the CTDI vol of PCD-CT and EID-CT were 10.27 mGy and 14.96 mGy, respectively, demonstrating a 31% dose reduction by PCD-CT. Qualitative assessment of the lung scan showed superior image quality for PCD-CT, with significantly higher spatial resolution in pediatric small anatomical regions, such as the temporal bone, pulmonary arteries, and lung nodules, compared to EID-CT. In ICU patient images, PCD-CT exhibited slightly lower CNR than EID-CT but achieved a 47% radiation dose reduction (white and gray matter: 1.66 vs. 2.09; ventricle: 5.12 vs. 6.06; hemorrhage: 8.23 vs. 9.16).

CONCLUSION

Our results demonstrate that mobile PCD-CT significantly reduces radiation dose compared to EID-CT while maintaining high-resolution imaging capabilities in pediatric protocols. This study highlights the potential of mobile PCD-CT as a valuable solution for pediatric imaging, particularly for critically ill patients who face risks associated with transportation and life-threatening conditions. By providing high-quality images at reduced radiation exposure, PCD-CT offers a promising approach for pediatric protocols.

CLINICAL RELEVANCE/APPLICATION

The low-dose high-resolution characteristics of mobile PCD-CT are critical for pediatric imaging protocols. Minimizing radiation exposure is essential for pediatric patients, who are highly sensitive to radiation. The high-resolution capabilities of PCD-CT enable precise delineation of anatomy and characterization of abnormalities in pediatric patients, where anatomical structures are significantly smaller than in adults.

R5A-SPPH-8 SIZE AND CONTRAST THRESHOLDS FOR LIVER LESION DETECTION IN REGULAR AND LOW-DOSE CT EXAMINATIONS: A READER STUDY OF 2,300 SYNTHETIC LESIONS ACROSS 100 PATIENTS

Paul Jahnke, MD (*Presenter*)
Li Yan (*Abstract Co-Author*)
Ulrich Genske (*Abstract Co-Author*)
Yang Peng (*Abstract Co-Author*)
Angelo Laudani (*Abstract Co-Author*)
Katharina Beller (*Abstract Co-Author*)
Thula C. Walter-Rittel, MD (*Abstract Co-Author*)
Moritz Wagner, MD (*Abstract Co-Author*)
Bernd K. Hamm III, MD (*Abstract Co-Author*)

PURPOSE

To determine the size and contrast required for liver lesion detection in oncologic and low-dose CT examinations.

METHODS AND MATERIALS

We collected 100 abdominal CT datasets retrospectively, with 50 from vendor A and 50 from vendor B. Each scanner had half the datasets using a regular dose oncologic protocol and half using a low-dose kidney stone protocol. Cylindrical liver lesions with 23 different combinations of size and contrast were synthetically inserted. A four-alternative forced choice reader experiment was conducted to determine lesion detectability, and image noise was measured within the liver.

RESULTS

Detection thresholds at regular dose were -30, -35, and -70 HU (vendor A) and -25, -35, and -65 HU (vendor B) for 15-, 10-, and 5-mm lesion diameters, respectively. At low dose, thresholds were -40 and -45 HU (vendor A) and -40 and -50 HU (vendor B) for 15- and 10-mm lesions, while 5 mm lesions were not reliably detectable. Noise levels were 21.5±2.3 HU (vendor A) and 25.9±4.9 HU (vendor B) at regular dose, and 22.2±2.0 HU (vendor A) and 30.9±3.1 HU (vendor B) at low dose.

CONCLUSION

In oncologic CT exams, liver lesions require contrasts of -30, -35, and -70 HU for reliable detection at 15-, 10-, and 5-mm diameters. In low-dose exams, the required contrasts increase to 40 and 50 HU for 15- and 10-mm lesions, while 5 mm lesions cannot be detected with confidence despite up to 70 HU lesion contrast.

CLINICAL RELEVANCE/APPLICATION

1. Higher contrast improves detection of smaller lesions, but is less important for larger lesions over 10 mm in diameter. 2. Dose reduction increases noise differently across CT vendors, yet lesion size and contrast detection remain consistent, making noise an unreliable predictor of detection accuracy. 3. Our results establish detection thresholds to support patient assessment and future liver lesion detection research.

R5A-SPPH-9 DEEPCT: A GENERAL DEEP LEARNING-BASED MODEL FOR CT IMAGE RESTORATION

Thomas C. Arnold, PhD (*Presenter*)
Zhihao Zhang (*Abstract Co-Author*)
Lei Xiang (*Abstract Co-Author*)
Qi Yang, MD (*Abstract Co-Author*)

PURPOSE

Reducing radiation dose while maintaining diagnostic-quality CT remains a key clinical goal. However, strategies such as lowering tube voltage/current, reducing views, or using static CT often introduce noise and artifacts, including sparse-view, nonuniform-view, and metal artifacts. To address this, we developed DeepCT, a general deep

learning model for restoring image quality across diverse CT degradations.

METHODS AND MATERIALS

A dataset of 860,000 training pairs was constructed, including low-dose CT images and corresponding normal-dose images with simulated artifacts. Nonuniform-view artifacts were generated by modeling the imaging mechanism of static CT.DeepCT was trained to jointly denoise and remove artifacts in both spiral and static CT images. To improve perceptual realism, a Noise Power Spectrum (NPS) loss guided the learning of natural noise textures by modeling spatial correlations. A Window-Range Focused (WRF) strategy improved training efficiency by focusing on clinically relevant intensity ranges.Evaluation was conducted on clinical low-dose (<40%) CT datasets from multiple hospitals, comprising 50 spiral and 50 static CT cases. Noise texture was assessed using 2D NPS, while PSNR, SSIM, and MAE were used to measure similarity to the corresponding normal-dose images.The effect of the NPS loss was evaluated using an abdominal enhanced CT case. The impact of the WRF strategy was assessed by tracking PSNR, SSIM, and MAE across epochs on the mediastinal window.

RESULTS

Compared to baseline methods, DeepCT achieved superior denoising and artifact removal, with more realistic textures, fewer HU deviations, and better anatomical detail preservation. It obtained the highest SSIM (0.873 ± 0.041), PSNR (28.91 ± 0.088), and the lowest MAE (2.2 ± 0.48), highlighting its advantage in both visual quality and quantitative metrics.Ablation studies on different loss functions showed that L1 and L1+SSIM produced over-smoothed textures, while perceptual loss failed to preserve fine vascular structures. In contrast, NPS loss maintained structural fidelity and generated noise patterns closer to normal-dose CT, as confirmed by 2D NPS analysis. The WRF strategy further enhanced DeepCT's performance by improving training stability and image quality within clinically relevant intensity ranges.

CONCLUSION

DeepCT is a general image restoration model trained on large-scale low-dose and simulated-artifact datasets using NPS loss and the WRF strategy, capable of achieving diagnostic-quality images comparable to normal-dose CT scans.

CLINICAL RELEVANCE/APPLICATION

DeepCT restores diagnostic-quality images from low-dose CT scans, enabling radiation dose reduction while also prolonging X-ray tube lifespan.

R5A-SPPH-10 CONFOUNDING EFFECT OF TEMPERATURE ON CHEMICAL SHIFT-ENCODED TRANSVERSE RELAXATION RATE (R2*) AND PROTON DENSITY FAT FRACTION (PDFF)

Felix Schoen (*Presenter*)
Florian Brandt (*Abstract Co-Author*)
Sophia Blum, MD (*Abstract Co-Author*)
Marie-Luise Kromrey, MD (*Abstract Co-Author*)
Ralf-Thorsten Hoffmann, MD (*Abstract Co-Author*)
Jens P. Kuehn (*Abstract Co-Author*)

PURPOSE

Chemical shift encoded magnetic resonance imaging (CSE-MRI) is widely used to determine the transverse relaxation rate (R2*) and proton density fat fraction (PDFF) as quantitative biomarkers for the assessment of liver iron and fat. Our aim was to investigate the impact of temperature changes on R2* and PDFF.

METHODS AND MATERIALS

Two agarose-based MRI phantoms were constructed, each containing vials filled with either 1) ferucarbotran-based MRI contrast agent or 2) peanut oil to modulate R2* and PDFF effects, respectively. The target concentrations for ferucarbotran and peanut oil were 16 µg/ml, 42 µg/ml, 70 µg/ml, 98 µg/ml, 126 µg/ml and 10%, 20%, 30%, 40%, respectively. The phantoms were evaluated at 3.0T CSE-MRI with five echo times across six different temperature levels (6 °C, 20 °C, 35 °C, 37 °C, 39 °C, and 41 °C). CSE-MRI datasets were post-processed to generate R2* and PDFF maps. Three measurements were performed in each vial. Results were evaluated using Intra-Class Correlation (ICC) to test for homogeneity within the vials and linear regression analysis to investigate temperature dependencies.

RESULTS

R2* and PDFF maps were obtained with homogenous values across all vials (ICCs = 1.00). Overall, R2* and PDFF values demonstrated a linear increase with rising concentrations of ferucarbotran and oil, respectively, across all temperature levels (coefficient of determination [R^2]: 0.990 - 0.999 for R2* and R^2: 0.964 - 0.999 for PDFF; both $p < 0.001$). For R2*, increasing temperatures were associated with decreasing values (slope: 7.90 at 6 °C and 5.92 at 41 °C). The average percentage decrease per °C in R2* ranged from -0.68% at 16 µg/ml to -0.50% at 126 µg/ml ferucarbotran concentration. For PDFF, increasing temperatures were associated with an increase in PDFF values (slope: 0.894 at 6 °C and 1.367 at 41 °C). The average percentage increase per °C in PDFF ranged from +0.87% at 10% to +1.42% at 40% oil concentration.

CONCLUSION

Temperature is a confounding factor for R2* and PDFF quantification, potentially causing significant deviations across different temperature levels. Therefore, studies for fat and iron quantification should incorporate algorithms to compensate for temperature effects.

CLINICAL RELEVANCE/APPLICATION

The results emphasize the need for temperature-compensating algorithms in fat and iron quantification to ensure accurate measurements, as temperature differences between a potentially cooler phantom compared to in-vivo conditions may lead to significant deviations.

R5A-SPVA-1 COMPARISON OF CORONARY CTA IMAGE QUALITY DURING SYSTOLE UNDER DIFFERENT ALGORITHMS

Shikuan Li (*Presenter*)
Feng Chen, MD, PhD (*Abstract Co-Author*)
Weiyuan Huang (*Abstract Co-Author*)
Xin Qin (*Abstract Co-Author*)
Kun Ma (*Abstract Co-Author*)

PURPOSE

To evaluate the image quality of coronary CTA during systole using deep learning image reconstruction (DLIR-H) combined with the second-generation motion correction technique (SnapShot Freeze 2, SSF2) and compare it with traditional methods (ASIR-V50% + SSF2 and ASIR-V50% + SSF1), providing a basis for high-quality imaging in patients with atrial fibrillation.

METHODS AND MATERIALS

This retrospective study included 30 patients with atrial fibrillation who underwent coronary CTA during systole.Three reconstruction algorithm combinations were used:Group 1: DLIR-H + SSF2;Group 2: ASIR-V50% + SSF2;Group 3: ASIR-V 50% + SSF1.?Quantitative Metrics?: CT value, noise standard deviation (SD), signal-to-noise ratio (SNR), contrast-to-noise ratio (CNR), and artifact index (AI).?Subjective Scoring?: A 5-point scale (1 = non-diagnostic, 5 = excellent) was used by two independent reviewers. Weighted Kappa coefficients (k = 0.8 indicating excellent agreement) were calculated to assess inter-observer consistency.

RESULTS

Right Coronary Artery : DLH + SSF2 showed the lowest SD values, highest SNR and CNR, and relatively lower AI across all segments (proximal, mid, and distal).AR50% + SSF1 performed the worst, with the highest SD values, lowest SNR and CNR, and higher AI. Left Coronary Artery : For the left main coronary artery, proximal left anterior descending artery, and proximal circumflex artery, DLH + SSF2 again demonstrated the lowest SD values, highest SNR and CNR, and relatively lower AI. Aortic Root : There were no significant differences in CT values among the three algorithm combinations. DLH + SSF2 showed the best performance in SNR and CNR, with relatively lower SD values and AI. Pairwise Comparisons ?DLH + SSF2 vs AR50% + SSF2?: Significant reductions in SD values ($P < 0.05$), increases in SNR and CNR by approximately 15%-20%, and decreases in AI by 30%-40% in the right coronary artery.

CONCLUSION

The combination of DLIR-H and SSF2 significantly reduces noise and motion artifacts, enhances image contrast and clarity, and outperforms traditional iterative reconstruction techniques (ASIR-V50%) in coronary CTA during systole. This technological advantage provides important support for precise diagnosis in patients with atrial fibrillation and high-quality imaging in the presence of arrhythmia, demonstrating significant clinical application potential.

CLINICAL RELEVANCE/APPLICATION

By significantly improving image quality, reducing noise, and artifacts, the combination of DLIR-H and SSF2 offers a more efficient and precise solution for coronary CTA examinations in patients with atrial fibrillation, holding clear clinical application prospects.

R5A-SPVA-2 AI-POWERED AUTOMATED DETECTION, SEGMENTATION, AND QUANTIFICATION OF PERIPHERAL ARTERIAL LESIONS ON CTA AXIAL IMAGES

Amin Katouzian, PhD (*Presenter*)
Kourosh Jafari-Khouzani, PhD (*Abstract Co-Author*)
Raj P. Shah, MD, MBA (*Abstract Co-Author*)
Justin Kline (*Abstract Co-Author*)
Sameer Suman (*Abstract Co-Author*)

PURPOSE

To develop and validate a novel AI pipeline for automated peripheral arterial disease assessment (PAD) on CTA, addressing three critical needs: 1) accelerating radiologist interpretation time, 2) replacing subjective qualitative assessments with accurate quantitative stenosis measurements, and 3) providing the first comprehensive end-to-end automated solution for peripheral arterial lesion analysis.

METHODS AND MATERIALS

We developed a two-stage AI pipeline processing CTA series from aorta to ATA bifurcation. From 500 patients, we excluded studies with stents, bypass grafts, or imaging artifacts, yielding 406 studies for training/validation and 58 for testing. Annotators provided labels for seven landmarks (aorta, common iliac, external iliac, common femoral, superficial femoral, popliteal, ATA bifurcation) and drew lumen/lesion contours. The landmark model used ResNet18 feature extraction, mean pooling, and fully connected regression layer, outputting values [1,7], each representing a landmark, using MSE loss. Results defined anatomical boundaries, limiting subsequent processing to slices between aorta and ATA bifurcation. A 2D bidirectional convolutional double-head U-Net was trained to segment lumen and lesion using Dice loss. Stenosis was automatically calculated, and studies flagged having lesions greater than 50% stenosis.

RESULTS

The landmark identification model achieved MSE of 0.0361 (SD: 0.0069, 95% CI: [0.03415, 0.03796]) on test set. For segmentation, we achieved 2D Dice scores of 91% and 66% for lumen and lesion respectively using 5-fold cross-validation on validation set (82 studies). On test set, we achieved 90% and 62% Dice for lumen and lesion. At patient-level for detecting lesions with greater than 50% stenosis, we achieved 92% sensitivity and 99% specificity on test set. When applied to 100 reportedly normal studies, our model identified 8 which had at least one lesion with greater than 50% stenosis that were missed in original radiology reports.

CONCLUSION

This first-of-its-kind AI pipeline successfully automated the entire workflow for PAD assessment on CTA axial series, providing accurate lesion detection and quantification comparable to expert interpretation while significantly reducing reading time.

CLINICAL RELEVANCE/APPLICATION

This novel AI solution represents a paradigm shift from subjective to objective PAD assessment, providing standardized quantitative measurements across institutions. It significantly improves radiologist efficiency, enables consistent disease monitoring, and facilitates data-driven clinical decision-making in PAD management.

R5A-SPVA-3 APPLICATION VALUE OF SPECTRAL CT MONOENEGY IMAGING COMBINED WITH DLIR IN CT ANGIOGRAPHY OF SUSPECTED PULMONARY EMBOLISM

Gaoyang Liu (*Presenter*)
Maofen Shi (*Abstract Co-Author*)
Suping Chen (*Abstract Co-Author*)
Lei Wu (*Abstract Co-Author*)

PURPOSE

To explore the impact of deep - learning - based image reconstruction algorithms on image quality and embolus display in pulmonary embolism patients' dual - energy CT pulmonary angiography (CTPA) virtual monochromatic imaging.

METHODS AND MATERIALS

In this retrospective study, 35 patients with pulmonary embolism who underwent dual-energy CTPA were enrolled. Virtual monochromatic images (VMIs) at 40 keV, 50 keV, and 60 keV were reconstructed using 50% ASIR-V and three different intensity deep learning reconstruction algorithms (DLIR-H, DLIR-M, and DLIR-L).Measure the CT values and SD values of the target regions, using the SD value of the erector spinae muscle as background noise to compute the SNR and CNR. Additionally, calculate the CNR for the embolus versus the normal-filled vessel.Two physicians subjectively scored overall image quality, thrombus visualization, and image noise on a scale of 0-5. Repeated - measures ANOVA and Friedman test were employed to compare inter - group differences.

RESULTS

With the same reconstruction algorithm, the SD, SNR, CNR of the pulmonary artery and clot - specific CNR decrease as keV increases. At the same keV, DLIR - H and DLIR - M algorithms show better objective image - quality parameters (all $P<0.05$), with DLIR - H the best - performing; but 50% ASIR-V and DLIR-L show no statistically significant differences (all $p>0.05$). The vascular noise of 50 keV DLIR-H images was lower than that of 60 keV ASIR-V images. At the same keV, DLIR-H had the highest thrombus-specific CNR of the three reconstruction methods, which was higher than that of ASIR-V and DLIR-L ($P<0.05$). The CNR of 40 keV DLIR-H was the highest among all. In subjective scores of overall image quality and noise, scores increased with increasing keV. At the same keV level, DLIR-H perform the best.Moreover, 50 keV DLIR-H images showed no statistically significant difference in scores compared to 60 keV ASIR-V images.In thrombus visibility score assessment, DLIR also led to an improvement, with DLIR-H delivering the most remarkable enhancement.

CONCLUSION

DLIR can remarkably reduce image noise of DE CTPA monochromatic images, improve the image quality of low - energy images from ASIR - V reconstruction, which were previously underused due to excessive noise, and sustain higher vessel enhancement and thrombus - depicting ability.

CLINICAL RELEVANCE/APPLICATION

Under ASIR-V reconstruction, low-energy images, despite high enhancement, are clinically unacceptable due to excessive noise. However, DLIR, particularly DLIR-H, can substantially reduce image noise. This makes low-energy images clinically applicable and is expected to enhance the detection of pulmonary embolism and even occult clots.

R5B-SPBR-1 OPTIMIZING AI POSITIVE FINDINGS ON PRIOR NEGATIVE MAMMOGRAMS FOR CONTRALATERAL BREAST CANCER DETECTION AFTER BREAST CANCER SURGERY: DISTINGUISHING TRUE FROM FALSE POSITIVES

Eun Kyung Park, MD, PhD (*Presenter*)
Nariya Cho, MD, PhD (*Abstract Co-Author*)
Ji-Jung Jung (*Abstract Co-Author*)
Hong-Kyu Kim (*Abstract Co-Author*)
Eunhye Kang (*Abstract Co-Author*)
Wonshik Han (*Abstract Co-Author*)

PURPOSE

Artificial intelligence (AI) systems can often accurately localize the missed cancers on prior mammograms before cancer diagnosis. However, for AI marks to lead to earlier cancer detection, radiologists must respond to them even without obvious suspicious findings. Therefore, this study aimed to identify the characteristics of true-positive (TP) AI marks on prior mammograms in which contralateral breast cancer (CBC) subsequently developed in women who had undergone breast cancer surgery, in comparison with false-positive (FP) AI marks observed in a control group.

METHODS AND MATERIALS

Between 2000 and 2018, 454 surveillance mammograms performed prior to CBC diagnosis and 460 matched controls without CBC were identified from a cohort of 15859 women (median age, 53 years [IQR, 46-60 years]) who had undergone breast cancer surgery. A commercial AI system (AI score, 0-100) was retrospectively applied to the mammograms. AI marks were considered TP if the score exceeded 10 and correctly localized subsequent cancer. FP marks were defined as those were benign or remained negative after = 2 years. Two radiologists classified AI findings by suspicion level (0, normal; 1, uncertain; 2, probably benign; 3, suspicious), lesion type (mass, asymmetry, architectural distortion, calcifications, and mass with calcifications), and presence of an adjacent vessel sign (a vessel converging toward the marked area) in consensus without clinical information. TP and FP groups were compared using the Wilcoxon rank-sum test and Fisher's exact tests.

RESULTS

Twenty-eight TP marks were identified a median of 7 months (range, 1-23 months) prior to CBC diagnosis and 66 FP marks were identified. The median AI score was significantly higher in TP than in FP marks (32.5 [IQR, 17.5-64.5] vs. 14.7 [IQR, 11.8-21.3]; P <.001). Compared to FP, TP mark findings more frequently showed high suspicion level (3: 68% [19/28] vs. 15% [10/66]; P <.001), was more associated with masses or architectural distortion (46% [13/28] vs. 8% [5/66]; P <.001), and showed a more adjacent vessel sign (50% [14/28] vs. 9% [6/66]; P <.001).

CONCLUSION

AI system correctly identified early signs of CBC in 6.2% of the CBC group, with a median of 7 months before diagnosis. TP marks were associated with significantly higher AI scores, more suspicious imaging features, and more frequent adjacent vessel sign compared to FP marks.

CLINICAL RELEVANCE/APPLICATION

Differentiating features between true and false positive AI marks enables radiologists to use AI systems for early detection of contralateral breast cancer while minimizing false recalls during postoperative surveillance, providing valuable guidance for refining radiologist-AI interaction.

R5B-SPBR-2 LEVERAGING THE DIAGNOSTIC COMPLEMENTARITY BETWEEN AI AND HUMAN READING TO REACH SUPERIORS OUTCOMES IN BREAST SCREENING

Annie Ng, PhD (*Presenter*)
Clarisse De Vries (*Abstract Co-Author*)
Gerald Lip, MBBCh, FRCR (*Abstract Co-Author*)
Roger T. Staff, PhD (*Abstract Co-Author*)
Peter D. Kecskemethy, PhD (*Abstract Co-Author*)
Ben Glocker, PhD (*Abstract Co-Author*)
Lesley A. Anderson, PhD,MPH (*Abstract Co-Author*)

PURPOSE

Double reading breast screening employs two human readers who ideally catch each other's errors to improve clinical outcomes, demonstrating diagnostic complementarity. As AI and human readers have different strengths and weaknesses, diagnostic complementarity can be enhanced when using AI in complementing workflows. Use of AI in dual roles, as an independent reader (IR) and additional reader (XR), has demonstrated significantly improved clinical and operational outcomes. This study assesses the diagnostic complementarity between first and second human readers versus standalone AI with single human reading, a key element in how AI-integrations can be so effective and beneficial.

METHODS AND MATERIALS

In a Scottish prospective service evaluation (N=10,899; Feb-Oct 2024), an AI system was deployed as an XR to flag cases for additional review, not recalled by standard double reading (DR). The AI was deployed live at a balanced sensitivity-specificity operating point (OP A2) and simulated at a higher-specificity OP (A1). The AI as an IR, acting as the second reader when it agreed with the first reader to not recall a case, was modelled at OP A2 and at a higher-sensitivity OP A3. This enabled four IR+XR combination AI workflows that use the AI at four OP combinations: 1) A2 and A1, 2) A2 and A2, 3) A3 and A1, and 4) A3 and A2, respectively, for the IR and XR roles. AI workflows 1-4 were compared to DR and assessed in terms of cancer detection rate (CDR), recall rate (RR), positive predictive value (PPV), and workload savings. Non-inferiority (a=0.05) was tested for CDR, RR, and PPV; superiority was tested when non-inferiority passed (a=0.1). The relative differences in sensitivity (SEN) and specificity (SPEC) between first (R1) and second readers (R2) and between standalone AI at OP A1-3 with R1 were compared.

RESULTS

All AI workflows 1-4 resulted in significant improvement across all metrics; superiority tests passed for CDR, RR, and PPV, and modelled workload savings were between 31-37%, except AI workflow 4 passing non-inferiority, but not superiority for RR. Relative differences between R1 and R2 were 2.0% for SEN and 1.3% for SPEC. Relative differences between AI and R1 were 3.0-9.9% for SEN and 4.1-17.2% for SPEC.

CONCLUSION

Greater SEN-SPEC diagnostic differences were demonstrated between AI and R1 compared to R1 and R2. Such differences have been leveraged to optimize diagnostic complementarity resulting in multiple AI-integrations that provide superior clinical outcomes and modelled operational outcomes.

CLINICAL RELEVANCE/APPLICATION

When the different performance of AI and human readers are leveraged to optimize diagnostic complementarity, superior clinical and operational outcomes can be achieved, demonstrating the power of complementing AI workflows.

R5B-SPBR-4 FACTORS DRIVING TIMELY COMPLETION OF SCREENING MAMMOGRAPHY EPISODES OF CARE

Anisha Konanur, MD (*Presenter*)
Yingke Xu (*Abstract Co-Author*)
Suzanne Kolb (*Abstract Co-Author*)
Mary Grace Asirot (*Abstract Co-Author*)
Janie M. Lee, MD, MSc (*Abstract Co-Author*)
Christoph I. Lee, MD,MS (*Abstract Co-Author*)
Marissa B. Lawson, MD (*Abstract Co-Author*)

PURPOSE

To evaluate disparities in timely diagnostic follow-up after positive screening mammography based on woman- and neighborhood-level social determinants of health (SDOH) using two composite measures, Area Deprivation Index (ADI) and County Health Rankings Health Factors (CHR).

METHODS AND MATERIALS

Positive screening mammograms—with a Breast Imaging Reporting and Data System (BI-RADS) 0 assessment and recommendation for additional imaging—obtained January 2010-December 2022 in women 40-89 years old were included. Diagnostic exams, defined as first follow-up mammogram or ultrasound, were positive if the final BIRADS assessment was 4 or 5, recommending biopsy. Woman-level variables included age, self-reported race and ethnicity, breast density, first-degree family history or personal history of breast cancer, prior biopsy, and time from last mammogram. Neighborhood-level SDOH were ADI quartiles (1 st quartile as the lowest deprivation) and CHR quartiles (1 st quartile as the healthiest). Median time with interquartile range (IQR) in days for three distinct diagnostic intervals was assessed: screening mammography to diagnostic exam, diagnostic exam to biopsy, and screening to biopsy. Two bootstrapped quantile regression models evaluated associations between woman- and neighborhood-level factors and timeliness metrics, using ADI or CHR.

RESULTS

There were 11,854 positive screening mammograms and 2,957 diagnostic exams. Median (IQR) time in days was 15.0 (11.2-27.3) from screening to diagnostic imaging, 3.0 (0-6.0) from diagnostic to biopsy, and 19.8 (14.1-35.3) from screening to biopsy, adjusting for ADI. Asian, Black and Hispanic women often experienced longer diagnostic intervals. For example, Hispanic women waited 3.6 (95% CI: 2.2, 4.7) days longer than White women between screening and diagnostic exams when adjusting for woman-level factors and ADI ($p<0.001$). Women in the highest ADI areas had 3.7 (95% CI: 2.4, 4.9) more days between screening and diagnostic exams and 3.9 (95% CI: 1.1, 7.2) more days between screening and biopsy than women in lowest ADI areas ($p<0.001$). Compared to women in the healthiest CHR counties, patients in the least healthy CHR counties had 5.3 (95% CI: 2.1, 8.5) fewer days from screen to diagnostic, ($p = 0.002$).

CONCLUSION

Minority race and ethnicity was associated with longer diagnostic follow-up after positive screening mammogram, after adjusting for other woman- and neighborhood-level factors. However, association between neighborhood-level SDOH and timely diagnostic follow up differed depending on the composite measure.

CLINICAL RELEVANCE/APPLICATION

Multilevel analysis of disparities and their interactions is needed to identify actionable factors to guide interventions to improve timely care.

R5B-SPBR-5 OPPORTUNISTIC LUNG CANCER SCREENING DURING BREAST MRI: PRELIMINARY RESULTS

PURPOSE

To investigate the feasibility of opportunistic lung cancer screening for patients undergoing breast MR imaging.

METHODS AND MATERIALS

This 48-month prospective study recruited outpatients undergoing contrast-enhanced breast MRI scans. All scans were performed on either 3.0 T or 1.5 T scanner, with prone positioning and a dedicated breast coil. To evaluate the thorax, we included an axial postdynamic 3D ultrafast gradient-echo acquisition to the standard breast MRI protocol.Breast coils were switched off, and a body array coil was placed onto the back of the patient in the same prone position. Data are reported as mean ± standard deviation (SD), range, or percentage as appropriate. Inter-observer agreement for image quality and nodule detection was analyzed using kappa statistics.

RESULTS

A total of 419 subjects met the inclusion criteria. Additional mean time was 27s and 20s for 1.5T and 3.0T scanners, respectively.Mean age was 50 years (SD ± 12). Most patients underwent breast MRI for evaluation of breast cancer (n = 236; 61.9%) or breast nodule (n = 96; 25.2%). The majority were never smokers (n = 220; 73.1%). Most cases were negative for lung cancer screening (Lung-RADS 1: n=340,89; 24%); and Lung-RADS 2: n = 31; 8.14%). Between the positive scans, the Lung-RADS scores found were 3 (n = 7;1; 84%), 4A (n = 2; 0.52%), and 4x (n = 1; 0.26%). None of these findings were visible in the standard breast MR sequences.

CONCLUSION

The opportunistic addition of a full-chest sequence during breast MRI is a quick and potentially reliable tool for lung cancer screening.

CLINICAL RELEVANCE/APPLICATION

Opportunistic lung cancer screening during breast MRI detects clinically significant nodules and extra-mammary findings, supporting its feasibility in high-risk patients.

R5B-SPBR-6 CRYOABLATION OF OLIGOMETASTATIC AXILLARY LYMPH NODES IN PATIENTS WITH BREAST CANCER INELIGIBLE FOR SURGERY: A THREE-YEAR SINGLE-CENTER EXPERIENCE

Jorge Rey, MD (*Presenter*)
Jose Maria Oliver-Goldaracena (*Abstract Co-Author*)
Vicenta Cordoba Chicote (*Abstract Co-Author*)
Maria Jose Roca Navarro, MD (*Abstract Co-Author*)
Diego Garrido Alonso (*Abstract Co-Author*)
Ylenia Navarro Monforte, MD (*Abstract Co-Author*)
Teresa Diaz de Bustamante, MD (*Abstract Co-Author*)
Fernando Garcia Martinez, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the feasibility, safety, and efficacy of ultrasound-guided cryoablation for the treatment of axillary lymph node oligometastases in breast cancer patients who are not candidates for surgery.

METHODS AND MATERIALS

In this single-institution retrospective study, 12 patients with breast cancer deemed ineligible for surgery underwent ultrasound-guided cryoablation of oligometastatic axillary lymph nodes between November 2021 and February 2025. Patient demographics, disease characteristics, and procedural details were recorded. Cryoablation was performed using the ICEfx Galil argon gas system (Boston Scientific, USA). A "triple-phase" protocol was applied: freeze, thaw, and freeze. Ultrasound follow-up was performed initially at 1-2 months post-procedure to assess for incomplete treatment, and subsequently every six months to monitor for recurrence. Procedural efficacy was evaluated based on morphological (sonographic) and/or functional (PET-CT) imaging criteria. Primary endpoints were technical success and major complications.The secondary endpoints were local control rate and time to progression. Events were classified according to the Common Terminology Criteria for Adverse Events (CTCAE), version 5.0, as grade 1 (mild), grade 2 (moderate), or grade 3 (severe).

RESULTS

The study cohort included 12 patients (mean age, 83 ± 7.64 years) who underwent 14 cryoablation procedures targeting 16 axillary lymph node oligometastases. The mean short-axis diameter of the targeted nodes was 1.3 ± 0.5 cm. Technical success was achieved in all 14 procedures (100%). Mild adverse events (grade 1) were reported in two patients.Local tumor control was achieved in all 16 treated nodal metastases over a median follow-up period of 15 months (range, 3-32 months). However, local progression with further spread to additional lymph nodes occurred in 2 out of 12 patients (16.6%). The median time for recurrence was 15 months.

CONCLUSION

Cryoablation of axillary lymph node oligometastases is a feasible, safe, and effective treatment option with favorable medium-term outcomes in breast cancer patients who are not candidates for surgery. Further studies are needed to evaluate the long-term efficacy of this technique and to better define its role in this patient population.

CLINICAL RELEVANCE/APPLICATION

This study highlights cryoablation as a minimally invasive and well-tolerated option for managing axillary lymph node metastases in breast cancer patients unfit for surgery.

R5B-SPCA-3 COMPARISON OF SINGLE- AND DUAL-PHASE METHODS ON PHOTON-COUNTING DETECTOR CT (PCD-CT) WITH DUAL-PHASE METHOD ON ENERGY-INTEGRATING DETECTOR CT (EID-CT) FOR MYOCARDIAL EXTRACELLULAR VOLUME (ECV): MRI AS THE REFERENCE

Mengzhen Wang, MD (*Presenter*)
Shouyu Bao (*Abstract Co-Author*)
Zhihan Xu, MD (*Abstract Co-Author*)
Wenjie Yang, MD (*Abstract Co-Author*)

PURPOSE

Aimed to evaluate the correlation and consistency of Extracellular volume (ECV) quantification between Photon-counting detector CT (PCD-CT) and Energy-integrating detector CT (EID-CT) using a dual-phase method, with cardiac magnetic resonance imaging as reference. Additionally, we validated an automatic and comprehensive three-dimensional single-phase ECV assessment method on PCD-CT that does not require first-pass coronary CT angiography images for segmentation.

METHODS AND MATERIALS

This retrospective study included 80 patients who underwent both CMR and cardiac CT (40 patients underwent PCD-CT and 40 underwent EID-CT). Pearson correlation coefficients and intraclass correlation coefficients (ICCs) were used to evaluate the correlation and reliability of CT ECV with CMR ECV. Subgroup analysis was performed based on heart rate (HR).

RESULTS

The single-phase and dual-phase ECV measurements on PCD-CT showed excellent correlation and consistency with CMR ECV (correlation coefficient: single-phase, 0.84; dual-phase, 0.91; ICC: single-phase, 0.90; dual-phase, 0.94). Both methods significantly outperformed EID-CT (correlation coefficient: 0.62; ICC: 0.76; all $p < 0.05$). No significant differences were observed between the two PCD-CT methods ($p > 0.05$). PCD-CT demonstrated high consistency across both HR subgroups (ICC: HR = 60 bpm: 0.89 for single-phase, 0.85 for dual-phase; HR > 60 bpm: 0.87 for single-phase, 0.88 for dual-phase), whereas EID-CT exhibited reduced consistency in patients with HR > 60 bpm (ICC: HR = 60 bpm: 0.78; HR > 60 bpm: 0.60).

CONCLUSION

PCD-CT demonstrated superior correlation and reliability in ECV analysis compared to EID-CT, especially in the high HR group. The single-phase ECV measurement method was as effective as the dual-phase method, showing excellent correlation and consistency with CMR.

CLINICAL RELEVANCE/APPLICATION

This study highlights that PCD-CT provides superior myocardial ECV quantification with better image quality, lower radiation exposure, and high consistency with CMR. Its automatic three-dimensional single-phase ECV assessment offers a safer, more efficient approach for evaluating myocardial fibrosis in clinical practice.

R5B-SPCA-4 DIAGNOSTIC ROLE OF NON-DEDICATED DUAL-ENERGY CT CALCIUM SCORING IN AORTIC STENOSIS DETECTION

Giuseppe Muscogiuri, MD (*Presenter*)
Gregorio Chierchia, MD (*Abstract Co-Author*)
Jessica Usai, MD (*Abstract Co-Author*)
Daniele Sferratore, MD (*Abstract Co-Author*)
Paolo Marra, MD (*Abstract Co-Author*)
Sandro Sironi, MD (*Abstract Co-Author*)

PURPOSE

This retrospective study evaluates the calcium score as a diagnostic indicator for aortic stenosis (AS) using dual-energy CT with virtual unenhanced images. Echocardiography, while considered the gold standard for AS evaluation, presents limitations in approximately one-third of patients due to discordant parameters. The calcium score offers an anatomical assessment independent of hemodynamic flow conditions that potentially complicate echocardiographic accuracy.

METHODS AND MATERIALS

The study analyzed 60 patients (36 males, 24 females; mean age 67.5 years; mean BMI 26.8) who underwent both dual-energy CT and echocardiography within a one-year timeframe. Calcium score was calculated using the Agatston method on virtual unenhanced images, while AS severity was classified according to European Society of Cardiology guidelines into four categories: no stenosis (n=42), mild (n=7), moderate (n=6), and severe stenosis (n=5). Statistical analysis included Mann-Whitney U test for group comparisons and ROC curve analysis with DeLong test for determining diagnostic accuracy.

RESULTS

Results demonstrated significantly higher calcium scores in patients with AS (median 134.5, IQR 5-455) compared to those without stenosis (median 0, IQR 0-8), with $p=0.0001$. ROC curve analysis revealed excellent diagnostic performance for detecting severe stenosis (AUC=0.93), moderate performance for moderate stenosis (AUC=0.73), and limited value for mild stenosis (AUC=0.60). DeLong test comparisons between stenosis categories confirmed statistically significant differences ($p<0.05$) in the discriminative ability of calcium score for severe stenosis compared to all other categories, while differences between "any stenosis" and mild or moderate stenosis were not significant.

CONCLUSION

This study confirms the feasibility of calcium scoring using non-dedicated dual-energy CT acquisitions for AS evaluation, with particular utility for identifying severe AS cases that might otherwise be misclassified by echocardiography alone.

CLINICAL RELEVANCE/APPLICATION

Identifying patients with severe aortic stenosis using non-dedicated CT scans can be pivotal in the management of oncology patients. Beyond the benefits of dual-energy acquisition for oncologic assessments, evaluating cardiac structures can be crucial for appropriate clinical management and prognostic stratification

R5B-SPCA-5 AI-DRIVEN MOTION COMPENSATION IN PROSPECTIVELY ECG-TRIGGERED CORONARY CTA: A STEP FORWARD IN DIAGNOSTIC PRECISION?

Aiste Matuleviciute-Stojanoska, MD (*Presenter*)
Faruk Colak (*Abstract Co-Author*)
Magin Eduardo Sosa Contreras (*Abstract Co-Author*)
Thorsten Klink, MD (*Abstract Co-Author*)

PURPOSE

To investigate the diagnostic benefit of AI-driven motion-compensated reconstruction (MCR) in prospectively ECG-triggered coronary CTA (cCTA). This study is one of the first to systematically evaluate the impact of MCR on objective and subjective image quality, and to identify patient-specific predictors of its utility.

METHODS AND MATERIALS

This retrospective single-center study includes 31 consecutive patients (19 females, 12 males; mean age 56.7 range 30-71) who underwent prospectively ECG-triggered cCTA using 256-slice dual-layer spectral CT scanner. For each patient, standard model-based iterative (IMR) and motion-corrected IMR reconstructions (MCR, Precise Cardiac) with a slice thickness of 0.67 mm were analyzed using a comprehensive cardiac analysis tool. The nine proximal coronary segments based on the 18-segment SCCT model were evaluated. Objective image quality was assessed based on contrast-to-noise ratio (CNR), signal-to-noise ratio (SNR), full width at half maximum (FWHM), and line spread function (LSF). Subjective image quality was evaluated using a 5-point Likert scale. A subgroup analysis was conducted for segments affected by motion artifacts.

RESULTS

MCR significantly reduced FWHM in the left main coronary artery (?FWHM-0.0590, p =0.0157), while other segments showed non-significant differences (p >0.05). Heart rate (HR) was the strongest predictor of ?CNR and ?SNR (p <0.001), with younger age and female sex showing non-significant trends. Higher heart rate variability (HRV) correlated with improved edge sharpness (?LSF, p =0.027), suggesting greater benefit in patients with rhythm irregularities. MCR images achieved higher subjective image quality scores compared to standard reconstruction (p <0.05), particularly in motion-affected segments (p <0.01). MCR upgraded 4 of 12 non-diagnostic segments to interpretable (33.3%; McNemar's test, p=0.125).

CONCLUSION

Preliminary results indicate that MCR improves objective metrics, notably FWHM and LSF, as well as subjective image quality and may lead to more reliable coronary artery assessment in CTA patients with motion artifacts.

CLINICAL RELEVANCE/APPLICATION

MCR not only improves coronary CTA images at higher heart rates but may also turn previously unreadable segments into diagnostically assessable ones—offering a real step forward in clinical confidence.

R5B-SPCA-7 FRAGILITY OF DEEP LEARNING MODELS FOR CORONARY ARTERY DISEASE DETECTION IN CARDIAC MRI: A FIRST LOOK AT ADVERSARIAL VULNERABILITY

Basudha Pal (*Presenter*)
Muhammad Umair, MBBS (*Abstract Co-Author*)

PURPOSE

Deep learning systems have demonstrated high accuracy in detecting coronary artery disease (CAD) from cardiac MRI and are increasingly considered for noninvasive screening. However, their reliability under real-world image perturbations has not been systematically assessed. While prior work explored adversarial attacks in other modalities such as chest X-rays, to our knowledge, there has been limited evaluation on the robustness of CAD classifiers trained on cardiac MRI. This work presents a comprehensive vulnerability analysis in this setting, demonstrating how even high-performing models can be sensitive to visually imperceptible perturbations.

METHODS AND MATERIALS

A ResNet-18 backbone was trained on the CAD Cardiac MRI Dataset, consisting of 75,064 cardiac MRI images labeled for CAD presence or absence. Images of 512x512 dimensions were preprocessed to include grayscale conversion, median and Gaussian denoising, CLAHE-based contrast enhancement. The dataset was partitioned into training (70%), validation (15%), and test (15%) subsets. The model was trained using cross-entropy loss and optimized with Adam and the best check point was chosen on the basis of validation AURoC. We established a baseline performance on clean test data followed by a stress test using three white-box, gradient-based adversarial attacks: Fast Gradient Sign Method (FGSM, epsilon=0.03), Projected Gradient Descent (PGD, epsilon=0.03, 40 steps), and the Carlini-Wagner (CW) attack. These attacks introduced targeted perturbations designed to alter model predictions while preserving image appearance.

RESULTS

The model achieved an AURoC of 99.6% on clean test data. However, AURoC dropped markedly under adversarial conditions: to 54.27% with FGSM, 51.21% with PGD, and 63.63% with CW. Adversarial examples remained visually indistinguishable from the originals but induced misclassification of CAD labels. The sharp performance drop across all three attack types highlights a critical vulnerability.

CONCLUSION

CAD classifiers trained on cardiac MRI are highly susceptible to minimal input perturbations, despite near-perfect clean performance. This discrepancy underscores the need to go beyond conventional accuracy metrics and adopt robustness evaluation as part of model validation using methods such as adversarial training.

CLINICAL RELEVANCE/APPLICATION

We present a systematic evaluation of adversarial vulnerability in the context of CAD detection from cardiac MRI, an area that has not been previously explored in depth. Understanding model fragility through structured attacks can support the development of more reliable and clinically acceptable deep learning systems, especially as AI tools move toward deployment in cardiac imaging workflows.

R5B-SPCA-9 MACHINE LEARNING MODEL USING 3D CARDIAC MR SUBSTRATE FEATURES FOR POST-MYOCARDIAL INFARCTION RISK PREDICTION: A MULTICENTER STUDY

Lujing Wang (*Presenter*)
Xiaoying Zhao (*Abstract Co-Author*)
Xinxiang Zhao (*Abstract Co-Author*)

PURPOSE

To explore the predictive value of machine learning (ML) models based on 3D cardiac MR substrate features for assessing the risk of major adverse cardiovascular events (MACE) after myocardial infarction (MI).

METHODS AND MATERIALS

This retrospective study included MI patients who underwent cardiac MR imaging between May 2015 and August 2024. The primary outcome was a composite MACE endpoint, including all-cause mortality, recurrent MI, heart failure rehospitalization, ventricular arrhythmias, and stroke. External validation was performed using independent datasets from multiple centers. 3D substrate features, including core scar, border zone, and abnormal electrophysiological corridors, were extracted using ADAS 3D software. In addition to clinical and functional cardiac MR parameters, feature selection was conducted using univariate logistic regression and the Boruta algorithm. Eight ML models, including TabPFN, were trained and evaluated using ROC curve analysis. The optimal ML model was used to construct multimodal prediction models, and model interpretability was enhanced using SHAP analysis.

RESULTS

A total of 292 MI patients were included, with a median follow-up of 35 months. MACE occurred in 91 patients. Nine key variables were retained after feature selection, including three clinical variables: high-density lipoprotein, chronic kidney disease, tricuspid regurgitation degree, two CMR functional parameters: left ventricular ejection fraction, left ventricular global circumferential strain, and four 3D substrate features: border zone mass, corridor mass, corridor burden, corridor length. Six multimodal models were developed using the best-performing ML algorithm, TabPFN. Model 4 (clinical + 3D substrate features) demonstrated robust predictive performance across the training (AUC = 0.91), internal test (AUC = 0.82), and external validation (AUC = 0.89) cohorts. Model 3 (only 3D substrate features) achieved an external AUC of 0.90, significantly outperforming models using only clinical features (Model 1: AUC = 0.63) or functional parameters (Model 2: AUC = 0.49). Decision curve analysis confirmed the superior clinical net benefit of models incorporating 3D substrate features. SHAP analysis identified corridor mass and corridor burden as the most influential predictors.

CONCLUSION

ML models based on 3D CMR substrate features effectively predict the risk of MACE in MI patients and outperform models relying solely on traditional clinical or functional CMR parameters.

CLINICAL RELEVANCE/APPLICATION

These models offer a novel, interpretable tool to support precision risk stratification and individualized treatment planning in post-MI management.

R5B-SPCA-13 EFFECT OF DEEP LEARNING RECONSTRUCTIONS ON THE INTERPRETATION OF RADIOMICS FEATURES IN CARDIAC MR IMAGING

Durga Udayakumar, MD (*Presenter*)
Mohamed Gamal, MD (*Abstract Co-Author*)
Huan Lu, MD (*Abstract Co-Author*)
Vincenzo Scialo (*Abstract Co-Author*)
Spencer Waddle (*Abstract Co-Author*)
Ananth J. Madhuranthakam, PhD (*Abstract Co-Author*)
Tim Leiner, MD, PhD (*Abstract Co-Author*)

PURPOSE

Deep learning-based reconstruction (DLR) methods are increasingly used to improve cardiac magnetic resonance (CMR) image quality. Radiomics offers a complementary approach by extracting high-dimensional, quantitative features for insights into cardiac structure and function. This pilot study evaluated the effect of DLR methods on radiomic features and their influence on the interpretation of radiomic analysis in cardiac imaging.

METHODS AND MATERIALS

This IRB approved study included CMR images from 42 healthy subjects (M/F: 14/28; Age: 39±12 years), acquired using cine balanced steady-state free precession with compressed sensing acceleration factor 4 (CS4). The images were also reconstructed with DLR methods (Philips Healthcare) - product SmartSpeed (SS) for improving signal-to-noise ratio (SNR) and work-in-progress Precise Super Resolution (SR) for increasing spatial resolution. ROIs were drawn on 3D Slicer® covering the entire myocardium on a single center slice at mid-diastole (MD) and mid-systole (MS), followed by radiomics features extraction using PyRadiomics. Consistency of radiomics features were evaluated with Pearson correlation coefficients (?) between the following pairwise comparisons: CS4 vs. CS4-SS and CS4 vs. CS4-SR for both MD and MS images and visualized using histograms and heatmaps on R software.

RESULTS

A total of 105 radiomics features were included in the analysis. Excellent correlation (?=0.8; all P<0.05) was observed for a substantial number of radiomics features between CS4 and CS4-SS (MD: 97/105, MS: 93/105), whereas correlations between CS4 and CS4-SR were notably lower (MD: 72/105, MS: 68/105). All shape and first-order features showed consistently high correlations (?=0.8) between CS4 and CS4-SS across both MD and MS images, a consistency that was not observed between CS4 and CS4-SR. Features exhibiting lower correlations (?<0.8) predominantly included those related to "Low Gray Level Emphasis," indicating variations in gray-level intensity introduced by DLR methods.

CONCLUSION

DLR methods that improve SNR without altering spatial resolution (e.g., SmartSpeed) preserve the integrity of most radiomics features, especially shape and first-order metrics, enabling reliable comparisons across reconstruction methods. While this study found the works-in-progress Super Resolution model affected more features, further studies are needed to assess DLR methods that enhance spatial resolution for comparative analyses with other reconstruction methods.

CLINICAL RELEVANCE/APPLICATION

Understanding of DLR methods and their effects on spatial resolution is essential for accurate radiomics-based interpretation of cardiac MR images and their utility in precision diagnostics and personalized care.

R5B-SPCH-3 ENHANCING RADIOLOGIST PERFORMANCE IN LUNG NODULE DETECTION ON CHEST RADIOGRAPHS USING AN AI-ASSISTED TOOL

Sean D. Raj, MD, MBA (*Presenter*)
Barry J. Sadegi, MD (*Abstract Co-Author*)
Xiaowei Hong (*Abstract Co-Author*)
John Simon, MD (*Abstract Co-Author*)

PURPOSE

This study aims to evaluate the diagnostic performance of a commercially available, FDA-approved, artificial intelligence (AI) system for lung nodule detection on chest radiographs and to assess its impact on radiologists' accuracy and efficiency.

METHODS AND MATERIALS

This multi-center study was conducted across five imaging centers in four states across the US. In Phase 1, a retrospective dataset of 2,181 chest radiographs was used to assess the standalone performance of the AI tool. In Phase 2, a multi-reader, multi-case study was conducted using 400 cases sampled from Phase 1. Twenty radiologists (including thoracic and non-thoracic specialists) reviewed all 400 images twice - once with and once without AI assistance - separated by a one-month washout period to reduce recall bias.Performance metrics included area under the ROC curve (AUC), sensitivity, specificity, and interpretation time per image. Analysis was performed overall and across patient subgroups (age, gender, ethnicity). Lesion-based performance (AFROC and sensitivity) was assessed by size and density. Ground truth was established by consensus of three board-certified radiologists.

RESULTS

The AI-assisted tool detects nodules on chest X-rays with high sensitivity (88.5% (95% CI: 86.4-90.3%), specificity (83% (95% CI: 80.7-90.3%), and AUC (84.1% (95% CI: 82.7-85.5). Performance remains robust across subgroups. Readers' performance significantly improved with AI assistance (AUC=85.8% (95% CI: 85.2-86.5%)) compared to without (AUC=80.7% (95% CI: 80-81.5%)). Sensitivity and specificity increased from 79.8% to 89.4% (p <.001) and 82.4% to 85.1% for all readers. The interpretation time per image was reduced by 23.3%. Results per lesion size and density are presented in Table 1.

CONCLUSION

This study shows that Radiologists enhanced by an AI-assisted tool achieve higher diagnostic accuracy and efficiency than either Radiologists or the AI tool alone. These results support the complementary role of AI in clinical Radiology and its potential to enhance patient care.

CLINICAL RELEVANCE/APPLICATION

These findings highlight the potential of AI-assisted systems to improve Radiologists' diagnostic accuracy and efficiency, contributing to better patient care and reduced workload.

R5B-SPCH-6 RADIOLOGICAL FEATURES AND CLINICOPATHOLOGICAL ASSOCIATIONS WITH RECURRENCE IN RESECTED PATHOLOGICAL STAGE 0-1A NON-SMALL CELL LUNG CANCER

Lijing Zhang, MD (*Presenter*)
Wenchao Ma (*Abstract Co-Author*)
Rowena Yip, PhD, MPH (*Abstract Co-Author*)
Louis Gros, MD (*Abstract Co-Author*)
David F. Yankelevitz, MD (*Abstract Co-Author*)
Claudia I. Henschke, PhD, MD (*Abstract Co-Author*)

PURPOSE

This study aimed to identify radiologic features associated with recurrence in early stage lung cancer patients.

METHODS AND MATERIALS

This study was a secondary review of CT findings and clinicopathologic data from an integrated health care system with participants enrolled in the Initiative for Early Lung Cancer Research on Treatment(IELCART) from February 2016 to March2024. Follow up was calculated from the date of surgery of their first primary lung cancer to the date for recurrence or December 12th , 2024, whichever comes first. Recurrence was classified as metastatic or local recurrence (including suture-line recurrence). Preoperative radiologic features, volume doubling time (VDT) and PET maximum standardized uptake value were evaluated. Multivariable logistic regression with LASSO selection was used to identify factors associated with recurrence, adjusting for demographic, clinical, and pathological covariates. Model performance was assessed using the area under the receiver operating characteristic curve (AUC).

RESULTS

We reviewed a total of 820 cases with resected NSCLCs, of which 128 cases with pathological Stage 0-1A NSCLCs met the inclusion criteria. Among these, 34 had recurrence and 94 had non-recurrence. Median follow-up was 70 months (IQR: 61-81.5 months). They were predominantly White (62%; 13% Black, 12.5% Asian, 12.5% Other), 81% were non-Hispanic, and 71% were former smokers (23% never smokers, 6% current smokers). Compared to the non-recurrence group, the recurrence group had higher pack-years of smoking (35.5 vs 12.8, p=0.015) and were more likely to have self-reported COPD (52% vs 48%, p=0.002). Angiolymphatic invasion were more common in the recurrence group compared to non recurrence group(P<0.001)In a multivariable logistic regression combining clinicopathological and radiological features, COPD (OR = 3.76,p=0.04) and presence of the lollipop sign(Lollipop sign is defined as a single blood vessel entry in the middle of the lung cancer nodule on any multiplanar reconstructive CT image.) (OR = 5.69, p=0.005) were independent predictors of recurrence. This model demonstrated good discriminatory performance with an AUC of 0.87 (95% CI: 0.81,0.94).

CONCLUSION

A combination of radiological and clinicopathological features may help predict postoperative recurrence in patients with pathological Stage 0-IA NSCLC, potentially informing decisions about adjuvant treatment after surgery.

CLINICAL RELEVANCE/APPLICATION

Identifying radiologic and clinicopathologic predictors of recurrence in pathologic Stage 0-IA NSCLCs can help tailor postoperative management and guide decisions on adjuvant therapy.

R5B-SPCH-7 "TRY BEFORE YOU BUY": COMPARATIVE EVALUATION OF FDA-APPROVED AI ALGORITHMS FOR CORONARY CALCIUM SCORING ON LUNG CANCER SCREENING CTS

Syed Muhammad Awais Bukhari, MD (*Presenter*)
Sreyes Venkatesh (*Abstract Co-Author*)
Annie Singh (*Abstract Co-Author*)
Cody R. Johnson, MD (*Abstract Co-Author*)
Robert C. Gilkeson, MD (*Abstract Co-Author*)
Amit Gupta, MD, MBBS (*Abstract Co-Author*)

PURPOSE

While FDA-approved AI tools for coronary artery calcium (CAC) scoring have demonstrated utility on non-gated chest CTs, their performance on low-dose CTs (LDCTs) from lung cancer screening programs, where incidental CAC detection is critical, remains less clear. Given the cardiovascular risk overlap in this population and the lack of LDCT-specific training in these algorithms, our objective was to benchmark and compare the performance of three commercially available, FDA-cleared CAC scoring AI tools. This study underscores the need for local validation prior to clinical and commercial adoption.

METHODS AND MATERIALS

We retrospectively identified 44 patients (mean age: 61±5.6 years; 57.8% females, 42.2% males) who underwent both ECG-gated calcium scoring CT (CSCT) and LDCT within a 16-day interval. CAC scores were calculated on LDCTs using three FDA-approved AI tools (CAC-AI A , CAC-AI B , and CAC-AI C) via a vendor-neutral AI deployment platform (CARPL.AI). A semi-automated CAC score measured by a board-certified radiologist on CSCT (CAC G) served as the reference standard. All CAC scores were stratified into Agatston-based risk categories: Very Low (0), Low (1-99), Moderate (100-399), and High (=400). Performance metrics included ANOVA for mean comparisons, concordance correlation coefficient (CCC), Bland-Altman analysis, and weighted kappa (?) statistics for risk classification agreement.

RESULTS

Mean CAC scores were as follows: CAC G = 314.33 ± 651.84; CAC-AI A = 295.0 ± 533.2; CA C -AI B = 317.2 ± 595.9; CAC-AI C = 313.4 ± 623.0 (p = 0.998). CCC values with the ground truth (CAC G) were 0.96 (CAC-AI A), 0.97 (CAC-AI B), and 0.93 (CAC-AI C). Mean differences from CACG were: CAC-AI A : -18.6 ± 161.9 (95% CI: -67.9 to 30.6); CAC-AI B : +2.9 ± 128.2 (95% CI: -36.1 to 41.8); CAC-AI C : -1.0 ± 226.5 (95% CI: -69.8 to 67.9). Risk category agreement (?) compared to CAC G was highest for CAC-AI B (? = 0.76), followed by CAC-AI C (? = 0.69) and CAC-AI A (? = 0.47).

CONCLUSION

All three AI tools demonstrated reasonable agreement with gated CSCT for CAC scoring on LDCTs. However, in our institutional setting, vendor B's tool (CAC-AI B) showed the most reliable performance for both quantitative scoring and risk stratification, followed by vendor C. Vendor A underperformed relative to the others.

CLINICAL RELEVANCE/APPLICATION

As AI tools enter clinical practice, particularly in high-impact domains such as incidental CAC detection, local validation remains essential. Despite regulatory approval, differences in real-world performance across platforms can influence clinical utility. Vendor-neutral platforms now enable institutions to "try before you buy," facilitating informed, data-driven decisions that align with local imaging protocols and patient populations.

R5B-SPCH-9 DIFFUSION-WEIGHTED IMAGING (DWI) WITH REVERSE ENCODING DISTORTION CORRECTION (RDC) TECHNIQUE: IMPROVING IMAGE QUALITY AND DIFFERENTIATION CAPABILITY FOR LYMPH NODE METASTASIS AS CONVENTIONAL DWI IN NON-SMALL LUNG CANCER

Yoshiyuki Ozawa, MD, PhD (*Abstract Co-Author*)

PURPOSE

To determine the capability of diffusion weighted imaging (DWI) with reverse encoding distortion correction (RDC) technique for improving image quality and diagnostic capability for lymph node metastasis in non-small cell lung cancer (NSCLC) patients, when compared with conventional DWI.

METHODS AND MATERIALS

40 pathologically NSCLC patients underwent STIR FASE imaging, DWIs with and without RDC at 1.5T system, FDG-PET/CT, transbronchial or mediastinal biopsies, surgical treatment, pathological examinations and more than 2 years follow-up examinations. Then, 69 metastatic nodes and 69 out of 354 non-metastatic nodes were computationally selected. To determine the utility of RDC for DWI, deformation ratios (DRs) between each DWI and STIR images and signal-to-noise ratio (SNRs) of each primary lesion and selected lymph node were determined by region-of-interest (ROI) measurements. Then, overall image quality, artifact and lesion conspicuity of each lesion and lymph node were assessed by 5-point scales. Then, apparent diffusion coefficients (ADCs) on DWIs with and without RDC (i.e. RDC DWI and DWI) and maximum values of standard uptake value (SUV max) of metastatic and non-metastatic lymph nodes were also evaluated by ROI measurements. To compare each index between metastatic and non-metastatic lymph nodes, Student’s t-test was performed. To compare diagnostic performance for lymph node metastasis, ROC analysis was performed among DWIs and PET/CT. Finally, sensitivity (SE), specificity (SP) and accuracy (AC) were compared among all methods by McNemar’s test.

RESULTS

DR of RDC DWI was significantly smaller than that of DWI (p=0.003). Overall image quality and artifact of RDC DWI were significantly improved as compared with DWI (p<0.05). There was significant difference of each index between two groups (p<0.05). Area under the curve (AUC), SP and AC of RDC DWI (AUC=0.95, p<0.0001; SP=84.1%, p<0.0001; AC=79.7%, p<0.0001) were significantly better than those of DWI (AUC=0.84, p<0.0001; SP=84.1%, p<0.0001; AC=79.7%, p<0.0001) and PET/CT (AUC=0.85, p=0.006; SP=81.2%, p<0.0001; AC=81.2%, p<0.0001).

CONCLUSION

RDC technique has better potential for improving distortion, image quality and diagnosis of lymph node metastasis as compared with conventional DWI and FDG-PET/CT in NSCLC patients.

CLINICAL RELEVANCE/APPLICATION

RDC DWI can improve distortion, image quality and diagnosis of lymph node metastasis as compared with conventional DWI and FDG-PET/CT in NSCLC patients.

R5B-SPCH-11 PILOT NATIONAL LUNG CANCER SCREENING – SUMMARY OF THE NORTHERN MACROREGION RESULTS

Edyta Szurowska, MD, PhD (*Presenter*)
Joanna Bidzinska, PhD, MBA (*Abstract Co-Author*)
Julia Rymarowicz (*Abstract Co-Author*)
Katarzyna Kobylecka (*Abstract Co-Author*)
Katarzyna Dziadziuszko, MD (*Abstract Co-Author*)
Witold Rzyman (*Abstract Co-Author*)

PURPOSE

The study aimed to evaluate the outcomes of Pilot National Lung Cancer Screening Program in the northern macroregion of the country.

METHODS AND MATERIALS

Following primary prevention, lung cancer screening is considered a key strategy to reduce lung cancer-related mortality.A total of 3,068 asymptomatic volunteers aged 50 - 74 years, with a smoking history of at least 20 pack-years, underwent low-dose computed tomography (LDCT) LCS with smoking cessation program.Nodule management protocol was designed for a two-year follow-up. It was intentionally developed for the national program and implemented uniformly across the country. LDCT scans in the northern macroregion of the country were performed in four radiology centers. All participating radiologists received dedicated training.

RESULTS

Invasive diagnostic procedures were carried out in 85 participants (2.77%). As of the time of abstract submission, lung cancer was diagnosed in 59 participants (1.92%) with 31 (52.54%) being female.Surgery was performed in 45 participants (76%), of whom 22 (52%) were female. Early lung cancer including stages I and II was diagnosed in 42 participants (71%). In the group of 58 operated patients, 12 participants (20%), underwent resection for benign lesions, and one participant underwent surgery for a thymoma. Primary oncological treatment was provided in 21 instances, including 3 who received stereotactic body radiotherapy (SBRT). The false-positive rates were 11.6% at baseline, 1.4% at the first annual round, and 0.49% at the second annual round. Adherence to the screening program remained high, with 89% retention after the first year and 78% after the second year. In addition, we assessed (or are currently analyzing) the number and types of pulmonary nodules, the presence of emphysema, coronary artery calcification (CAC), incidental findings, and the effectiveness of the smoking cessation intervention.

CONCLUSION

Lung cancer screening with LDCT has proven to be an effective tool in reducing lung cancer mortality.Moreover, LDCT is also effective in identifying other diseases. Therefore, it should be implemented as a National Screening Strategy as soon as possible. Limitations Quality control at one of the screening sites indicated that periodic retraining of radiologists is necessary.

CLINICAL RELEVANCE/APPLICATION

A governmental decision regarding full implementation is expected in May 2025.

R5B-SPCH-12 IMAGING FEATURES OF PATHOLOGICALLY CONFIRMED SMOKING-RELATED INTERSTITIAL FIBROSIS: IDENTIFYING CHARACTERISTIC FEATURES TO DIFFERENTIATE FROM COMBINED PULMONARY FIBROSIS AND EMPHYSEMA

Yong Deok Lee (*Presenter*)
Chohee Kim, MD (*Abstract Co-Author*)
Myung Jin Chung, MD (*Abstract Co-Author*)
Tae Jung Kim, MD, PhD (*Abstract Co-Author*)
Joungho Han (*Abstract Co-Author*)
Yoon Ki Cha, MD, PhD (*Abstract Co-Author*)

PURPOSE

To differentiate SRIF (CPFE-histologic SRIF) from CPFE (CPFE-IPF) using chest computed tomography (CT).

METHODS AND MATERIALS

This retrospective study included 72 patients who underwent surgical lung biopsy or resection between January 2015 and January 2025, all of whom had histopathological confirmation. Preoperative chest CT images were independently reviewed by three radiologists. Imaging features assessed included centrilobular and paraseptal emphysema, multiple thin-walled cysts (MTWC), honeycombing, traction bronchiectasis, subpleural ground-glass opacities (GGO)/reticulation, smoking-related disease (SRD), and pulmonary hypertension (PH). CT features were assessed using univariable and multivariable logistic regression analyses. Receiver operating characteristic (ROC) curve analysis was used to quantify the performance of imaging features. The log-rank test was used to compare overall survival (OS), and associations between OS and patient characteristics were evaluated using Cox proportional hazards regression analysis.

RESULTS

A total of 72 patients (mean age, 66.24 years ± 7.86; 63 male) with SRIF (n = 29) or CPFE (n = 43) were included. Among the evaluated CT features, MTWC was significantly more prevalent in SRIF (72.4%) than in CPFE (25.6%), whereas honeycombing (39.5% in CPFE, 6.9% in SRIF) and PH (62.8% in CPFE, 17.2% in SRIF) were more frequently observed in CPFE. Centrilobular and paraseptal emphysema were observed in both groups, with higher frequencies in SRIF. Traction bronchiectasis and subpleural GGO/reticulation were present in all patients in both groups. In both univariable and multivariable analyses comparing SRIF and CPFE, MTWC was a predictive feature of SRIF ($p < 0.05$), whereas honeycombing and PH were predictive features of CPFE (all $p < 0.05$). ROC curve analysis to evaluate the predictive value of the logistic model based on the imaging features of SRIF, and the area under the curve (AUC) value was 0.958. There was no difference in OS between the SRIF and CPFE groups (log-rank $p = 0.1098$). Notably, PH was identified as an independent predictor of poor OS (hazard ratio [HR] = 0.24 [95% CI: 0.07, 0.91], $p = 0.036$).

CONCLUSION

For differentiating SRIF from CPFE, MTWC and honeycombing are valuable CT features; the presence or absence of PH may serve as a supplemental role for identifying CPFE.

CLINICAL RELEVANCE/APPLICATION

SRIF and CPFE have overlapping imaging/clinical features. While SRIF is known to have a benign clinical course, CPFE is associated with high morbidity and mortality burden. Therefore, accurate differentiation based on imaging findings is essential for improving prognosis.

R5B-SPCH-13 FEEL THE STRAIN: RADIOLOGIST AGREEMENT ON RIGHT HEART STRAIN IN ACUTE PULMONARY EMBOLISM

Renee Friedman (*Presenter*)
Linda B. Haramati, MD, MS (*Abstract Co-Author*)

Stuart L. Cohen, MD (*Abstract Co-Author*)
Charles S. White, MD (*Abstract Co-Author*)
Jonathan Alis, MD (*Abstract Co-Author*)

PURPOSE

Evaluation of right heart strain (RHS) on CTPA is a risk stratification metric used to guide clinical management in acute pulmonary embolism (PE). The purpose of this study is to evaluate agreement and reproducibility of RHS assessment using subjective assessment and right ventricle (RV) to left ventricle (LV) diameter ratio.

METHODS AND MATERIALS

10 acute PE cases with variable degrees of RHS were selected by a single cardiothoracic radiologist. Axial series DICOM images were anonymized and uploaded to a secure online platform. Fellowship trained cardiothoracic radiologists were invited to participate voluntarily in the study. For each case, they were asked to provide subjective assessment for RHS (yes/no) and subsequently measure RV and LV diameters using their typical clinical practice method. No measurement technique instructions were given. A second survey was completed 3 months later with the same cases in a different order. Interobserver and intraobserver agreement analysis was performed.

RESULTS

32 cardiothoracic radiologists completed both surveys. 6 were excluded due to incomplete data. Cases were classified based on the European Society of Cardiology threshold of RV/LV ratio of 1. We defined cases positive if the interquartile range (IQR) was above 1 (5 cases), negative if the IQR was below 1 (2 cases) and borderline if the IQR crossed the threshold of 1 (3 cases). Overall interobserver agreement for subjective assessment was 85%. Agreement was lowest for borderline cases (63%) and 41% of readers changed their subjective assessment from time 1 to time 2 for these cases. For quantitative RV/LV ratio, overall intraclass correlation coefficient (ICC) was 0.79. ICC for individual cases ranged from 0.12-0.67, suggesting that while radiologists could reliably differentiate between cases, the measurement precision for any single case was poor. Using the RV/LV ratio cutoff of 1, 44% of readers had a different outcome from time 1 to time 2 for borderline cases. Bland Altman analysis showed minimal systemic bias but differences in reliability across cases.

CONCLUSION

Overall agreement for RHS assessment in acute PE was high for subjective assessment and RV/LV ratio. However, agreement and reproducibility were poor for borderline cases both in qualitative and quantitative assessment. This is of clinical relevance because inconsistencies in measurements for borderline cases could lead to different management decisions based on current guidelines.

CLINICAL RELEVANCE/APPLICATION

Inconsistent assessment of RHS on CTPA for borderline cases could lead to divergent clinical decisions based on current guidelines. The variability observed in this study may have impacted datasets used for outcomes studies and guidelines, meriting further evaluation.

R5B-SPER-1 PHOTON COUNTING CT CALCIUM OVERLAY AND VIRTUAL NON-CALCIUM TECHNIQUE TO DIFFERENTIATE ATYPICAL INTRACRANIAL CALCIFICATION FROM HEMORRHAGE

Khanin Khanungwanitkul, MD (*Presenter*)
Fides Schwartz, MD (*Abstract Co-Author*)
Aaron D. Sodickson, MD, PhD (*Abstract Co-Author*)

PURPOSE

Differentiating atypical intracranial calcifications (Ca) from hemorrhage (Hem) on non-contrast head CT can be challenging, and often prompts follow-up imaging. Dual energy CT three material decomposition methods that create Calcium overlay (Ca) and Virtual Non-Calcium (VNCa) images have been demonstrated to be effective at this task, but have not yet been investigated using Photon Counting CT (PCCT). The purpose of this study was to reproduce this algorithm on PCCT, and to investigate its diagnostic performance.

METHODS AND MATERIALS

Hyperattenuating foci on non-contrast head PCCT were included if they measured <100 HU, and had reference standard comparison imaging. Hem was confirmed for CT hyperdense foci that were not present on prior CT/MRI within 2 weeks, or dynamic change on follow up CT/MRI. Ca was confirmed by stability at least 1 month before or after the index CT. Typical basal ganglia and choroid plexus Ca were excluded. 54 lesions from 37 patients were included, confirmed by reference standard to be 27 Hem and 27 Ca. A blinded reader classified each lesion on a Likert scale (1 definite Ca, 2 probable Ca, 3 unsure, 4 probable Hem, 5 definite Hem), first on the conventional scan, and then with the addition of 3 mm and subsequently 0.8 mm paired Ca/VNCa image series.

RESULTS

Conventional CT gave the correct diagnosis of 59% Ca (Likert scores 1/2) and 70% Hem (Likert 4/5; Cohen's weighted Kappa 0.67 compared to reference standard). The addition of 3 mm Ca/VNCa images yielded 70% Ca and 93% Hem (k 0.87) and 0.8 mm Ca/ VNCa yielded 81% Ca and 89% Hem (k 0.92). Diagnostic certainty (Likert 1+5) increased from 15% with conventional CT to 74% with additional of either 3 mm or 0.8 mm Ca/VNCa images. (Chi square $p<0.001$ for overlays versus conventional, no significant difference between overlay thicknesses).

CONCLUSION

Dual-energy Ca/VNCa post-processing is a promising tool on clinical photon-counting non-contrast head CT, enabling improved differentiation and diagnostic confidence in differentiating calcium from hemorrhage.

CLINICAL RELEVANCE/APPLICATION

The ability to more definitively characterize hyperattenuating foci on non-contrast head CT may yield clinical benefits, including earlier definitive diagnosis of intracranial hemorrhage to prompt treatment, or a reduction in follow-up imaging and ED length of stay for calcifications.

R5B-SPER-2 VALUE ASSESSMENT OF AUGMENTATIVE ARTIFICIAL INTELLIGENCE FOR ASSESSMENT OF PULMONARY EMBOLI ON CT

Igor M. Kitanovski, BA (*Presenter*)
Steven C. Schoettler Woll, MD,MS (*Abstract Co-Author*)
Abdul M. Zafar, MD (*Abstract Co-Author*)

PURPOSE

Artificial Intelligence (AI) algorithms in radiology are currently deployed as tools to augment radiologists rather than autonomous readers. An augmentative tool should improve performance above and beyond the baseline performance achieved by the user alone. We conducted a meta-analysis to elucidate the added value of augmentative AI to radiologists for detecting Pulmonary Embolism (PE) on CT scan.

METHODS AND MATERIALS

Using PRISMA guidelines, studies in which both AI and Human Interpreter (HI) assessed CT scans for pulmonary emboli were selected. We only included studies in which independent adjudication by radiologist(s) was used to establish the ground truth. Studies using the original reader as ground truth for AI were excluded. Data extracted from these studies were used to compare diagnostic performance of AI vs a HI.

RESULTS

Both HI and AI performed similarly with no statistically significant difference in the pooled estimates of sensitivity (AI=0.997, HI=0.998, p=0.546), specificity (AI=0.876, HI=0.823, p=0.69), positive predictive value (AI=0.949, HI=0.960, p=0.727), negative predictive value (AI=0.99, HI=0.986, p=0.589), and accuracy (AI=0.988, HI=0.984, p=0.506). Subsequent analysis focusing on the differences between performance of AI and HI within each study, followed by pooled estimates, also did not demonstrate any significant difference ($p<0.05$).

CONCLUSION

In a meta-analysis of nearly sixteen thousand CTs, AI and HI had similar performance for detection of pulmonary emboli. On one hand, this buttresses AI's use for triaging and for second reads. On the other hand, the outcomes may or may not be different when AI is added-on. The findings of this meta-analysis can be used to re-examine the use-scenarios of AI and to re-calibrate its value proposition. It may be argued that the value proposition of AI may be better as an augmentative tool rather than a stand-alone entity.

CLINICAL RELEVANCE/APPLICATION

This meta-analysis provides evidence to guide the clinical implementation of augmentative AI in pulmonary embolism detection. The comparable performance between AI and radiologists suggests that AI could be effectively deployed for preliminary screening of studies, prioritizing radiologist worklists, and expediting reporting of actionable findings. The lack of statistically significant improvement in diagnostic metrics reframes the value proposition of AI, since AI only evaluates one of several potential findings on each scan and a human reader is required to evaluate each study regardless of AI deployment. Healthcare systems considering AI implementation should carefully evaluate the cost-benefit ratio, focusing on workflow optimization rather than diagnostic improvement.

R5B-SPGI-1 DIFFUSION-WEIGHTED IMAGING-BASED VIRTUAL ELASTOGRAPHY IN METABOLIC DYSFUNCTION-ASSOCIATED FATTY LIVER DISEASE

Jie Yuan, MD (*Presenter*)
Fuhua Yan, MS (*Abstract Co-Author*)
Huimin Lin (*Abstract Co-Author*)
Zhiwei Qin (*Abstract Co-Author*)

PURPOSE

Virtual magnetic resonance elastography (vMRE), based on diffusion-weighted imaging (DWI), presents a promising alternative to traditional magnetic resonance elastography (MRE) for assessing chronic liver disease, particularly without the specialized hardware and expertise typically required for MRE. However, research on metabolism-related fatty liver disease (MAFLD) remains limited. This study aimed to develop and evaluate a vMRE method using DWI to assess MAFLD and compare its performance with traditional MRE and liver biopsy.

METHODS AND MATERIALS

In this prospective study, based on international expert consensus on the definition of fatty liver associated with metabolic dysfunction, 69 patients were included, including 54 patients with MASH. DWI and MRE imaging were performed after the liver biopsy. Pathological steatosis and liver inflammation were assessed using the NAFLD activity score (NAS), with NAS=4 indicating metabolic dysfunction-related steatohepatitis (MASH). The correlation between shear modulus derived from MRE and apparent diffusion coefficient (ADC) was analyzed, and the diagnostic effect was evaluated by deducing vMRE formula.

RESULTS

ADC values, particularly ADC 0-800 ,ADC1 50-800 ,ADC 150-1000 ,ADC 200-800 ,ADC 200-1000 ,ADC 200-1200 showed significant correlations with MRE elasticity values in MASH patients(r=-0.619,r=-0.647,r=-0.620,r=-649,r=-0.675,r=-0.645;P<0.01)in MASH patients. The strongest correlation was observed with ADC values at b-values of 200 and 1000 s/mm². The vMRE formula was determined as:vMRE=11.686-0.006×ADC.

CONCLUSION

DWI-based vMRE can assess MASH without the need for mechanical vibration equipment, offering a non-invasive and practical alternative to traditional MRE for evaluating MAFLD.

CLINICAL RELEVANCE/APPLICATION

DWI-based vMRE eliminates the need for mechanical vibration hardware, enabling non-invasive, cost-effective evaluation of MASH severity, aiding early diagnosis and therapeutic monitoring without liver biopsy.

R5B-SPGI-2 PUSHING THE LIMITS OF LIVER MRI: ENHANCED DETECTION OF SUBPHRENIC LESIONS WITH COMPRESSED SENSING VIBE

Fabio Pivetta, MD (*Presenter*)
Johannes Kolck, MD (*Abstract Co-Author*)
Dominik Geisel, MD (*Abstract Co-Author*)

PURPOSE

Imaging of liver lesions is of significant importance for systemic and interventional therapy planning, as well as oncologic follow-up. However, their visualization can be particularly challenging when localized subphrenically. Magnetic resonance imaging (MRI), with its superior contrast resolution - especially when combined with gadoxetic acid (GdEOB-DTPA, commercially known as Eovist or Primovist) - is an invaluable tool for evaluating these lesions and often provides definitive characterization. Despite this, precise MRI imaging of subphrenic lesions is frequently impaired by respiratory and cardiac motion. This study aimed to evaluate, both qualitatively and quantitatively, the effectiveness of compressed sensing Volumetric Interpolated Breath-hold Examination (VIBE CS) in hepatobiliary phase imaging following GdEOB-DTPA administration.

METHODS AND MATERIALS

Patients who underwent liver MRI between September 1 st , 2022 and April 30 th , 2024 were prospectively enrolled. Quantitative analysis focused on the smallest lesion size (mm) and contrast between liver parenchyma and lesion. Qualitative assessment comprised lesion detectability, image quality, diagnostic confidence, sharpness, contrast, and artifacts (all evaluated on a 1-4 scale). Performance of a standard VIBE (VIBE S) and compressed sensing (VIBE CS) were compared using the paired Wilcoxon signed-rank test, with statistical significance defined as $p < 0.05$.

RESULTS

VIBE CS demonstrated superior performance compared to VIBE S in detecting small lesions ($p = 0.035$) and providing enhanced image sharpness ($p < 0.001$). Overall image quality, contrast, and lesion detectability were comparable to VIBE S (all $p > 0.05$).

CONCLUSION

VIBE CS outperforms VIBE S in detecting small subphrenic lesions and offering higher image sharpness.

CLINICAL RELEVANCE/APPLICATION

Compressed sensing VIBE enhances liver lesion detection, crucial for systemic therapy, interventional procedures, and oncologic follow-up - potentially leading to more accurate treatment planning and improved patient outcomes.

R5B-SPGI-3 ULTRASOUND SHEAR WAVE ELASTOGRAPHY THRESHOLDS FOR DIAGNOSTIC ENRICHMENT IN MASLD - A MULTIVENDOR META-ANALYSIS

Tanya Wolfson, MS (*Abstract Co-Author*)
Jake Weeks, BS (*Abstract Co-Author*)
Rohit Loomba, MD, MSc (*Abstract Co-Author*)
Sarah P. Sherlock, PhD (*Abstract Co-Author*)
Kathryn J. Fowler, MD (*Abstract Co-Author*)
Claude B. Sirlin, MD (*Abstract Co-Author*)
Anthony E. Samir, MD, MPH (*Abstract Co-Author*)
Michael S. Middleton, MD, PhD (*Abstract Co-Author*)

PURPOSE

To identify satisfactory ultrasound shear wave elastography (SWE) thresholds for clinical trial diagnostic enrichment of 'significant' liver fibrosis (F=2) and 'at-risk' metabolic dysfunction-associated steatohepatitis (MASH) in patients with metabolic dysfunction-associated steatotic liver disease (MASLD) based on prior non-alcoholic steatohepatitis (NASH) and non-alcoholic fatty liver disease (NAFLD) research.

METHODS AND MATERIALS

A systematic literature search of PubMed, Embase, and Web of Science identified studies with 2D SWE or point SWE (pSWE) in adults with NAFLD who underwent liver biopsy within six months. Sensitivity (Sn), specificity (Sp), and SWE thresholds for F=2 fibrosis and 'at-risk' NASH (NASH + F=2 fibrosis + NAFLD Activity Score =4) were extracted. Summary receiver operating characteristic (sROC) curves were generated using vendor-agnostic and technique-specific models to enable identification of SWE thresholds satisfactory for diagnostic enrichment. Satisfactory thresholds were defined as having Sn = 70% and positive predictive value (PPV) = 50% assuming a 30% pre-test probability (typically achievable through clinical/hematologic biomarker risk stratification). Point estimates and, for Sn and Sp, 95% confidence intervals (CIs) are presented.

RESULTS

Thirty-one studies (16 2D SWE, 13 pSWE, 2 both; 2,801 patients) with F=2 fibrosis outcome, and 5 studies (2 2D SWE, 3 pSWE; 265 patients) with 'at-risk' NASH outcome were included. For F=2 fibrosis, two SWE technique-agnostic thresholds that met satisfaction criterion were: 6.8 kPa (Sn 80% [95% CI: 75%, 84%], Sp 78% [95% CI: 72%, 83%], PPV 60%) and 10.1 kPa (Sn 70% [95% CI: 62%, 78%], Sp 83% [95% CI: 77%,88%], PPV 64%). When stratified by technique, two satisfactory pSWE thresholds were 5.8 kPa (Sn 80% [95% CI: 67%,89%], Sp 76% [95% CI: 63%, 86%], PPV 59%) and 7.0 kPa (Sn 70% [95% CI: 54%, 83%], Sp 84% [95% CI: 72%, 91%], PPV 65%). Two 2D SWE thresholds identified were 7.9 kPa (Sn 80% [95% CI: 72%, 89%], Sp 84% [95% CI: 78%, 89%], PPV 69%) and 8.7 kPa (Sn 70% [95% CI: 57%, 80%], Sp 90% [95% CI: 85%, 94%], PPV 75%). For 'at-risk' NASH, a single satisfactory threshold was 7.7 kPa (Sn 80% [95% CI: 16%, 98%], Sp 74% [95% CI: 14%,98%], and PPV 57%).

CONCLUSION

We identified satisfactory SWE thresholds for diagnostic enrichment in MASLD clinical trials. SWE thresholds varied by SWE technique. Prospective validation of these thresholds is needed.

CLINICAL RELEVANCE/APPLICATION

SWE has the potential to provide effective diagnostic enrichment in clinical trials, thereby reducing screen-fail rates, need for liver biopsy, and cost. This could improve participant safety and accelerate drug development. -The 1st and 2nd names in the author list contributed equally.

R5B-SPGI-4 SYSTEMIC INFLUENCE OF METABOLIC SYNDROME ON RECURRENCE IN EARLY-STAGE HEPATOCELLULAR CARCINOMA AFTER LOCAL THERAPY

Zahra Mohammadigoldar, MD (*Presenter*)
David S. Lu, MD (*Abstract Co-Author*)
Pedram Keshavarz, MD (*Abstract Co-Author*)
Brian Nguyen (*Abstract Co-Author*)
Jihane Benhammou (*Abstract Co-Author*)
Steven S. Raman, MD (*Abstract Co-Author*)
Jason Chiang, MD, PhD (*Abstract Co-Author*)

PURPOSE

To investigate the association between metabolic syndrome (MetS) and recurrence patterns, local and intrahepatic distant, as well as progression free survival (PFS) and overall survival (OS) in hepatocellular carcinoma (HCC) patients treated with curative-intent therapies.

METHODS AND MATERIALS

In this IRB-approved single-institution retrospective cohort study, 270 patients with HCC who met Milan criteria and were treated at UCLA between 2005 and 2022, were included. Patients were divided into two groups based on presence or absence of MetS (n = 144 versus n = 126, respectively). MetS was defined by the presence of at least three of the following criteria adapted from the NCEP ATP III guidelines: BMI >30 kg/m² (used as a surrogate for central obesity), elevated triglycerides (=150 mg/dL or on lipid-lowering therapy), reduced HDL cholesterol (<40 mg/dL in men, <50 mg/dL in women or on therapy), hypertension (=130/85 mmHg or on antihypertensives), and fasting glucose =100 mg/dL or diabetes diagnosis. Treatment modalities included surgical resection, microwave ablation (MWA), and Y90 radioembolization. Recurrence was categorized as overall, local, and intrahepatic distant, and OS was evaluated using Kaplan-Meier curves with log-rank test.

RESULTS

Over a cumulative follow-up duration of approximately 250 months, non-MetS patients, patients with MetS had a significantly higher rate of intrahepatic distant recurrence (40.3%, (58/144) vs 21.4% (27/126)), local recurrence (26.4%, (38/144) vs 20.6%, (26/126)). The overall PFS was significantly reduced in MetS patients (median time 27 versus 48 months; p=0.0027). Intrahepatic distant PFS was significantly lower the MetS subcohort compared to non-MetS subcohort (median time 46 months versus 116 months; p=0.0058). OS was similar between MetS and non-MetS subcohorts, (median time 179 vs 184 p=0.823).

CONCLUSION

Metabolic syndrome significantly correlates with increased recurrence risk, both local and intrahepatic distant among early-stage HCC patients eligible for curative therapies, even when they meet strict Milan criteria.

CLINICAL RELEVANCE/APPLICATION

Metabolic syndrome has been linked to pro-oncogenic metabolic pathways. Despite its prevalence, MetS is frequently overlooked but can potentially be a clinically relevant predictor of recurrence in early-stage HCC - indicating the need for enhanced follow-up and possible adjuvant therapeutic approaches beyond local treatment. This relationship reflects the oncogenic role of underlying metabolic dysfunction and emphasizes the need to consider MetS status in post treatment monitoring strategies.

R5B-SPGI-5 FULLY AUTOMATED PREDICTION OF LIVER FIBROSIS PATHOLOGICAL STAGING APPLYING T1-WEIGHTEDAND T2-WEIGHTED MRI BASED DEEP LEARNING

Yuejun Sun (*Presenter*)
Qizhi Wang (*Abstract Co-Author*)
Wenxin Ma (*Abstract Co-Author*)
Xutong Huang (*Abstract Co-Author*)
Xiong Wang (*Abstract Co-Author*)
Jie Yuan, MD (*Abstract Co-Author*)

PURPOSE

To develop and validate a fully automated deep learning approach based on T1-weighted imaging (T1WI) and T2-weighted imaging (T2WI) MRI for segmenting the liver and predicting liver fibrosis pathological stages as determined by biopsy.

METHODS AND MATERIALS

In this retrospective study, T1WI and T2WI data from 245 participants with suspected chronic liver disease who underwent liver biopsy was analyzed. Based on biopsy results, the participants were categorized into four fibrosis stages S1/S2/S3/S4, with distributions of 40/86/70/49, respectively. We employed the nnUNet for automated liver segmentation and proposed a novel classification architecture named Dual-sequence MRI Fusion ResNet (DMF-ResNet) for liver fibrosis stages prediction. We evaluate the performance of a multi-stage classification framework through systematic combinations of distinct stages (S1, S2, S3, S4) across six key metrics: accuracy, precision, sensitivity, specificity, F1 score, and area under the curve (AUC).

RESULTS

The liver segmentation model yielded a Dice coefficient of 0.952 on the T1WI validation set and 0.924 on the T2WI validation set. The area under the curve (AUC) values for the T1WI, T2WI, and combined T1WI + T2WI models were 0.895, 0.806, and 0.916, respectively, for classifying liver fibrosis from stages S1 to S4. Among the tested configurations, the S1-S2-S3/S4 model demonstrated superior performance, achieving the highest accuracy (0.962), sensitivity (0.976), and AUC (0.963), alongside balanced precision (0.917) and specificity (0.917). Other configurations exhibited notable trade-offs: for instance, S1/S2-S3-S4 yielded exceptional precision (0.958) but lower sensitivity (0.750), while S1-S2/S3-S4 achieved harmonized sensitivity and specificity (0.929 each) with strong AUC (0.956).

CONCLUSION

T1WI+T2WI-based architecture can accurately predict liver fibrosis stages as suggested by biopsy, offering a fully automated and noninvasive alternative for assessing liver fibrosis.

CLINICAL RELEVANCE/APPLICATION

It offers a non-invasive, fully automated alternative for liver fibrosis staging, reducing the need for biopsy. It promotes the use of routine MRI sequences for disease staging, which could inform public health strategies in regions with limited access to biopsy or advanced imaging techniques. The study propose seven staging combinations (e.g., S1/S2/S3/S4 or grouped stages like S1-S2/S3-S4) for tailored clinical applications.

R5B-SPGI-8 DESIGN AND VALIDATION OF A ROBOT-ASSISTED VIBRATION CONTROLLED TRANSIENT ELASTOGRAPHY (VCTE) SYSTEM FOR LIVER IMAGING

Srikarran Sowrirajan (*Presenter*)
Xinyue Liu (*Abstract Co-Author*)
Efe Ozkaya, PhD, MSc (*Abstract Co-Author*)
Laurent Sandrin, PhD (*Abstract Co-Author*)
Bachir Taouli, MD (*Abstract Co-Author*)
Long Wang (*Abstract Co-Author*)

PURPOSE

The aim of this work was to design and validate a robot-assisted Vibration Controlled Transient Elastography (VCTE) system that can reduce operator dependence and maximize the precision and consistency of liver stiffness measurements.

METHODS AND MATERIALS

We developed a robot-assisted VCTE system using a modular 7-DOF Kinova Gen3 robotic arm and an ATI Net Gamma force/torque (F/T) sensor to ensure consistent probe-phantom interaction. A custom 3D-printed end-effector was created to securely mount the FibroScan Expert 630 probe (Echosens, France), and a resolved-rate based force control framework was implemented to maintain stable contact. The system uses a two-layer control strategy: a high-level controller modulates the probe's pose based on real-time force feedback, and a low-level loop ensures smooth and accurate motion. To evaluate the system, simulations were conducted in the Gazebo environment (an open source 2D/3D robotic simulator) using a simplified elastic phantom created via a rigid block and custom force plugin to mimic soft tissue contact (Figure 1a). A target contact force of 7 ± 0.5 N was set as the desired regulation point. A prototype gripper was also designed to enable automatic switching between standard ultrasound and VCTE probes, facilitating a more standardized imaging workflow (Figure 1b).

RESULTS

Simulation results showed that the contact force increased steadily and stabilized at the target value, while the torque remained under 0.2 Nm, indicating proper alignment and stable contact (Figure 1c). These findings validate that the hierarchical control approach enables precise and compliant probe positioning without reliance on complex dynamic models.

CONCLUSION

This study successfully demonstrates that a robot-assisted VCTE system can maintain stable and precise contact force during liver stiffness assessments through a hierarchical force control approach. The system's modular design and reliable probe handling have the potential to streamline liver imaging by reducing operator variability and enabling automated probe transitions.

CLINICAL RELEVANCE/APPLICATION

Current liver stiffness assessments require manual switching between B-mode ultrasound and VCTE probes, contributing to measurement inconsistencies, procedural delays, and increased operator workload. This robotic solution offers a more consistent, automated alternative for clinical liver elastography.

R5B-SPGI-9 COMPARISON OF OPEN 1.16T MR AND CONVENTIONAL CLOSED 1.5/3.0T MR SCANNERS IN THE EVALUATION OF PANCREATIC LESIONS: ASSESSMENT OF IMAGE QUALITY AND DIAGNOSTIC PERFORMANCE

Soumyadeep Ghosh, MBBS, MD (*Presenter*)
Shravya Srinivas Rao, MD (*Abstract Co-Author*)

Shane Vahjen (*Abstract Co-Author*)
Abbas Rezaei (*Abstract Co-Author*)
Aliva Nayak, MD, MBBS (*Abstract Co-Author*)
Mukesh G. Harisinghani, MD (*Abstract Co-Author*)
Anuradha S. Shenoy-Bhangle, MD (*Abstract Co-Author*)
Avinash R. Kambadakone, MD, FRCR (*Abstract Co-Author*)

PURPOSE

Pancreatic lesions are increasingly identified on cross-sectional imaging, with a prevalence of 2.4 - 13.5% in individuals who undergo abdominal imaging for non-pancreatic indications. MRI plays a crucial role in the characterization and follow-up of pancreatic lesions. In patients with claustrophobia or larger body habitus, open MRI may improve compliance and access. This study aims to evaluate image quality and diagnostic performance of the 1.16T open MRI system for pancreatic lesion assessment compared to conventional 1.5T/3.0T scanners.

METHODS AND MATERIALS

This retrospective study included adult patients who underwent contrast-enhanced abdominal MRIs on both the open 1.16T (Oasis, Hitachi) and closed-bore 1.5T/3.0T scanners (Artist and Premier, GE Healthcare) between January 2017 and December 2022. Qualitative assessment of image quality was based on technical adequacy or repeat scan recommendations on the reports. Quantitative analysis includes estimation of signal-to-noise ratio (SNR) for pancreas and contrast-to-noise ratio (CNR) for focal pancreatic lesions. SNR estimation included ratio of pancreas signal to background noise and CNR was estimated by dividing the difference between average signal intensities of the focal lesion and the pancreas by background noise. Statistical comparisons of SNR and CNR were performed using Wilcoxon signed rank test with significance set at $p<.05$ and inter-reader agreement.

RESULTS

The final cohort included 64 abdominal MRIs in 32 patients (n=32 for both open and closed MR), consisting of 14 males and 18 females with a median age of 63.5 years (IQR: 59, 68). Median body mass index (BMI) was 28.6 (IQR: 24.8, 33.9) with 31.3% (n=10/32) and 40.6% (n=13/32) in the overweight and obese categories respectively. Focal pancreatic lesions were seen in 93.8% (n=30/32). These included intraductal papillary mucinous neoplasms (IPMNs; 27/32), pancreatic ductal adenocarcinoma (PDAC; 2/32), and serous cystadenoma (1/32). The mean pancreatic SNR was significantly higher on the 1.16T scanner [37.5 (SD of 17.6) compared to 23.9 (SD of 12.4) on the closed systems ($p<.001$)]. CNR for pancreatic lesions was 49.2 (SD of 33.9) vs. 53.3 (SD of 38.0) ($p=.72$). Technical inadequacy was reported in 3.1% (n=1/32). Repeat imaging was recommended in 6.3% (n=2/32) - one with higher field MR and abdominopelvic CT each.

CONCLUSION

The 1.16T open MRI system demonstrates higher SNR and comparable CNR compared to higher-field closed scanners in evaluating pancreatic lesions.

CLINICAL RELEVANCE/APPLICATION

Open MRI systems may be a viable alternative in select patient populations for pancreatic lesion follow-up and characterization.

R5B-SPGI-12 PERFORMANCE OF NON-ENHANCED ABBREVIATED LIVER MRI COMBINED WITH CT FOR LIVER METASTASIS SCREENING IN RECTAL CANCER STAGING

Eun Sun Choi, MD (*Presenter*)
Hae Young Kim, MD, PhD (*Abstract Co-Author*)
Subin Heo, MD (*Abstract Co-Author*)
Jong Keon Jang, MD (*Abstract Co-Author*)
So Yeon Kim, MD, PhD (*Abstract Co-Author*)
Seong Ho Park, MD (*Abstract Co-Author*)

PURPOSE

Since non-enhanced pelvic MRI is routinely performed for staging rectal cancer, an additional scan of the liver during pelvic MRI could be easily acquired. This study aimed to evaluate the utility of routinely adding non-enhanced abbreviated MRI (NE-AMRI) for liver metastasis screening, in comparison to CT alone (the current guideline-recommended modality), and CT combined with AMRI using hepatobiliary phase imaging (HBP-AMRI) (another potential alternative).

METHODS AND MATERIALS

This retrospective study included patients diagnosed with rectal cancer between 2017 and 2022 at a tertiary institution. AMRI was simulated using full-protocol liver MRI. Two readers independently evaluated the presence of liver metastasis using 1) CT alone, 2) CT+NE-AMRI and 3) CT+HBP-AMRI. Per-patient sensitivity and specificity for liver metastasis were compared using generalized estimating equations. Technical imaging cost of incorporating NE-AMRI was assessed using reimbursement data and the literature.

RESULTS

A total of 476 patients (mean age 61.3±11.9 years; 302 males) were included, 144 (30.3%) of whom had liver metastasis. CT+NE-AMRI had sensitivity higher than CT alone (96.5% [92.6-98.4%] vs. 86.8% [81.0-91.1%]; $p<.001$), and similar to CT+HBP-AMRI (96.9% [93.8-98.5%]; $p=0.54$). No significant difference was noted in specificity between the three protocols (91.3% [88.3-93.5%] for CT; 92.3% [89.4-94.5%] for CT+NE-AMRI; and 91.7% [88.6-94.0%] for CT+HBP-AMRI; $p=0.24$-0.72).). The cost incurred by incorporating NE-AMRI was estimated as $113.26 per patient, in comparison to $131.90 using the current guideline (i.e., CT used primarily and MRI added if needed).

CONCLUSION

CT+NE-AMRI showed higher sensitivity for liver metastasis screening than CT alone, without a reduction in specificity. Integrating NE-AMRI of the liver into routine pelvic MRI protocol in rectal cancer patients may improve tumor staging accuracy without added cost.

CLINICAL RELEVANCE/APPLICATION

Since non-enhanced pelvic MRI is routinely performed for rectal cancer, additional scan of the liver can be easily acquired during pelvic MRI. Adding non-enhanced abbreviated liver MRI for rectal cancer staging may improve sensitivity in detecting metastasis without added cost.

R5B-SPGI-14 LEVERAGING LOCALLY-TRAINED LARGE LANGUAGE MODELS FOR AUTOMATED SYNOPTIC REPORTING AND RESECTABILITY CATEGORIZATION IN PANCREATIC DUCTAL ADENOCARCINOMA

Zoe Z. Hu, MD, BSc (*Presenter*)
Umaseh Sivanesan, MD (*Abstract Co-Author*)
Shane Natalwalla, MD (*Abstract Co-Author*)
Jacob Peoples (*Abstract Co-Author*)
Amber Simpson (*Abstract Co-Author*)
Andrew D. Chung, MD (*Abstract Co-Author*)

PURPOSE

Pancreatic ductal adenocarcinoma (PDAC) treatment relies on imaging to guide decisions. However, inconsistent CT reporting makes extracting key imaging features for staging and resectability an ongoing challenge. Large language models (LLMs) show promise in extracting this data, but proprietary models (e.g. ChatGPT) may lack security. This study aims to develop a secure, locally trained LLM to generate synoptic reports from non-synoptic PDAC staging reports, and assess whether the extracted data accurately determines resectability.

METHODS AND MATERIALS

109 consecutive non-synoptic PDAC staging reports from 2018-2024 at a tertiary care centre were retrospectively reviewed to manually extract 20 key synoptic features based on the 2014 joint consensus statement published by the Society of Abdominal Radiologists and American Pancreatic Association. Using 5-fold cross-validation, the Gemma-2 27B open-source LLM was fine-tuned to extract these features from the reports, and the LLM-extracted values were compared to the manually extracted reference standard. To assess the utility of LLM-extracted data in resectability classification, a retrospective chart review was conducted for the 109 patients with non-synoptic reports and 40 patients with synoptic reports to identify the resectability category as decided by hepatobiliary surgeons. The 2024 National Comprehensive Cancer Network criteria for predicting resectability based on imaging features was applied to both LLM-extracted features from non-synoptic reports and manually extracted features from synoptic reports written by fellowship trained subspecialty radiologists. Both sets of predictions were compared to the surgical decision.

RESULTS

For feature extraction, our trained LLM achieved mean area under the ROC curve (AUC) of 0.95, with positive predictive value of 0.90 and negative predictive value of 0.81. AUC varied when broken down into features associated with the pancreatic tumour (0.96), involved vasculature (0.92), and metastatic disease (0.96). For resectability category, the LLM achieved accuracy of 0.90 with quadratic-weighted Cohen's kappa of 0.92, in comparison to accuracy of 0.95 from manual synoptic reports.

CONCLUSION

We successfully trained an open-source LLM to securely generate synoptic reports by accurately extracting key features, which can be used to predict resectability with performance comparable to synoptic staging reports written by fellowship-trained radiologists.

CLINICAL RELEVANCE/APPLICATION

This study supports the viability of locally trained open-source LLMs to securely generate synoptic reports which reduce variability in radiology reporting, improving treatment planning and patient outcomes in PDAC care.

R5B-SPGI-15 INTERPRETABLE MACHINE LEARNING MODEL BASED ON MRI INTRA- AND PERITUMORAL RADIOMICS FOR PREDICTING BIOCHEMICAL RECURRENCE AFTER RADICAL PROSTATECTOMY

XUELIAN ZHAO (*Presenter*)
Hao Li (*Abstract Co-Author*)
Ning Zhang (*Abstract Co-Author*)
Guangyao Liu (*Abstract Co-Author*)
Kai Ai (*Abstract Co-Author*)

PURPOSE

To investigate the impact of intratumoral and peritumoral MRI radiomics features combined with clinical risk factors on biochemical recurrence (BCR) in prostate cancer patients after radical prostatectomy (RP).

METHODS AND MATERIALS

A retrospective analysis was conducted on 277 RP patients with complete follow-up data (=1 year), all of whom underwent preoperative MRI before biopsy. Patients were divided into training and validation sets (7:3 ratio). Tumor regions of interest (ROIs) were manually segmented by three experienced radiologists on T2-weighted imaging (T2WI) and apparent diffusion coefficient (ADC) maps. Peritumoral features were obtained by expanding ROIs using the SimpleITK package in Python (v3.7.12), followed by manual removal of non-prostatic tissues. Radiomics features from both intratumoral and peritumoral regions were extracted. Machine learning models (radiomics, clinical, and combined radiomics-clinical models) were constructed. Predictive performance was evaluated using receiver operating characteristic (ROC) curve analysis in both training and validation sets. SHapley Additive exPlanations (SHAP) analysis was applied to interpret the combined model's decision-making process.

RESULTS

The C-indices for the IntraPeri_4mm ADC and IntraPeri_4mm T2 models were 0.902 and 0.842, respectively, while the RadR model achieved C-indices of 0.706 and 0.662 in the validation set. The clinical (Clinic) model yielded AUCs of 0.897 and 0.731, whereas the combined radiomics-clinical (Combined) model demonstrated superior performance with AUCs of 0.978 and 0.810. Decision curve analysis (DCA) confirmed greater clinical net benefit for the Combined model.

CONCLUSION

The integration of preoperative MRI-based intratumoral and peritumoral radiomics features with clinical data enables accurate prediction of early BCR after RP.

CLINICAL RELEVANCE/APPLICATION

The integration of preoperative MRI-based intratumoral and peritumoral radiomics features with clinical data enables accurate prediction of early BCR after RP, facilitating proactive surveillance for high-risk patients and improving outcomes. Additionally, SHAP-based interpretability transforms "black-box" predictions into quantifiable feature contributions, aiding clinicians in identifying risk factors and tailoring personalized treatment strategies.

R5B-SPGU-2 IMPACT OF ADDING PSMA PET ON THE DIAGNOSTIC PERFORMANCE OF MRI FOR PROSTATE CANCER AFTER CRYOABLATION THERAPY

Benjamin Fletcher, MD (*Presenter*)
David J. Bartlett, MD (*Abstract Co-Author*)
Patrick Navin, MBBCh, FFR(RCSI) (*Abstract Co-Author*)
Daniel A. Adamo, MD (*Abstract Co-Author*)
Scott M. Thompson, MD, PhD (*Abstract Co-Author*)
David A. Woodrum, MD, PhD (*Abstract Co-Author*)
Hiroaki Takahashi, MD, PhD (*Abstract Co-Author*)

PURPOSE

Post-cryoablation imaging of prostate cancer is challenging; we assessed whether adding PSMA PET improves diagnostic performance over MRI alone.

METHODS AND MATERIALS

Patients with biopsy-proven prostate cancer treated with focal cryoablation and subsequent imaging by PSMA PET/MRI alone or MRI and PSMA PET/CT within 6 months between January 1, 2010 and July 1, 2024 were retrieved. All patients were otherwise treatment naive. Biopsy (Gleason 3+4 or more was considered as positive) or follow-up imaging after subsequent treatment served as the reference standard and required for inclusion. Images were reviewed by three fellowship-trained radiologists using established scoring systems, first MRI alone, then PET with MRI. In cases with PET/CT, the PET images registered onto the accompanying MRI were provided. Evaluation was limited to the prostate gland. The readers evaluated the diagnostic confidence of malignancy (0-100, with more than 25 as positive) on a per-patient basis as well as a per-lesion basis within and outside the ablation cavity. The area under the curve (AUC) of PI-FAB and TARGET for MRI and PRIMARY score for PET were determined for each individual reader. Performance metrics were reported based on consensus among the three readers. Differences in performance between the available modalities were analyzed by using the McNemar test.

RESULTS

A total of 23 patients were evaluated (10 positive and 13 negative by reference standard). In the ablation cavity, the three readers by consensus identified 7 lesions on MRI alone versus 9 lesions on PET+MRI. Outside the ablation cavity, readers respectively identified 0, 0, and 1 lesions on MRI versus 7, 6, and 7 areas of focal PSMA uptake within the prostate on PET+MRI. In 7 cases, the inclusion of PET images upgraded the consensus diagnosis from negative to positive while the remaining 16 cases were unchanged ($p<0.023$). The per-patient diagnostic performance comparing MRI alone versus PET+MRI yielded sensitivities of 50% vs 80%, specificities of 92% vs 62%, positive predictive values of 83% vs 62% and negative predictive values of 71% vs 80% when considered by consensus. Diagnostic performance of the scoring systems for the three readers measured by AUC ranged from 0.56-0.81 for PI-FAB, 0.62-0.87 for TARGET, and 0.73-0.82 for PRIMARY score.

CONCLUSION

In prostate cancer patients treated with focal cryoablation, adding PSMA PET increased lesion detection and sensitivity compared to MRI alone. The PRIMARY score demonstrated similar diagnostic performance with reduced inter-reader variability relative to PI-FAB and TARGET.

CLINICAL RELEVANCE/APPLICATION

Adding PSMA PET to post-ablation evaluation reveals lesions missed by MRI alone, increasing sensitivity for detecting residual or recurrent disease.

R5B-SPGU-4 AUTOMATED ADRENAL INCIDENTALOMA IDENTIFICATION IN NON-CONTRAST CT: A DUAL-CENTER STUDY INTEGRATING DEEP LEARNING AND RADIOMICS

Fanxing Meng (*Presenter*)
Tuo Zhang (*Abstract Co-Author*)
Yuwei Xia (*Abstract Co-Author*)
Yinghui Ge (*Abstract Co-Author*)

PURPOSE

Adrenal incidentalomas are common findings in medical imaging, with most being benign but some requiring clinical attention[1] . Missed detection can delay treatment and worsen patient outcomes. This study develops an AI-driven framework combining 3D nnU-Net-based adrenal segmentation with radiomics to differentiate normal adrenal glands from adrenal incidentalomas on non-contrast CT scans, validated across dual-center datasets.

METHODS AND MATERIALS

We retrospectively analyzed non-contrast CT scans from 558 patients (279 normal, 279 tumor) across two centers (January 2020-January 2025). All tumors were surgically pathology-confirmed (248 adenomas, 22 pheochromocytomas, 9 myelolipomas). Preprocessing included resampling, normalization, and noise reduction. A 3D nnU-Net model was trained on 200 cases (100 normal, 100 tumor) with five-fold cross-validation, evaluated by Dice Similarity Coefficient (DSC), 95% Hausdorff Distance (HD95), and Average Symmetric Surface Distance (ASSD). The remaining 358 cases were processed by the segmentation model, and the cohort was split 8:2 into training (n=446) and testing (n=112) sets. From each adrenal gland's Volume of Interest (VOI), 1,904 radiomics features were extracted and key features selected using MRMR and LASSO. A support vector machine (SVM) was used for classification, evaluated by AUC, sensitivity, specificity, precision and F1 score.

RESULTS

The segmentation model achieved excellent performance, with a mean DSC of 0.907, HD95 of 8.153 mm, ASSD of 0.092 mm, and a processing time of 10.3 seconds per case—far surpassing manual labeling (10-15 min/case). For classification, 24 key features were selected, and the SVM achieved an AUC of 0.978 (95%CI : 0.947-0.995), sensitivity of 0.953, and specificity of 0.955, with over 95% accuracy on the test set. It has showcased a superior degree of adaptability and precision compared to enhanced CT-based models.

CONCLUSION

This study successfully developed a fully automated pipeline for adrenal incidentalomas identification using non-contrast CT.

CLINICAL RELEVANCE/APPLICATION

The deep learning segmentation model accurately segments adrenal glands, while the classification model precisely differentiates between normal adrenal glands and those containing incidentalomas. This method leverages the advantages of non-contrast CT—being non-invasive, cost-effective, and widely available—while achieving high diagnostic accuracy. Fully automated processing further enhances clinical utility, making it a practical alternative to contrast-enhanced CT for incidentaloma detection.

R5B-SPGU-5 QUANTITATIVE EVALUATION OF RENAL MICROSTRUCTURAL ALTERATION USING R2*-MRI IN DIABETIC KIDNEY DISEASE

Jongjin Yoon, MD, PhD (*Presenter*)
Jae Hyon Park, MD (*Abstract Co-Author*)
Dae Chul Jung, MD (*Abstract Co-Author*)
Byung Chul Kang (*Abstract Co-Author*)
Young Taik Oh, MD (*Abstract Co-Author*)

PURPOSE

To determine whether R2*-weighted MRI can serve as a noninvasive quantitative imaging biomarker for renal microstructural alteration in patients with type 2 diabetes mellitus (T2DM) and early-stage chronic kidney disease (CKD). We aimed to compare whole-kidney R2* values between T2DM patients with mild CKD (Stage 2, eGFR 60-90 mL/min/1.73 m²) and those with preserved renal function (eGFR > 90), and to evaluate the correlation between R2* metrics and glomerular filtration rate (eGFR).

METHODS AND MATERIALS

This retrospective study included 395 adults (median age 59.0 years, 69.1% male) who underwent 3.0 T MRI for liver elastography between January 2010 and November 2024. Inclusion required the presence of T2DM and/or hypertension without other metabolic disease. Forty-one patients had T2DM, and 354 were non-diabetic. R2*-weighted sequences were used to segment both kidneys in 3D and extract first-order pixel intensity features (minimum, maximum, mean, median, uniformity, and variance). CKD stage was defined by CKD-EPI eGFR. Group comparisons were performed using unpaired tests, and Pearson correlation was used to evaluate R2*-eGFR relationships. Statistical significance was set at $p < 0.05$. Statistical analyses were performed using Python (ver. 3.13.3), Scikit-learn (ver. 1.6.1), and R (ver. 4.3.3).

RESULTS

In T2DM patients, those with stage 2 CKD showed significantly higher mean and median R2* values than those with preserved renal function ($p = 0.012$ and $p = 0.008$, respectively). Diabetic patients with stage 2 CKD also had significantly higher R2* values than non-diabetic patients, regardless of CKD stage. An inverse correlation was found between eGFR and both mean and median R2* values in diabetic patients ($r = -0.48$, $p = 0.001$), but not in non-diabetic patients.

CONCLUSION

R2*-weighted MRI enables noninvasive quantification of renal microstructural alterations in diabetic kidney disease. Elevated R2* values and their inverse correlation with eGFR suggest early hypoxia and perfusion imbalance before measurable functional decline. In particular, increased renal oxygen consumption driven by hyperglycemia may lead to tissue hypoxia and accumulation of paramagnetic deoxyhemoglobin, thereby elevating R2* values. Limitations include the retrospective design, lack of histologic correlation, and a relatively small diabetic CKD subgroup, which may affect generalizability and statistical power.

CLINICAL RELEVANCE/APPLICATION

R2*-weighted MRI may serve as a promising imaging biomarker for early detection and monitoring of diabetic kidney disease. Physiologically, R2* increases may reflect hyperglycemia-induced oxygen demand and tissue hypoxia, enabling noninvasive assessment of subclinical renal damage in diabetic patients.

R5B-SPGU-6 DUAL-LAYER SPECTRAL DETECTOR CT FOR IMPROVED ASSESSMENT OF RIGHT ADRENAL VEIN IN PATIENTS WITH PRIMARY ALDOSTERONISM

Ryuya Yoshida (*Presenter*)
Yasunori Nagayama, MD (*Abstract Co-Author*)
Takumi Esaki (*Abstract Co-Author*)
Taiga Matsumoto, MD (*Abstract Co-Author*)
Yoshitaka Tamura (*Abstract Co-Author*)
SOICHIRO ISHIUCHI (*Abstract Co-Author*)
Taihei Inoue, MD, PhD (*Abstract Co-Author*)
Daisuke Sakabe, MS (*Abstract Co-Author*)
Masafumi Kidoh, MD, PhD (*Abstract Co-Author*)
Seitaro Oda, MD, PhD (*Abstract Co-Author*)
Takeshi Nakaura, MD (*Abstract Co-Author*)
Hiro Kiyosue (*Abstract Co-Author*)
Toshinori Hirai, MD, PhD (*Abstract Co-Author*)

PURPOSE

To investigate whether virtual-monoenergetic images (VMI) from dual-layer spectral-detector CT (DLCT) improve right adrenal vein (RAV) assessment before adrenal venous sampling (AVS), and portal-venous phase (PVP) images alone can replace conventional multiphase CT combining late-arterial phase (LAP) and PVP.

METHODS AND MATERIALS

Sixty-three patients with primary aldosteronism (28 males, 35 females; 53.0 ± 11.4 years) who underwent LAP and PVP DLCT before AVS were retrospectively analyzed. Conventional polyenergetic images (PEI) and VMI at 40-70 keV (VMI 40-70) were reconstructed. Image noise and contrast-to-noise ratio (CNR) of RAV were quantified. VMI with the highest CNR was predefined as the best-VMI. Two radiologists evaluated four image series (PEI and best-VMI at LAP and PVP) separately for RAV visibility, accessory hepatic vein (AHV) assessability, and image noise using five-point scales. RAV detectability and AHV assessability rates were compared among image series.

RESULTS

VMI 40-70 showed lower image noise and higher CNR than PEI (all $p<0.001$), with VMI 40 providing the highest CNR. VMI 40 demonstratedlower subjective noise and better RAV visibility than PEI in both phases (all $p<0.001$). Using the same reconstructions, RAV visibility was better in LAP, while AHV assessability was better in PVP (all $p<0.001$). VMI 40 improved RAV detectability rate (89.7% vs. 54.8%) and AHV assessabilityrate (96.8% vs. 80.2%) at PVP compared to PEI, achieving equivalent RAV detectability rate to PEI at LAP (89.7%, $p=1.0$).

CONCLUSION

DLCT-VMI improved RAV assessments before AVS. VMI 40 at PVP provided RAV depiction equivalent to PEI at LAP and better AHV assessability than PEI at PVP, potentially serving as a surrogate for dedicated multiphase CT.

CLINICAL RELEVANCE/APPLICATION

The use of VMI 40 at routine PVP CT has the potential to serve as a promising surrogate for dedicated multiphase CT before AVS, allowing for radiation dose reduction while maintaining or even improving the RAV assessments.

R5B-SPHN-2 DEEP LEARNING METHOD FOR TOOTH DEVELOPMENT STAGING ON PEDIATRIC PANORAMIC RADIOGRAPHY

Meng You (*Presenter*)

PURPOSE

Panoramic radiography is a widely utilized imaging technique in pediatric dentistry for assessing tooth development and detecting anomalies. This study aimed to establish a deep learning method with improved performance to determine the development stages of all permanent teeth on pediatric panoramic radiography.

METHODS AND MATERIALS

Three independent cohorts comprising panoramic images of patients aged between 3 and 15 years were collected from the dental hospitals of three provinces (Sichuan, Zhejiang, Henan) in China. A two-step framework was developed to automatically estimate tooth development stages, utilizing the core cohort from Sichuan. First, CenterNet was employed to detect and number permanent teeth. Subsequently, the Dental Position-Based Attention Enhancement Network (DPBAE-Net) was introduced to accurately identify tooth development stages based on a modified Demirjian method. DPBAE-Net uses ResNeXt101 as its backbone network and incorporates two key modules: the Attention-Based Feature Pyramid Enhancement Module (ABFPEM) and the Dental Auxiliary Feature Module (DAFM). The model's performance was validated across the three cohorts.

RESULTS

Ablation studies demonstrated the effectiveness and interpretability of ABFPEM, DAFM, and the post-processing strategy, resulting in a 6.15% improvement in the F1 score. Both quantitative and qualitative results confirmed the efficacy of each DPBAE-Net component, with a weighted precision of 84.05%, weighted sensitivity of 84.78%, and a weighted F1 score of 84.34%. The accuracy of tooth development staging (weighted F1 score) across different centers was 84.43%, 84.19%, and 83.35% for the Sichuan, Zhejiang, and Henan cohorts, respectively.

CONCLUSION

The proposed automated framework enhances the tooth development staging process in a fast and standard manner. The multicenter study validated the method's applicability across a diverse population.

CLINICAL RELEVANCE/APPLICATION

The proposed automated framework not only standardizes and accelerates tooth development staging but also provides population-specific reference data for dental age assessment. Additionally, the deep learning-based staging network facilitate the precise identification of permanent teeth with abnormal growth, improving the effectiveness and comprehensiveness of dental diagnoses using pediatric panoramic radiography.

R5B-SPHN-6 DIAGNOSTIC ACCURACY OF TIRADS ULTRASONOGRAPHY CLASSIFICATION IN EVALUATION OF THYROID NODULES WITH HISTOPATHOLOGY RESULTS

Rita Maia (*Presenter*)
Ana Margarida Frederico (*Abstract Co-Author*)

PURPOSE

The extensive use of ultrasonography has contributed to increased detection of thyroid nodules. TIRADS (thyroid imaging reporting and data system) is a reporting data system for thyroid lesions, that can be understood by clinicians and also to stratify the risk of malignancy of a lesion based on ultrasound findings. This study aims to compare the agreement of TI-RADS's ultrasonography (US) and to assess the diagnostic performance of these scores against histological findings in suspicious thyroid nodules.

METHODS AND MATERIALS

We conducted a cross-section study diagnostic test evaluation, between January 2023 and December 2024. Thyroid nodules were characterized by using the five TI-RADS systems and US-guided fine needle aspiration (US-FNA) was done for nodule with the highest TI-RADS score. Correlation between TI-RADS and US-FNA results were analyzed. Nodules with either size less than 1 cm and non-diagnostic or inconclusive US-FNA results were excluded. Details of all patients was introduced in a proforma, the data documented in Microsoft Excel and processed using SPSS for Windows, Version 17. Variables were plotted and analyzed using Chi square and Fisher exact test. A p value less than 0.05 was considered statistically significant.

RESULTS

Out of 106 thyroid nodules studied, 91.51% were benign and 8.49% were malignant. High specificity, negative predictive value and accuracy for detecting malignancy were noted with the following parameters: taller than wide shape and irregular margin. Highest specificity (96,91%) was noted with irregular margin. However, nodules that presented calcifications had a sensitivity of 67.01% and a specificity of 88.89%, statistically significant association was noted between presence of macrocalcification and risk of malignancy with p value < 0.05. On retrospective comparison of final pathological diagnosis with the assigned TIRADS score, it was noticed that majority of benign nodules were assigned benign TIRADS- 3 and all malignancies were assigned malignant TIRADS score (4 and 5).

CONCLUSION

Although there were no TIRADS-3 malignant diagnoses, and the malignant cases corresponding to the TIRADS-4 and 5, we can conclude that current results reassert the notion that TIRADS shows at least some correlation between benign or malignant cytology diagnoses. Nevertheless, further studies may be needed to improve TI-RADS criteria for improved specificity and positive predictive value.

CLINICAL RELEVANCE/APPLICATION

TI-RADS can achieve meaningful reduction in the number of benign thyroid nodules recommended for biopsy, avoiding unnecessary procedures.

R5B-SPHN-8 ISOLATED UNILATERAL INTRACAVERNOUS OCULOMOTOR NERVE ENHANCEMENT ON 3D CONTRAST-ENHANCED T1 VIBE MRI: CLINICAL CHARACTERISTICS AND OUTCOMES IN PATIENTS WITH DIPLOPIA

YoonSeo Choi, MD (*Presenter*)
Eunhee Kim, MD, PhD (*Abstract Co-Author*)
Hyeji Lee (*Abstract Co-Author*)
Hongseok Ko, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the clinical characteristics and outcomes of patients with isolated unilateral intracavernous oculomotor nerve (CNIII) enhancement on 3D contrast-enhanced (CE) T1 volumetric interpolated breath-hold examination (VIBE) MRI, and to determine its diagnostic and prognostic value in patients presenting with diplopia.

METHODS AND MATERIALS

We retrospectively analyzed 274 consecutive patients with diplopia who underwent MRI including coronal 3D CE T1 VIBE sequences from April 2022 to April 2025. Among these, 40 patients (14.6%) demonstrated CNIII enhancement. After excluding 22 patients with identifiable pathologies (multiple neuritis, tumor, cavernous dural AVF, inflammatory pseudotumor, etc.), we focused on 18 patients (6.6%) with isolated unilateral intracavernous CNIII enhancement, analyzing clinical profiles, treatments, and outcomes.

RESULTS

The 18 patients (4 female; mean age 60 years, range 32-80) underwent MRI at mean 15 days post-symptom onset (range 1-90). Unilateral neural enhancement was observed on the right side (61%, 11/18) and left (39%, 7/18). All presented with ipsilateral third nerve palsy with diplopia. Ptosis occurred in 66.7% (12/18), while pupillary involvement was rare (5.6%, 1/18). Mild headache/ocular pain was reported in 33.3% (6/18). Comorbidities included diabetes mellitus (72.2%, 13/18) and hypertension (55.6%, 10/18). Treatment comprised antiplatelet therapy (61.1%, 11/18), steroid monotherapy (22.2%, 4/18), combined steroid/antiplatelet therapy (11.1%, 2/18), and observation (5.6%, 1/18). All patients achieved complete resolution within 1-6 months. Presumptive diagnoses included diabetic microvascular ischemic neuropathy (66.7%, 12/18), inflammatory neuropathy (11.1%, 2/18), and inconclusive ischemic versus inflammatory neuropathy (22.2%, 4/18).

CONCLUSION

Isolated unilateral intracavernous CNIII enhancement on CE T1 VIBE in patients with diplopia was frequently associated with microvascular ischemic etiology, with favorable clinical outcomes observed in all cases.

CLINICAL RELEVANCE/APPLICATION

High-resolution 3D CE T1 VIBE MRI facilitates precise visualization of the oculomotor nerve within the cavernous sinus, aiding in the diagnosis and management of related dysfunctions. When isolated unilateral intracavernous CNIII enhancement is identified in patients with diplopia, it often indicates a benign, self-resolving condition, emphasizing the vulnerability of this nerve segment to microvascular ischemia.

Janice M. Newsome, MD (*Abstract Co-Author*)
Hari Trivedi, MD (*Abstract Co-Author*)

PURPOSE

Artificial Intelligence (AI) models for triaging radiological cases have shown promise in improving report dictation efficiency. However, limited evidence exists on their impact on radiologist interpretation times, especially among residents. AI-generated alerts may also introduce diagnostic bias. This study investigates whether deploying an AI triage tool for intracranial hemorrhage (ICH) and pulmonary embolism (PE) detection affects interpretation times among resident and attending radiologists.

METHODS AND MATERIALS

A retrospective analysis compared exam interpretation time (EIT) before and after deployment of an FDA-cleared AI tool for ICH (non-contrast head CT) and PE (CT pulmonary angiography). EIT was defined as the time from report creation to preliminary submission (residents) or sign-off (attendings), stratified by resident training year and report outcome (positive/negative). Statistical significance was assessed using the Mann-Whitney test. We used bootstrapped means with 95% CI, as the mean reflects the impact of outliers (i.e., difficult cases), which are clinically relevant in this context. Ground truth was extracted from final reports and compared to AI outputs to analyze EIT by triage accuracy (TP, FP, TN, FN).

RESULTS

AI triage significantly reduced exam interpretation time (EIT) for first- and second-year residents in both ICH and PE cases. For example, R1 mean EIT for ICH-positive reports decreased from 1265s (95% CI: 1134-1400) to 1072s (963-1188), and for negative reports from 1545s to 1354s. R2s showed similar reductions (e.g., ICH-negative: 519s to 474s). These differences were statistically significant ($p < 0.05$), particularly for negative cases. No significant time change was observed for R3, R4, or attendings post-deployment. Stratification by AI triage accuracy revealed longer EITs for false positives across all groups. For PE, residents spent 736s (CI: 579-927) on false positives vs. 695s (678-712) on true negatives; attendings: 746s vs. 590s. For ICH, residents: 707s vs. 531s; attendings: 572s vs. 412s. These results suggest AI misclassifications increase review time, while accurate triage supports more efficient interpretation.

CONCLUSION

AI triage reduced interpretation times for junior residents in ICH and PE cases but had limited impact on senior residents and attendings. Both groups spent more time on false positives, suggesting increased scrutiny, while accurate AI predictions were associated with faster interpretation.

CLINICAL RELEVANCE/APPLICATION

AI triage may enhance efficiency for trainees but can increase workload when results are inaccurate. Ongoing evaluation is essential to balance utility with risks of over-reliance in clinical practice.

R5B-SPIN-2 TIMING OF AI AND HUMAN INTERACTION: A MULTI-MODALITY MULTI-CENTER STUDY ACROSS SWITZERLAND

Natalie Heracleous, PhD (*Presenter*)
Sergey Morozov, PhD, MPH (*Abstract Co-Author*)
Octave Novarina (*Abstract Co-Author*)
Benoit Rizk, MD (*Abstract Co-Author*)
Benoit Dufour (*Abstract Co-Author*)
Simon Pericou (*Abstract Co-Author*)
Cyril Thouly (*Abstract Co-Author*)

PURPOSE

Integrating AI into radiology workflows poses challenges in result timing. While AI promises efficiency, the timing of AI outputs relative to radiologist report creation critically affects AI clinical utility and potential liability. Understanding these temporal patterns is key for optimal use.

METHODS AND MATERIALS

We retrospectively analyzed 4 months of AI use provided via an AI platform, covering 12,398 studies processed by 7 AI solutions across multiple modalities (XR, CT, MR, MG) in the Swiss Imaging Network 3R. Metrics included AI latency (image extraction, transfer, processing, return), AI output availability before report creation/validation, and radiologist report TATs.

RESULTS

AI outputs were consistently available before report validation in the vast majority of cases (94.85%), but their availability before initial report creation varied widely by imaging modality, from as low as 11.12% for trauma and orthopedic X-ray to as high as 52.96% for mammography. Processing times also differed: X-ray AI solutions delivered results most rapidly (median 2.5-3.25 minutes), with chest X-ray AI achieving 92.20% pre-validation and 17.29% pre-creation availability (radiologist TAT 2-3 minutes). Mammography AI showed 95.77% pre-validation and 52.96% pre-creation availability (median latency 3.5 minutes; TAT 15 minutes). In contrast, MRI and chest CT required substantially longer processing (median 13.65-15.52 minutes), with chest CT AI achieving 92.42% pre-validation and 45.42% pre-creation availability (radiologist TAT 22 minutes), while neurological AI solutions (brain volumetry, multiple sclerosis lesion detection) had high pre-validation rates (88.89%-90.48%) but low pre-creation availability and the longest radiologist TATs (25-36 minutes). Thus, while bone and mammography applications provided the most timely AI support, complex modalities like MRI and chest CT were limited by longer processing times and lower early availability.

CONCLUSION

AI performance and timing vary significantly by application, with trauma XR and mammography solutions demonstrating superior technical performance. Although AI outputs are generally available before report validation, variability before report creation highlights the need for workflow optimization. Modality-specific processing times and availability patterns should inform implementation strategies. This study provides benchmarking data for future AI integration projects.

CLINICAL RELEVANCE/APPLICATION

AI timing findings offer actionable guidance for radiology departments adopting AI, supporting optimized workflow integration, and realistic expectations for clinical AI use.

R5B-SPIN-3 OPEN WEIGHT LANGUAGE MODELS TO IDENTIFY CRITICAL FINDINGS IN RADIOLOGY REPORTS

Patricia W. Wu, MD (*Presenter*)
Chun-Shan Yam, PhD (*Abstract Co-Author*)
Bettina Siewert, MD (*Abstract Co-Author*)
Seth J. Berkowitz, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the performance of open weight language models (LMs) for identifying critical findings in free-text radiology reports to provide timely communication of potentially life-threatening conditions and facilitate audits for compliance with institutional critical result reporting policies.

METHODS AND MATERIALS

We retrospectively collected 6743 radiology reports that were previously audited by radiologists for the presence or absence of critical findings that required immediate notification as per departmental policy. The dataset included 171 reports that were flagged as containing critical results. Using zero-shot prompt engineering techniques, we prompted 3 locally hosted LMs to analyze the reports to identify and classify critical findings based on a predefined list of 19 findings outlined in our communication policy. We evaluated several models across a range of sizes, including Llama 3.2 (3B), Mistral (7B), and Gemma-3 (27B), to assess performance. Model inference was run on a single GPU within a locally hosted high-performance computing environment. Models were evaluated for sensitivity and specificity.

RESULTS

Llama 3.2 (3B), Mistral (7B), and Gemma-3 (27B) achieved a sensitivity/specificity of 0.84/0.43, 0.82/0.70, and 0.94/0.68, respectively, in identifying reports containing critical findings. Error analysis revealed that most false negatives involved ambiguous results or findings that were not explicitly included in the predefined list which included a catch-all category for miscellaneous critical findings. Inference times were less than 1 second for all models.

CONCLUSION

Open weight language models can accurately and efficiently identify critical findings in radiology reports according to departmental policy. The models were able to flag critical findings in near real-time, running locally within the hospital, showing potential for integration into the clinical workflow as a system for prospective alerting and compliance auditing.

CLINICAL RELEVANCE/APPLICATION

Automated identification of critical findings using open weight language models can reduce delays in communication, enhance patient safety, facilitate quality assurance, and improve workflow in radiology practice.

R5B-SPIN-4 IMAGING BIOMARKERS OF CARDIOVASCULAR RISK: FAT RADIOMICS IN PREOPERATIVE CT OF HIP FRACTURE PATIENTS

Sheen-Woo Lee, MD, PhD (*Presenter*)
Ieun Yoon, MD (*Abstract Co-Author*)

PURPOSE

To investigate if body composition features of lower extremity on preoperative CT images can predict major cardiovascular events (MACE) in patients with hip fracture.

METHODS AND MATERIALS

Patients with CT-confirmed hip fractures were included in this retrospective study. CT images of bilateral lower extremity were analyzed using body segmentation programs (DeepCatch Medical IP, and Aview Coreline, Korea). Quantitative and qualitative characteristics of muscle and fat were extracted, which included cross-sectional area, intermuscular adipose tissue [IMAT], low-attenuation muscle area [LAMA], normal-attenuation muscle area [NAMA], and radiomics features. The primary outcome was MACE within 30 days post-surgery, defined as a composite of all-cause mortality, myocardial infarction, stroke, or heart failure hospitalization. Pearson correlation and logistic regression analyses were performed to determine the association between MACE and the variables. SPSS and MedCalc programs were utilized, and statistical significance was determined at $p<0.001$.

RESULTS

Of 356 patients (female:male=239:117, median age 81), 72 (20.2%) experienced MACE during a median follow-up of 13.1 months. Muscle metrics showed no significant association with MACE, except for a shape feature termed roundness ($p=0.0005$). Fat cross-sectional area, shape compactness, first-order mean value, GLSZM, GLCM,and GLDM features showed significant correlation with MACE ($p < 0.0001$). Multivariate analysis revealed that selected fat GLSZM and shape characteristics were independently associated with MACE ($p < 0.001$).

CONCLUSION

The cross-sectional area and radiomics features of lower extremity fat from preoperative CT may serve as imaging biomarkers for predicting cardiovascular risk after hip fracture surgery in elderly patients.

CLINICAL RELEVANCE/APPLICATION

CT-based imaging informatics can aid the management of elderly patients at risk.

R5B-SPIN-6 RADIOLOGY REPORT ENHANCEMENT WITH LLAMA-4 AND AGENTIC WEB BROWSER: AUTOMATED TRANSCRIPTION, GRAMMAR CORRECTION, STRUCTURED FINDINGS, AND RADIOPAEDIA-POWERED EDUCATIONAL AUGMENTATION

Shahriar Faghani, MD (*Presenter*)
Mana Moassefi, MD, MD (*Abstract Co-Author*)

PURPOSE

To develop and evaluate an agentic AI assistant—combining an open-source Whisper transcription engine, LLaMA-4 for grammar correction and structured key-item extraction, and a web-orchestrated Radiopaedia retrieval pipeline—that (1) converts spoken radiologist dictation into error-free text, (2) identifies and organizes key findings and impressions, and (3) retrieves peer-reviewed Radiopaedia articles and exemplar images to enhance diagnostic confidence and trainee education.

METHODS AND MATERIALS

We implemented a modular pipeline that: Speech Transcription : Processes radiologist narration with Whisper, yielding initial text. Grammar & Structure : Uses LLaMA-4 to correct grammar and typos, then extracts key findings, impressions, and relevant items. Agentic Web Orchestration : Leverages a goal-driven browser agent to construct and iteratively refine Radiopaedia search queries. Retrieval Augmented Generation (RAG) & Summarization : Retrieves top Radiopaedia articles and images via a retrieval-augmented generation (RAG) framework, then summarizes and integrates them through LLaMA-4. Performance was assessed on 80 de-identified radiology dictations (40 routine, 40 rare/atypical cases) spanning neuroradiology, musculoskeletal, and body imaging. Ground truth comprised expert-corrected transcripts, annotated key items, and relevance judgments for Radiopaedia outputs.

RESULTS

Transcription Accuracy : Mean word error rate (WER) improved from 5.3% to 0.4% post-LLM correction, corresponding to a final transcription accuracy of 99.6%. Key-Item Extraction : Achieved 94% precision and 91% recall for identifying findings and impressions. Radiopaedia Retrieval : Returned at least one highly relevant article in 95% of routine cases and 80% of rare cases (overall 87.5% success), covering 84% of atypical entities. Mean of 3.1 pertinent articles and 2.4 exemplar images per query.

CONCLUSION

This LLM-driven, agentic browser-enabled platform reliably transcribes and refines radiologist speech, structures critical report elements, and seamlessly augments reports with Radiopaedia-sourced educational materials.

CLINICAL RELEVANCE/APPLICATION

It offers robust decision support in challenging cases and serves as an interactive learning tool for trainees. Future work will integrate with PACS, validate prospectively in clinical workflows, and extend to subspecialty-specific knowledge bases.

R5B-SPIN-7 AI IMPROVEMENTS TO RADIOLOGY WORKFLOW: NOT THE EXPECTED BLESSING

Ali Ghasemi, MD (*Presenter*)
Avneesh Chhabra, MD, MBA (*Abstract Co-Author*)
Azin Etemadimanesh (*Abstract Co-Author*)

PURPOSE

To explore how artificial intelligence (AI) is shaping the practice of radiology through changes in workflow efficiency, economic performance, and workforce well-being, with attention to both observed benefits and emerging challenges.

METHODS AND MATERIALS

A narrative synthesis of studies published between 2018 and 2025 was conducted, focusing on AI implementations in diagnostic imaging and radiology workflow. Evidence was drawn from economic models, real-world interventions, and meta-analyses reporting outcomes related to cost, efficiency, burnout, and policy alignment.

RESULTS

AI adoption has led to measurable efficiency gains in specific settings. A study integrating structured EHR and PACS systems reported a 38% reduction in turnaround time (from 11.2 to 6.9 minutes, $p < 0.05$). A deployment of AI triage tools for pneumothorax reduced median reporting time from 186 to 100 minutes ($p < 0.001$). Simulation models estimate up to 30% cost savings when radiologists focus on complex cases while AI handles initial screening ($p < 0.01$). Additionally, natural language processing tools and remote workflows have contributed to administrative relief and reduced task redundancy. However, pooled data across 48 workflow studies showed no statistically significant reduction in task time due to wide variation in AI deployment and clinical context ($I^2 > 95\%$). Oversight responsibilities required by AI systems have also introduced new cognitive burdens, often referred to as "tech stress." Cross-sectionalsurvey data suggest a positive correlation between AI use and emotional exhaustion among radiologists. Financial incentives remain misaligned, with most reimbursement systems offering no differentiation for AI-assisted interpretations. Concerns around case complexity clustering, data governance, and lack of standard evaluation metrics persist, potentially limiting sustained adoption.

CONCLUSION

AI technologies are contributing to improvements in radiology operations and may reduce costs under certain conditions. Yet, without policy updates, reimbursement reform, and targeted support for AI oversight, these benefits may be unevenly realized. Further prospective research is needed to clarify long-term outcomes for workflow, well-being, and compensation.

CLINICAL RELEVANCE/APPLICATION

AI technologies are contributing to improvements in radiology operations and may reduce costs under certain conditions. Yet, without policy updates, reimbursement reform, and targeted support for AI oversight, these benefits may be unevenly realized. Further prospective research is needed to clarify long-term outcomes for workflow, well-being, and compensation.

R5B-SPIN-9 ZERO-SHOT CT EMBEDDINGS FOR OVARIAN TUMOR CLASSIFICATION AND FEATURE DETECTION

Yu-Fu Wu, MD (*Presenter*)
Gigin Lin, MD (*Abstract Co-Author*)

PURPOSE

To determine the potential of zero-shot CT embeddings produced by a publicly available vision-language model in the tasks of (1) discriminating between benign and malignant ovarian tumors and (2) detecting clinically relevant morphologic and disease-spread features without additional model training.

METHODS AND MATERIALS

We retrospectively collected 3,679 pathology-proven abdominopelvic CT studies (CGMH OVCTCL archive, 2010-2020). After removing sequential examinations and retaining a single contrast-enhanced axial series per patient, 3,449 studies remained. Cases were labeled as benign (benign, endometriosis, n = 2,420) or malignant (ovarian cancer, borderline tumor, metastasis, n = 1,029).Images were embedded using the MedImageInsight model without further fine-tuning. Anonymized radiology report findings sections were parsed with the GPT-4o JSON tool-calling method to generate binary labels for 11 CT descriptors, including tumor features (solid component, septation, calcification), size and location, uterus status (fibroids, endometrial thickening), lymphadenopathy, ascites, and carcinomatosis.Five-fold cross-validation logistic regression probes were fitted on the frozen embeddings. Performance metrics included AUC, sensitivity, specificity, and confusion-matrix analysis.

RESULTS

For malignancy classification: The AUC was 0.79; the optimal Youden threshold yielded a specificity of 0.78 (361/464) and a sensitivity of 0.68 (153/226), with a positive predictive value of 0.73. For feature recognition: The mean AUC across the 11 descriptors was 0.72 ± 0.07 (range 0.63-0.83). The highest performance was observed for peritoneal carcinomatosis (AUC 0.83), followed by ascites (AUC 0.77) and septation (AUC 0.75). Calcification proved to be the most challenging target (AUC 0.63).

CONCLUSION

CLIP-style model has the potential to capture enough CT image information and generate embedding vectors that are suitable for downstream tasks.

CLINICAL RELEVANCE/APPLICATION

These model can runs on resource limited settings, and could assist in prioritizing high-risk cases in clinical settings.

R5B-SPIN-10 AI PATENTS IN RADIOLOGY: HOW INVOLVED ARE ACADEMIC PHYSICIANS?

Ali Ghasemi, MD (*Presenter*)
Azin Etemadimanesh (*Abstract Co-Author*)
Laura M. Fayad, MD (*Abstract Co-Author*)
Shivani Ahlawat, MD (*Abstract Co-Author*)

PURPOSE

Artificial Intelligence (AI) has revolutionized medical imaging, particularly with advanced modalities like Magnetic Resonance Imaging (MRI) and Computed Tomography (CT). Our objective was to map the evolution of patent filings over the past decade, identify thematic innovation trends with an emphasis on understanding the roles of academia, industry, and cross-sector collaborations.

METHODS AND MATERIALS

We analyzed global patent filings from 2015 to 2025 related to AI-driven MRI and CT applications, using harmonized datasets from the U.S. Patent Office (USPTO) and European Espacenet databases. Patents were filtered using key AI terminology and three broad CPC classifications that anchor the field: A61B6/03 (MRI), A61B6/545 (CAD), and A61B34/20 (AI for diagnosis). Universities and other non-academic sectors were separately analyzed.

RESULTS

A total of 382 unique patent families were identified and classified by assignee type: University-only, Collaboration, and Non-academic. The results reveal growing innovation activity in all three domains of computer-aided diagnosis, synthetic imaging, and AI-enhanced reconstruction. There was a steady increase in annual filings starting in 2019, with peaks occurring around 2022-2024. This aligns with broader adoption trends of AI in clinical settings and the maturation of deep learning architectures suitable for medical applications. Academic institutions accounted for 23% of filings, and university-industry collaborations represented a significant proportion. Non-academic entities accounted for the largest share of filings (e.g., medical device companies, software firms, healthcare conglomerates).

CONCLUSION

This patent landscape offers valuable insights into technological priorities and institutional dynamics driving AI advancement in radiology with a dynamic interplay between academia and industry in advancing AI applications in medical imaging. Future research could expand this analysis to include patents from Asia, track regulatory approvals, and examine citation networks to assess the impact and influence of such innovations.

CLINICAL RELEVANCE/APPLICATION

Understanding the patent landscape of AI in radiology helps clinicians and stakeholders anticipate emerging technologies likely to impact diagnostic workflows. By revealing academic and industry contributions to innovations in AI-driven MRI and CT, this study informs strategic planning, fosters translational research, and supports evidence-based adoption of new imaging tools in clinical practice.

R5B-SPIN-11 DIAGNOSTIC ACCURACY OF MACHINE LEARNING MODELS FOR LIVER FIBROSIS STAGING IN CHRONIC HEPATITIS C: A SYSTEMATIC REVIEW AND META-ANALYSIS

Victor Arthur Ohannesian (*Presenter*)
Henrique Lecomte (*Abstract Co-Author*)
Wagner Rios-Garcia (*Abstract Co-Author*)
Filipe R. Barra, MD (*Abstract Co-Author*)
Luiz Felipe Simoes Antunes Nery Dos Santos (*Abstract Co-Author*)
Isabelle Menezes (*Abstract Co-Author*)
Matheus Da Silva Ferreira (*Abstract Co-Author*)
Miriana E. Mariussi, MD (*Abstract Co-Author*)
Luciano Falcao (*Abstract Co-Author*)
Miguel J. Francisco Neto, MD, PhD (*Abstract Co-Author*)
Marcelo R. Silva, MD (*Abstract Co-Author*)
Marcos R. Queiroz, MD, MBA (*Abstract Co-Author*)

PURPOSE

To systematically evaluate the diagnostic accuracy of various machine learning (ML) models for staging liver fibrosis in patients with chronic hepatitis C (CHC). The aim was to estimate pooled sensitivity, specificity, likelihood ratios (LR), diagnostic odds ratio (DOR), and area under the curve (AUC).

METHODS AND MATERIALS

This meta-analysis was conducted according to PRISMA-DTA guidelines. Studies that applied ML models to classify fibrosis stage using liver biopsy or 2D shear-wave ultrasound as the reference standard were included. Extracted outcomes were sensitivity, specificity, AUC, DOR, and LR+/LR-. A bivariate random-effects model was used via the midas package in Stata v15. Heterogeneity and threshold effects were assessed. Included models were Random Forest, Support Vector Machine, Gradient Boosting, Artificial Neural Networks, ANFIS, Bayesian Networks, XGBoost, and others.

RESULTS

Twenty-one studies were included. A total of 8473 patients were analyzed (1733 with fibrosis, 6740 without). Pooled sensitivity was 89% (95% CI: 85-92%). Pooled specificity was 92% (95% CI: 87-95%). AUC was 0.95 (95% CI: 0.93-0.97). DOR was 90 (95% CI: 39-208). LR+ was 10.7 (95% CI: 6.4-17.8) and LR- was 0.12 (95% CI: 0.08-0.17). Assuming a pre-test probability of 20%, the post-test probability was 74.1% for a positive result and 2.9% for a negative result. Significant heterogeneity was observed (I^2 = 80%), mainly explained by the diversity of ML models. A strong threshold effect was present (correlation = 1.00). No significant publication bias was detected (p = 0.098).

CONCLUSION

ML models demonstrated high diagnostic accuracy for staging liver fibrosis in CHC. They outperform traditional noninvasive methods. Neural networks, Random Forest, and boosting-based models showed the best combined performance to date.

CLINICAL RELEVANCE/APPLICATION

ML models may support noninvasive staging of liver fibrosis, particularly when biopsy or elastography is unavailable. Their high sensitivity and specificity allow for safe and reproducible assessment. However, external validation and technical implementation remain necessary, currently representing the main limitations to clinical application.

R5B-SPIN-12 THE IMPACT OF DIFFERENT ITERATIVE ALGORITHMS AND SPECTRAL PARAMETERS ON ABDOMINAL CT IMAGE QUALITY IN DUAL-ENERGY SPECTRAL SCANNING MODE

Xiao Ma (*Presenter*)
Wu Jinhua, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the effects of varying weighted iterative algorithms (Adaptive Statistical Iterative Reconstruction-V, ASiR-V) and spectral parameters on image quality in abdominal dual-energy spectral CT and determine the optimal ASiR-V level for abdominal imaging.

METHODS AND MATERIALS

A prospective study enrolled 47 patients requiring abdominal CT angiography (CTA). Scans were performed at 120 kV tube voltage with automatic tube current modulation (Smart mA, range: 140-740 mA) and a noise index (NI = 9). Images were reconstructed using ASiR-V at three weight levels (30%, 40%, and 50%) with a slice thickness of 1.25 mm. Portal venous phase images were analyzed. Regions of interest (ROIs, 50-150 mm^2) were delineated to measure CT values, noise (standard deviation, SD), and signal-to-noise ratio (SNR) of the portal vein. One-way ANOVA was used to compare differences in SD and SNR among ASiR-V weight groups for spectral parameters, including effective atomic number (Effective-Z) and material decomposition pairs (iodine-water, water-iodine) ($P < 0.05$ for statistical significance).

RESULTS

In 47 patients, increasing ASiR-V weights (30% to 50%) progressively reduced SD values and improved SNR. At ASiR-V 50%, the portal vein SD values were 0.38 ± 0.13 HU (Effective-Z), 10.73 ± 3.39 HU (iodine-water), and 8.66 ± 2.00 HU (water-iodine). Optimal image quality was achieved at ASiR-V 50% with the Effective-Z parameter, demonstrating the lowest SD and highest SNR ($P < 0.05$ for all comparisons). ASiR-V weights exhibited similar effects on Effective-Z and material decomposition pairs (iodine-water, water-iodine), with statistically significant intergroup differences ($P < 0.05$).

CONCLUSION

ASiR-V iterative algorithms significantly enhance abdominal dual-energy spectral CT image quality. The combination of ASiR-V 50% and Effective-Z parameter optimization yields the highest image clarity for abdominal visualization.

CLINICAL RELEVANCE/APPLICATION

Dual-energy spectral CT with ASiR-V iterative algorithms improves abdominal image quality by leveraging atomic number-based parameters, enabling enhanced diagnostic precision without increasing radiation exposure.

R5B-SPIR-1 OUTCOMES OF GENICULAR ARTERY EMBOLIZATION FOR OSTEOARTHRITIS-RELATED KNEE PAIN: A SINGLE-CENTER STUDY

Sina Golzarian (*Presenter*)
Seyed A. Astani, MD, MBA (*Abstract Co-Author*)
Jafar Golzarian, MD (*Abstract Co-Author*)

PURPOSE

Genicular artery embolization (GAE) is a minimally invasive procedure for treating knee pain associated with osteoarthritis (OA). This study evaluates its short-term effectiveness and clinical success rates in a single-center outpatient population.

METHODS AND MATERIALS

This retrospective study included 153 patients treated with GAE at a single outpatient center between March and December 2024. Embolization targeted hyperemic genicular branches identified on angiography and cone-beam CT using Embo ASSIST (GE HealthCare). Embolic agents included imipenem/cilastatin or 100-300 µm Embosphere particles. Pain and function were assessed using the Visual Analog Scale (VAS) and Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC), collected pre-procedure and at 1-, 3-, and 6-month follow-ups. Clinical success was defined as a =20% improvement in either score. Paired t-tests were used to compare pre- and post-treatment outcomes.

RESULTS

Clinical success, defined as a =20% improvement in either WOMAC or VAS score, was achieved in 85% of patients at 1 month, 80% at 3 months, and 79% at 6 months. Among responders, mean WOMAC scores improved from 63.0 to 26.2 at 1 month and to 23.3 at 6 months ($p < 0.001$). Mean VAS scores decreased from 6.4 to 2.3 by 1 month and remained stable through 3 and 6 months ($p < 0.001$). No major complications occurred. Clinical success rates were similar across BMI categories.

CONCLUSION

GAE is a safe and effective outpatient treatment for knee OA, providing sustained symptom improvement through 6 months. These findings support its use as a minimally invasive alternative to more invasive therapies.

CLINICAL RELEVANCE/APPLICATION

GAE may offer an effective, low-risk option for patients with knee OA seeking pain relief without undergoing surgery.

R5B-SPIR-3 IMAGE TRACKING OF ABLATION PROBES AND ULTRASOUND WITH 3D CAMERA AND DEEP LEARNING IN AN INTERVENTIONAL CT SUITE

Laetitia Saccenti, MD (*Presenter*)
Rayal Prasad (*Abstract Co-Author*)
John W. Karanian, PhD (*Abstract Co-Author*)
Ankur Kapoor, PhD (*Abstract Co-Author*)
Ming Li, PhD (*Abstract Co-Author*)
Bradford J. Wood, MD (*Abstract Co-Author*)

PURPOSE

To develop, deploy, and assess a 3D camera and custom software to track an ablation probe and an ultrasound transducer without a fiducial or sensor in an Interventional CT suite.

METHODS AND MATERIALS

Custom deep-learning software was developed and integrated with a 3D camera in a fixed location adjacent to an interventional CT gantry. The input in the software of 3D models (CAD files) of a microwave ablation probe (IntelliBlate, Varian) and an ultrasound transducer (Siemens Healthineers) allowed the detection and tracking of those objects in real-time. Calibrated camera feedback updated the position and direction of the needle or ultrasound transducer in real-time display. The needle and ultrasound transducer were manipulated and tracked in multiple angles and relationships to an anthropomorphic phantom. To evaluate the accuracy of the ablation probe tracking, the 3D coordinates of the ablation needle in the CT space were computed from camera 2D images. The projected position and angle of the needle were compared to the real CT position and angle with Euclidian geometry.

RESULTS

The ablation probe and the ultrasound transducer were successfully tracked via a 3D camera and deep learning. Multiple angles were imaged and transformed into planning software with superimposed graphics updating the location and angulation of the probe and ultrasound in real-time following manual manipulation. Preliminary results showed the cosine similarities between camera estimation and CT image of inserted ablation probes ranged between 0.892-0.944 (1 being perfectly parallel vectors).

CONCLUSION

A 3D camera and custom deep learning software were used to track an ablation probe and ultrasound transducer in real-time. Such a novel approach to interventional ablation planning has the potential for combining ultrasound, needle, and CT data during multimodality fusion ablation without ergonomically cumbersome conventional hardware-based tracking methods.

CLINICAL RELEVANCE/APPLICATION

Image tracking of medical devices with 3D camera and deep learning may design the future of multimodality fusion or registration workflows. Such technologies may theoretically be interfaced with ablation planning and guidance software towards obviating conventional registration with fiducials or electromagnetic sensors.

R5B-SPIR-4 COMPARISON OF CONVENTIONAL VERSUS PHARMACOMECHANICAL CATHETER-DIRECTED THROMBOLYSIS: A MULTI-CENTER ANALYSIS

Zain Hussain, MD (*Presenter*)
Hailey Carruthers, MD (*Abstract Co-Author*)
Arif Musa, MD, MS (*Abstract Co-Author*)
Hussein Chahrour, BS,MD (*Abstract Co-Author*)
Ali N. Harb, MD (*Abstract Co-Author*)

PURPOSE

Large-scale clinical trials, including ATTRACT, CAVA, and CaVenT, have shown strict patient selection is necessary for optimal outcomes when performing conventional catheter-directed thrombolysis (cCDT) and pharmacomechanical CDT (pmCDT). Our purpose is to directly compare post-procedure safety endpoints between cCDT and pmCDT.

METHODS AND MATERIALS

This retrospective analysis compared two cohorts based on thrombolytic treatment modalities: cCDT (n = 2,047 before matching; n = 2,041 after matching) and pmCDT (n = 3,007 before matching; n = 2,041 after matching). Given the 2013 change in CDT CPT definitions, patients in both cohorts must have underwent a documented procedure between January 1, 2013 and January 1, 2023 (10-year time interval). For the cCDT group, the procedure was identified with CPT 37212, while the pmCDT group was defined by 37187 and 37188. Patients were required to have a diagnostic ICD code for thromboembolic event (I80.1 or I80.2 for phlebitis/thrombophlebitis of the lower extremities or I82.4 for acute embolism/thrombosis of deep veins), appearing within 3 months before CDT, thereby confirming the indication for thrombolysis. Exclusionary criteria included a history of PE occurring before CDT. Baseline patient demographics were balanced across the cohorts. Outcome measures included risks of acute PE, chronic PE, and all-cause mortality. Kaplan-Meier (KM) analyses were conducted. Hazard ratios (HR) and absolute risk differences (ARD) were calculated. 95% confidence intervals were reported; statistical significance was achieved at $p<0.05$.

RESULTS

Acute PE occurred in 121/1,246 cCDT patients (9.71 %) versus 130/1,268 pmCDT patients (10.25 %) (RD -0.54 %, 95 % CI -2.89 to 1.80; HR 0.883, 95 % CI 0.689-1.131; p = 0.65). Chronic PE developed in 112/1,974 cCDT patients (5.67 %) versus 78/1,970 pmCDT patients (3.96 %) (RD 1.71 %, 95 % CI 0.38-3.05; HR 1.342, 95 % CI 1.005-1.792; p = 0.012). All-cause long-term mortality was 116/1,919 (6.05 %) for cCDT versus 127/1,922 (6.61 %) for pmCDT (RD -0.56 %, 95 % CI -2.10 to 0.98; HR 0.819, 95 % CI 0.636-1.054; p = 0.47).

CONCLUSION

In our large cohort analysis of lower extremity DVT cases, pmCDT was associated with a significantly reduced risk of chronic PE compared to cCDT. Larger prospective cohorts could further clarify our endpoints.

CLINICAL RELEVANCE/APPLICATION

The significant reduction of chronic PE risk associated with pmCDT compared to cCDT suggests that the mechanical adjunct provided in pmCDT may mitigate residual embolic risk by enhancing thrombus clearance.

R5B-SPIR-5 BODY COMPOSITION AND CLINICAL RISK SCORES AS PREDICTORS OF 6-MONTH MORTALITY AFTER TIPS: A COMPARATIVE ANALYSIS OF PATIENTS WITH REFRACTORY ASCITES VS. VARICEAL BLEEDING

Destina Gizem Aydemir, MD (*Presenter*)
Jennifer Erley, MD (*Abstract Co-Author*)
Isabel Molwitz, MD, MBA (*Abstract Co-Author*)
Felix Piecha (*Abstract Co-Author*)
Gerhard B. Adam, MD (*Abstract Co-Author*)
Peter Bannas, MD (*Abstract Co-Author*)
Lennart Well, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the prognostic value of body composition (myosteatosis, adipose tissue analysis) compared to established clinical risk scores (Freiburg index of post-TIPS survival [FIPS], Model for End-Stage Liver Disease [MELD], and Chronic Liver Failure Consortium Acute Decompensation [CLIF-C AD] for 6-month mortality in patients undergoing transjugular intrahepatic portosystemic shunt (TIPS) due to refractory ascites (RA-TIPS) or acute variceal bleeding (early TIPS).

METHODS AND MATERIALS

This retrospective monocentric study included patients who underwent early-TIPS at our hospital between January 2014 and July 2024 (n=51; 29 male, mean age 53.4 years) and patients who underwent TIPS due to RA between July 2020 und July 2024 (n=37; 29 male, mean age 60.3 years). Patient survival was monitored over six months after implantation of TIPS. Body composition analysis was performed on abdominal CT scans at the level of the third lumbar vertebra (L3). The cross-sectional areas of visceral adipose tissue (VAT), subcutaneous adipose tissue (SAT), and intramuscular adipose tissue (IAT) were quantified. Patients were classified as sarcopenic below a skeletal muscle index (SMI) of 52.4 cm 2 /m 2 in men and 38.5 cm 2 /m 2 in women and below a mean muscle radiation attenuation (mMRA) of 34.2 HU in men and 27.1 HU in women (myosteatosis). Both patient groups were categorized regarding FIPS, MELD, and CLIF-C AD scores. For statistical analysis, analysis of variance (ANOVA) was performed.

RESULTS

Six-month mortality was 21% (8/37) in the RA-TIPS group and 42% (22/51) in the early TIPS group (p=0.03). In both groups, increased mortality was associated with higher FIPS (RA-TIPS: p=0.021; early TIPS: p=0.004), higher MELD (RA-TIPS: p=0.033; early TIPS: p=0.021), higher CLIF-C AD (RA-TIPS: p=0.008; early TIPS: p=0.001) and presence of myosteatosis (RA-TIPS: p=0.045; early TIPS: p=0.012). IAT was significantly higher in non-survivors in the early TIPS group (54 vs. 39 cm^2, p=0.04), but not in the RA-TIPS group (51 vs. 42 cm^2, p=0.09). Mean VAT was higher in non-survivors than survivors in both groups, but the difference was only significant in the early TIPS group (RA-TIPS: 1012 ± 420 cm^2, vs. 812 ± 310 cm^2, p=0.09; early TIPS: 950 ± 340 cm^2 vs. 730 ± 260 cm^2, p=0.04).

CONCLUSION

FIPS, MELD, CLIF-C AD and myosteatosis were all significantly associated with 6-month mortality in both groups (all $p<0.05$). The association between mortality and IAT / VAT was only significant in the early TIPS group (p=0.04), but not in the RA-TIPS group (p=0.09).

CLINICAL RELEVANCE/APPLICATION

Integrating CT-based body composition analysis with established clinical risk scores enhances risk stratification for mortality especially after early TIPS and helps improve patient management.

R5B-SPIR-6 TREATMENT OF PRIMARY AND SECONDARY BRAIN TUMORS USING INTRAARTERIAL CHEMOPERFUSION (IAC): THERAPY RESPONSE AND SURVIVAL RATES

Thomas J. Vogl, MD, PhD (*Presenter*)
Hamzah Adwan, MD (*Abstract Co-Author*)
Tatjana Gruber-Rouh (*Abstract Co-Author*)

PURPOSE

To evaluate the efficacy of intraarterial chemoperfusion (IAC) in patients with malignant primary or secondary brain tumors regarding overall survival time and therapy response.

METHODS AND MATERIALS

In total, 64 patients (mean: 52 years; range: 21-80; 34 women, 30 men), who were treated using IAC in 290 sessions (mean: 4.5 sessions/patient; range: 1-16) were analyzed and included in this retrospective study. 39 patients had primary brain tumors and 25 patients secondary brain tumors. Overall survival time was calculated using the Kaplan-Meier method. Therapy response was determined according to the RECIST criteria.

RESULTS

The mean overall survival time was 1018 days with a six-month survival rate of 65.5% for all patients. The mean overall survival time for patients with primary brain tumors was 1412 days and 516 days for patients with secondary brain tumors, (p-value: 0.1). Two patients achieved complete response (3.4%), 7 patients of partial response (12.1%) and 29 cases of stable disease (50%). Progressive disease was observed in 20 cases (34.5%). RECIST could not be performed in six cases due to loss of follow-up.

CONCLUSION

This study shows that IAC is a potentially effective treatment option for primary and secondary brain malignancies. The patients had promising overall survival and therapy response. However, further prospective studies are required.

CLINICAL RELEVANCE/APPLICATION

IAC is a relevant targeted therapy option for brain malignancies

R5B-SPMK-1 MEASURING LUMBAR INTERVERTEBRAL MOTION USING REAL-TIME MRI IN A STANDARD 3T HORIZONTAL BORE SCANNER

Fiona Mellor, PhD, BSc (*Presenter*)

PURPOSE

Develop an MRI technique to measure dynamic lumbar vertebral motion during passive and active movements. Evaluate automated tracking algorithms for detecting x- and y-position of vertebral bodies throughout dynamic sequences. Background: Understanding intervertebral motion is key to identifying biomechanical contributors to back pain. Quantitative fluoroscopy captures this reliably but involves ionizing radiation. Kinetic MRI offers a non-ionising alternative. This study explores the feasibility of a radiation-free method to visualize and quantify lumbar spine motion using a standard closed-bore 3T MRI system.

METHODS AND MATERIALS

Ten healthy participants (five male, five female; aged 18-51) underwent passive and active lumbar motion imaging in a horizontal 3T MRI scanner. Mid-sagittal images were acquired using adapted sequences from patellar and TMJ tracking: TRUFISP and HASTE. Image quality was subjectively rated on a 4-point Likert scale, and tracking algorithms were applied to vertebral bodies from the most promising sequences. Passive motion was facilitated using inflatable bolsters: for flexion, participants lay prone on a deflating bolster; for extension, they lay supine. Active motion involved voluntary flexion to extension to neutral. Participant acceptability was assessed via a post-scan questionnaire. All images were reviewed for incidental findings.

RESULTS

HASTE sequences produced superior image quality, supported by subjective ratings and tracking performance. Vertebral visualization and artefact reduction succeeded in 89% of HASTE images versus 49% with TRUFISP. Passive motion yielded minimal intervertebral rotation but greater variability in positioning, reducing reproducibility and participant comfort. Active motion was better tolerated, more reproducible, and resulted in shorter scan times with greater vertebral rotation. No incidental findings warranted further investigation. TRUFISP: 40 measurements over 30 seconds (TR 741.68 ms) HASTE: 30 measurements over 42 seconds (TR 1400 ms)

CONCLUSION

Dynamic lumbar spine imaging is feasible using a standard 3T MRI scanner but is limited by body habitus, with BMI >30 reducing motion range and affecting SAR limits. Further work will evaluate algorithm reliability and support the development of a validated kMRI protocol for clinical and biomechanical applications.

CLINICAL RELEVANCE/APPLICATION

This technique may aid in identifying sources of spinal dysfunction or pain by enabling detailed biomechanical analysis. It establishes a foundation for future studies in clinical populations and may enhance diagnostic and therapeutic strategies for spine-related conditions.

R5B-SPMK-2 NONSPECIFIC LOW BACK PAIN: HIGH RATES OF RADIOGRAPHS AND MRI EARLY IN THEIR MANAGEMENT NOT CONSISTENT WITH CLINICAL GUIDELINES

Katelyn E. Rudisill, MPH, BS (*Presenter*)
Gwyneth Maloy (*Abstract Co-Author*)
Jonathan Grauer (*Abstract Co-Author*)

PURPOSE

Nonspecific lower back pain (LBP) is one of the most common clinical diagnoses worldwide. Although diagnostic imaging may aid in the management of nonspecific LBP, guidelines do not recommend this prior to six weeks of conservative management. While radiographs are typically thought of as first line imaging, the use of magnetic resonance imaging (MRI) has increased. The current study evaluates trends in radiographs and/or MRI among patients diagnosed with nonspecific LBP.

METHODS AND MATERIALS

Data were abstracted from the 2010 to 2021 M151Ortho PearlDiver national, multi-insurance, administrative dataset. The use and timing of lumbar spine radiograph and/or MRI within one year of diagnosis were characterized. Patient characteristics were compared across imaging groups using multivariable analyses.

RESULTS

For a large cohort of 17,558,141 patients with nonspecific LBP, imaging was obtained within the first year for 952,072 (5.4%). Of these, lumbar radiographs only were obtained for 569,107 (59.8%), MRI only was obtained for 295,655 (31.0%), and both radiographs and MRI were obtained for 43,655 (4.6%). Within the first six weeks of diagnosis, 52.9% of the radiographs were obtained and 23.6% of MRIs were obtained. Independent predictors for receiving MRI relative to radiographs included male sex (OR 1.06) and non-clinical factors: region (relative to West, Midwest [OR 1.20], Northeast [OR 1.17], and South [OR 1.15]) and insurance type (relative to commercial, Medicare [OR 1.13] and Medicaid [OR 0.96]) ($p < 0.0001$ for each).

CONCLUSION

Despite guidelines discouraging imaging within six weeks of nonspecific LBP diagnosis, a substantial proportion of patients received radiographs and MRIs during this early period. MRI use remains common and is influenced by non-clinical factors. These findings highlight variation in practice and the need for improved adherence to evidence-based imaging guidelines.

CLINICAL RELEVANCE/APPLICATION

Imaging for nonspecific low back pain often occurs earlier than guidelines recommend, with use influenced by non-clinical factors. These findings highlight a need for more consistent adherence to evidence-based imaging practices.

R5B-SPMK-3 PROSPECTIVE, MULTICENTER, MULTIVENDOR CLINICAL ASSESSMENT OF PATIENT-CENTERED LUMBAR-SPINE MRI: FROM ULTRAHIGH-SPEED SCANNING TO SIMULTANEOUS AUTOMATED REPORT GENERATION IN JUST 5 MINUTES

Jiwoo Park, MD, PhD (*Presenter*)
Young Han Lee, MD (*Abstract Co-Author*)

PURPOSE

Magnetic resonance imaging (MRI) is a critical tool for diagnosing lumbar spine (L-spine) pathologies, but MRI scan is time-intensive, limiting patient throughput and increasing costs. Recent advancements in ultrahigh-speed MRI with deep learning (DL)-based enhancement and artificial intelligence (AI)-driven automated reporting offer potential solutions to these challenges. To demonstrate the clinical equivalence in quality and safety between ultrahigh-speed L-spine MRI with DL-based enhancement and conventional turbo spin echo (TSE) MRI, while simultaneously evaluating the clinical application of AI-generated automated radiologic reports.

METHODS AND MATERIALS

This prospective study included 70 patients enrolled from two institutions. All participants underwent both conventional L-spine MRI and ultrahigh-speed L-spine MRI with DL-based enhancement during the same session, resulting in a total of 140 MRI scans. Quantitative analyses included signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) measurements, while qualitative assessments were conducted by four radiologists blinded to scan type and patient information. Interchangeability between conventional and ultrahigh-speed MRI protocols was evaluated using predefined equivalence criteria for five key pathologic findings. Diagnostic agreement was assessed by comparing AI-generated reports with radiologist consensus reports. Statistical analyses were performed, with $p < 0.05$ considered statistically significant.

RESULTS

Ultrahigh-speed L-spine MRI with DL-based enhancement demonstrated significant reductions in acquisition time, achieving an approximate 80-86% decrease compared to conventional MRI, while maintaining interchangeability in diagnostic performance. Quantitative analysis revealed superior SNRs and CNRs for bone marrow and intervertebral discs in ultrahigh-speed MRI, with qualitative evaluations supporting comparable image quality. Automated report generation using AI software exhibited diagnostic agreement comparable to radiologists' reports, with substantial to almost perfect agreement.

CONCLUSION

Ultrahigh-speed L-spine MRI with DL-based enhancement, in conjunction with AI-driven reporting systems, demonstrated clinical feasibility and efficiency in practice, significantly reducing overall workflow time.

CLINICAL RELEVANCE/APPLICATION

The ultrahigh-speed reconstruction and automated reporting were executed with fully commercial, regulatory-cleared software rather than in-house research code. Using off-the-shelf solutions underscores the immediate, plug-and-play translatability of the 5-minute MRI-to-report workflow to routine clinical practice across vendor platforms.

R5B-SPMK-4 COMPARISON OF HIGH-RESOLUTION 3D VS. 2D LUMBAR SPINE MRI USING A NOVEL DEEP LEARNING RECONSTRUCTION ALGORITHM AND PROTOTYPE CONFORMAL SPINE COIL

Allison Lowe, BSc (*Presenter*)
Ek Tsoon Tan, PhD (*Abstract Co-Author*)
Darryl B. Sneag, MD (*Abstract Co-Author*)
Meghan Sahr, MD (*Abstract Co-Author*)
J. Levi Chazen, MD (*Abstract Co-Author*)
Richard Kijowski, MD (*Abstract Co-Author*)

PURPOSE

Conventional 2D MRI has limitations in image scoliotic spines, leading to longer scan times and reduced visualization of complex pathology. This study compared interobserver agreement and image quality between deep learning reconstructed (DLR) 3D and 2D MRI sequences. We hypothesized that a prototype conformal 72-channel posterior coil with DLR would yield high-resolution 3D lumbar-spine images comparable to 2D scans.

METHODS AND MATERIALS

30 scoliosis patients identified on previous imaging (68.5 years old ±14.5, 13 M/17 F) undergoing clinical lumbar spine MRI at 3T were prospectively recruited under an IRB-approved protocol. Isotropic 3D T1, T2 and STIR sequences were obtained with the standard three-plane 2D protocol using the prototype coil and DLR. Three radiologists averaging 14 years of experience assessed the randomized sequences for image quality, central and foraminal stenosis, disc herniation (presence, location, type), facet joint cyst, and fracture. Interrater agreement was evaluated by Gwet's agreement coefficient for categorical (AC1) and ordinal (AC2) variables, and intraclass correlation coefficient (ICC) for continuous variables. To compare 2D and 3D sequences, the sign test, Wilcoxon sign rank test, and McNemar test, were used for ordinal variables, continuous variables, and binary nominal data, respectively. Cobb's angle was measured in all subjects on MRI.

RESULTS

Interrater agreement was similar between 3D and 2D sequences of the same tissue weighting. Gwet's AC1 values for fracture were 0.84-0.85 (95% confidence interval: 0.682-1) for 3D and 0.86-0.88 (0.719-1) for 2D. Synovial cyst agreement was high: 0.87-0.88 (0.751-0.995) for 3D and 0.93-0.98 (0.837-1) for 2D. Disc herniation AC1 values were 0.48-0.53 (0.321-0.699) for 3D and 0.38-0.55 (0.23-0.711) for 2D. AC2 values for foraminal stenosis were 0.71-0.82 (0.535-0.936) for 3D and 0.72-0.80 for 2D (0.582-0.93). ICC values for canal stenosis were 0.95 (0.89-0.98) for 3D and 0.95 (0.89-0.98) for 2D. Significant differences were seen between CSF flow artifact in 2D and 3D T2 images ($p < 0.001$), with flow artifacts detect solely on 2D sequences. The image quality of 3D T1 sequences was lower than that of 2D images. Mean scoliosis across patients was mild (Cobb angle of 13o [3-39o]).

CONCLUSION

3D lumbar spine imaging with a conformal coil and DLR provides comparable image quality to 2D sequences and similar levels of interrater agreement for the assessment of common degenerative pathology.

CLINICAL RELEVANCE/APPLICATION

Robust 3D lumbar spine imaging enhances the visualization of complex pathology including scoliosis (>10 degrees of curvature) and reduces scan time by providing multiple reformatted scan planes at comparable image quality.

R5B-SPMK-6 PREDICTION OF INCIDENT VERTEBRAL FRACTURES USING AUTOMATED OPPORTUNISTIC OSTEOPOROSIS SCREENING IN LOW-DOSE COMPUTED TOMOGRAPHY: DATA FROM THE NATIONAL LUNG SCREENING TRIAL

Maximilian Loeffler, MD (*Presenter*)
Sebastian Ruhling (*Abstract Co-Author*)
Marco Reisert (*Abstract Co-Author*)
Susanne Rospleszcz (*Abstract Co-Author*)
Fabian Bamberg, MD, MPH (*Abstract Co-Author*)
Jan S. Kirschke, MD (*Abstract Co-Author*)
Jakob Weiss, MD, PhD (*Abstract Co-Author*)

PURPOSE

Guidelines in the US, China, and EU recommend low-dose computed tomography (LDCT) for lung cancer screening in adults with a history of heavy smoking. The US Preventive Services Task Force recommends screening for osteoporosis in women =65 years or older. We used a validated deep learning-based tool to investigate if opportunistic quantification of bone mineral density (BMD) predicts incident vertebral fractures in lung cancer screening eligible individuals.

METHODS AND MATERIALS

Participants of the National Lung Screening Trial (NLST) with available baseline and 1-year follow-up LDCT scans (n=16962, mean age 61.5±5.0 years, 41% women; n=9760 with incomplete data excluded) were evaluated for vertebral fractures and BMD using a fully-automated deep learning-based tool (SpineQ v. 1.1, Bonescreen GmbH). Baseline BMD was averaged over unfractured visualized vertebrae T11-L4 using asynchronous calibration and stratified into normal BMD (>120 mg/cm 3), low bone mass (80=BMD=120 mg/cm 3), and osteoporotic BMD (<80 mg/cm 3). Incident vertebral fractures were defined as a new fracture at follow-up or =1 grade increase in a previously fractured vertebra using the Genant classification. Odds ratios (ORs) and 95% confidence intervals (CIs) for incident vertebral fractures (=outcome) were calculated in multivariable logistic regression models adjusting for smoking status, pack years, prevalent type 2 diabetes, hypertension, past myocardial infarction and stroke and, also, in models using stepwise backward selection.

RESULTS

Vertebral fracture prevalence was 8.6% at baseline (n=1405; of those 638, 619, and 148 with =1 grade 1, 2, and 3 fractures, respectively). Vertebral fracture incidence after 1 year was 3.4% (n=580). Only BMD, baseline fractures, and hypertension were significantly associated with incident vertebral fractures and remained in multivariate models. Odds for incident vertebral fractures increased for low bone mass (OR=1.72, CI: 1.37-2.17), osteoporotic BMD (OR=3.09, CI: 2.35-4.07), and prevalent baseline fractures (eg OR=12.0, CI: 9.55-15.1, for grade 1) and decreased for prevalent hypertension (OR=0.80, CI: 0.66-0.97).

CONCLUSION

Deep learning allows for fully-automated opportunistic osteoporosis screening in a lung cancer screening scenario. We confirmed low BMD and prevalent vertebral fractures as important and independent risk factors for incident fractures beyond clinical risk factors.

CLINICAL RELEVANCE/APPLICATION

Clinical guidelines recommend screening for lung cancer in heavy smokers and for osteoporosis in older women. We showed that both screening aims can be met leveraging low-dose lung CT and artificial intelligence that allows for fully automated fracture detection and bone density evaluation.

R5B-SPMS-1 SYMPTOMATIC AND LIFE-THREATENING ADVERSE EVENTS FOR IVC FILTERS ARE MORE LIKELY TO BE RELATED TO OLDER SHELF LIFE PRODUCTS: A NATIONWIDE ANALYSIS OF IVC FILTER ADVERSE EVENTS

Ashima Kundu, BS (*Presenter*)
Sachin Govind (*Abstract Co-Author*)
Andrew C. Gordon, MD, PhD (*Abstract Co-Author*)

PURPOSE

Inferior vena cava (IVC) filters are widely used for pulmonary embolism prevention in patients who cannot receive or have failed anticoagulation, but they are associated with delayed complications. The impact of device age at implantation on adverse events remains poorly understood. This study evaluates whether IVC filters implanted late in their shelf life are more likely to result in symptomatic or life-threatening adverse events.

METHODS AND MATERIALS

A retrospective analysis was conducted using the FDA's Manufacturer and User Facility Device Experience (MAUDE) database, reviewing 34,372 adverse event reports for IVC filters from April 2019 to April 2025. Reports were included if both device manufacture and event dates were available, yielding 759 adverse event reports for analysis. The primary outcome was the occurrence of symptomatic or life-threatening adverse events.

RESULTS

Of the 759 reports, 15.5% of patients were female and the mean age at adverse event was 53.0 ± 17.1 years. Severe adverse outcomes (life-threatening or death) occurred in 26.7% of cases, and 35.3% required intervention. Among the six most common adverse event classes, thrombosis or occlusion (n=195) and cardiovascular injury (n=170) were most frequently associated with life-threatening outcomes (57.9% and 20.6%, respectively). Malposition (n=280) and deployment/removal complications (n=257) were the most common device problems, each associated with life-threatening outcomes (26.4% and 21.0%, respectively). Symptomatic adverse events (n=449) occurred at a median of 242 days post-manufacture, significantly later than asymptomatic events (median 190 days, $p<0.0001$). Events resulting in life-threatening outcomes or death (n=197) occurred at a later median latency than events related to less severe outcomes (328 vs. 195 days, $p<0.0001$).

CONCLUSION

IVC filter adverse events with symptomatic or life-threatening outcomes are more likely to be related to devices that are implanted later on in their shelf life. Future studies should evaluate these findings with prospective data, controlling for IVC filter dwell time.

CLINICAL RELEVANCE/APPLICATION

These findings suggest device age at implantation is an underrecognized risk factor for severe complications, emphasizing the importance of considering device shelf life in clinical decision-making.

R5B-SPNMMI-1 DISENTANGLING ENVIRONMENTAL AND GENETIC CONTRIBUTIONS TO AMYLOID AND TAU BURDEN IN PATIENTS ACROSS ALZHEIMER'S DEMENTIA CONTINUUM USING MACHINE LEARNING AND CAUSAL MODELING

Mahsa Mayeli, MD, MPH (*Presenter*)
David Matuskey (*Abstract Co-Author*)

PURPOSE

Socioeconomic disadvantage has been linked to increased risk for cognitive decline and dementia; however, its neurobiological underpinnings remain unclear. We investigated the relationship between the Area Deprivation Index (ADI) and amyloid and tau accumulation using positron emission tomography (PET), while also exploring the contributions of genetic risk (APOE -e4) and demographic factors through both statistical and machine learning approaches.

METHODS AND MATERIALS

Participants (n = 164 for [18F] florbetaben [FBB]) were grouped into cognitively normal (CN, CDR = 0) and mild cognitive impairment/mild dementia (CDR = 0.5-1). Linear regression and mixed-effects models were used to assess the association between ADI and PET-derived amyloid and tau burden, controlling for age, sex, and group. Moderation and mediation models were used to evaluate the interactive and indirect effects of APOE -e4. Additionally, an XGBoost machine learning model with SHAP (SHapley Additive exPlanations) interpretation was used to identify the most influential predictors of Centiloid values.

RESULTS

ADI was significantly associated with higher amyloid deposition in CN individuals across multiple brain regions ($p < 0.001$-0.01), with no significant associations observed in MCI/mild dementia. ADI also predicted tau deposition in various cortical and subcortical regions (p-values=0.017 - 0.044). SHAP analysis revealed that ADI and age were the most important predictors of Centiloid values, surpassing APOE -e4 status in model influence. A significant moderation effect (p=0.016) showed that the relationship between ADI and amyloid burden was stronger in APOE -e4 non-carriers. Mediation analysis did not support a significant indirect pathway from ADI to amyloid burden through APOE -e4.

CONCLUSION

Neighborhood disadvantage contributes significantly to dementia-related brain pathology, particularly in preclinical stages and non-carriers of APOE -e4. Machine learning and SHAP interpretation confirmed the relative dominance of social and demographic predictors over genetic risk in amyloid accumulation.

CLINICAL RELEVANCE/APPLICATION

Neighborhood disadvantage is a significant predictor of amyloid and tau burden detectable on PET imaging. These findings suggest that social determinants of health influence early neuropathological changes. Integrating ADI and demographic factors into imaging-based risk models, supported by machine learning tools such as SHAP, may enhance the stratification of preclinical AD risk. Clinically, this approach could inform targeted screening protocols, guide earlier intervention in socially vulnerable populations, and ultimately support more equitable, personalized dementia care.

R5B-SPNMMI-2 RETROSPECTIVE EVALUATION OF THE CORRELATION BETWEEN SOMATOSTATIN RECEPTOR PET/CT AND HISTOPATHOLOGY IN PATIENTS WITH SUSPECTED INTRACRANIAL MENINGIOMAS

Ricarda Ebner, MD (*Presenter*)
Lukas Salvermoser, MD (*Abstract Co-Author*)
Johannes Ruebenthaler, MD (*Abstract Co-Author*)
Clemens C. Cyran, MD (*Abstract Co-Author*)
Anna Hinterberger (*Abstract Co-Author*)
Matthias P. Fabritius, MD (*Abstract Co-Author*)
Nicola Fink, MD (*Abstract Co-Author*)
Jens Ricke, MD, PhD (*Abstract Co-Author*)
Rudolf A. Werner (*Abstract Co-Author*)
Freba Grawe, MD (*Abstract Co-Author*)

PURPOSE

The aim of this retrospective study was to evaluate the correlation between findings from somatostatin receptor (SSTR) positron emission tomography/computed tomography (PET/CT) and histopathological diagnosis in patients with suspected intracranial meningiomas, with PET/CT serving as a non-invasive imaging modality.

METHODS AND MATERIALS

A total of 223 SSTR-PET/CT scans were performed for suspected meningioma. 240 lesions were identified and matched with corresponding histopathological results within four months. Medical reports from both SSTR-PET/CT scans and histopathology were retrospectively reviewed to assess the presence of intracranial meningioma. The positive and negative predictive values (PPV/NPV), sensitivity, specificity, and overall diagnostic accuracy of SSTR-PET/CT were calculated. For each lesion, the maximum standardized uptake value (SUVmax) was determined.

RESULTS

In 222 of 240 lesions (92.5%), meningioma was accurately identified by SSTR-PET/CT and confirmed by histopathology. In 7 cases (2.9%), meningioma was suspected on SSTR-PET/CT but not confirmed by histopathology (false positive); these cases revealed, for example, anaplastic/malignant solitary fibrous tumor or metastasis from breast cancer. Furthermore, in 11 cases (5.0%), meningioma was neither suspected by SSTR-PET/CT nor confirmed by histopathology (true negative). There were no cases of false negatives in our cohort. SSTR-PET/CT demonstrated a sensitivity of 100% (95% CI: 98.4 - 100%) and a specificity of 61.1% (95% CI: 35.8 - 82.7%) in detecting meningiomas. PPV was 96.9% (95% CI: 93.8 - 98.8%), and NPV was 100% (95% CI: 71.5 - 100%). Overall diagnostic accuracy was 97.1%. The ROC analysis for SUVmax values in predicting histopathology results showed an AUC of 94.0%, indicating excellent discriminative performance of SUVmax.

CONCLUSION

SSTR-PET/CT is a precise imaging modality for detecting and assessing intracranial meningiomas, as demonstrated by its high sensitivity. However, in 2.9% of cases, despite a positive PET/CT result, histology did not confirm the presence of a meningioma. By integrating magnetic resonance imaging (MRI), histopathology, and SSTR-PET/CT, clinicians can achieve a comprehensive understanding of meningiomas and other intracranial lesions, enabling well-informed treatment strategies.

CLINICAL RELEVANCE/APPLICATION

SSTR-PET/CT reliably identifies intracranial meningiomas, guiding precise diagnosis and treatment planning, though false positives require confirmation through MRI and histopathology.

R5B-SPNPM-1 MISREADING THE READINGS: A QUALITATIVE STUDY OF PATIENT PERCEPTION AND UNDERSTANDING OF RADIOLOGY REPORTS

Benjamin Perrin Hee, MD, MPH (*Presenter*)
Alexander M. Beekman, MD (*Abstract Co-Author*)

PURPOSE

The advent of electronic medical records (EMR) has granted patients unprecedented access to their health information. This shift toward increased transparency, while beneficial, has highlighted a significant challenge: bridging the gap between complex medical language and patient understanding. This study aimed to examine the experience of participants tasked with interpreting radiology results without physician assistance. This experience mirrors the common scenario that occurs when patients receive results through an EMR. As digital health applications become increasingly common, it is crucial to understand how they impact the patient experience when accessing and interpreting health information.

METHODS AND MATERIALS

We conducted 20 qualitative interviews with participants aged 20 to 79 years. Prior to the interview, each participant was provided with an identical sample report of a coronary calcium CT scan to read as if it was their own report. The notable sample report findings included a coronary calcium score of zero and an incidental finding of pulmonary nodule. Participants were then asked to reflect on their experience, emotional response, and suggestions for improvement. Interview transcripts were independently coded by two MD/MPH students. Directed content analysis was used to identify themes in participant responses.

RESULTS

When presented with the sample report, 85% of the participants reported feeling concerned or overwhelmed by the information provided. Many participants were unable to derive useful information from the report, and about half expressed fear when interpreting it. One participant stated, “I’m more confused now than I was before I read it”. Major sources of confusion included scoring systems and medical jargon. Adding a lay summary, incorporating visual explanations, and removing citations were commonly suggested solutions. Notably, 95% of participants stated the inclusion of a lay summary would increase their understanding of the report.

CONCLUSION

The majority of participants felt confused or distressed after receiving the sample report. In a real-world scenario, receiving results in this manner could cause emotional distress. Many participants expressed uncertainty about next steps and desired guidance from their radiologist regarding the need for follow-up care.

CLINICAL RELEVANCE/APPLICATION

This study highlights the need for patient-centered communication in the field of radiology. These results provide a foundation for future investigations into the effectiveness of the interventions our participants suggested. By creating reports that are easier for patients to comprehend, the risk of miscommunication is minimized, and patients are empowered to become more involved in their own care

R5B-SPNR-2 C-DIR: DOUBLE INVERSION RECOVERY WITH CONTROLLED SIGNAL SUPPRESSION

Alexander Jaffray (*Presenter*)
Christina Graf, PhD (*Abstract Co-Author*)
Armin Rund (*Abstract Co-Author*)
Stefan Steinerberger (*Abstract Co-Author*)
Anthony Traboulsee, MD (*Abstract Co-Author*)
David K. Li, MD (*Abstract Co-Author*)
Alexander Rauscher, PhD, MSc (*Abstract Co-Author*)

PURPOSE

Double inversion recovery (DIR) is a magnetic resonance imaging (MRI) technique in which signal from two types of tissue are suppressed, usually cerebrospinal fluid and white matter. The suppression is achieved with two inversion pulses. In brain regions affected by strong inhomogeneity in the static magnetic field, inversion may be inadequate, resulting in bright signal from insufficient signal suppression. The purpose of our study was to develop a DIR scan with inversion pulses that are robust against such inhomogeneities.

METHODS AND MATERIALS

The DIR sequence was equipped with inversion pulses designed with optimal control theory. Robustness against field inhomogeneities was incorporated directly into the cost functional for pulse optimization. Experimental data with the conventional and the new inversion pulses were acquired and compared at 3 T in a phantom designed to exhibit strong inhomogeneities in the static field, and in human participants (3 healthy volunteers, 2 patients with multiple sclerosis, 1 patient with post-concussive symptoms, 2 participants with asymptomatic white matter hyperintensities). Images were acquired sagitally in three dimensions with 1 cubic mm isotropic resolution, 1st inversion time (TI1) = 2550 ms, 2nd inversion time TI2 = 470 ms, repetition time (TR) = 5500 ms, effective echo time (TE) = 293 ms. Images were assessed by a neuroradiologist with 42 years of MRI experience.

RESULTS

In the phantom, the new inversion pulse exhibited nearly perfect inversion across the phantom, whereas the conventional pulse resulted in bright artifactual signal in areas with inhomogeneous field. In human participants, such bright signal appear near the paranasal sinuses with the conventional pulse but were absent with the controlled double inversion recovery (C-DIR) scan. Image contrast of lesions in multiple sclerosis and in white matter hyperintensities were identical for DIR with the optimized pulses and C-DIR and DIR with the conventional pulses.

CONCLUSION

C-DIR shows elimination of artifacts caused by incomplete inversion, without altering image contrast of MS lesions and white matter hyperintensities.

CLINICAL RELEVANCE/APPLICATION

C-DIR requires no modifications to the scanner hardware and no new data sampling approaches. The method can be easily adopted into routine MRI, with direct beneficial clinical impact.

R5B-SPNR-6 OPTIMIZATION OF CORTICOSPINAL TRACTOGRAPHY WITH MULTI-BAND HIGH-RESOLUTION DTI COMPARED TO STANDARD DTI

Matthew L. White, MD (*Presenter*)
Devin A. DeLuna, MD, MBA (*Abstract Co-Author*)
Yan Zhang, MD, PhD (*Abstract Co-Author*)
Michele Aizenberg, MD (*Abstract Co-Author*)
Jie Chen (*Abstract Co-Author*)
Sean Kelly, MD (*Abstract Co-Author*)

PURPOSE

Multi-Band MRI allows for marked acceleration of MRI acquisitions. We utilized a 3x faster approach(MB3) to increase the spatial and angular resolution of our DTI brain mapping exams. Our hypothesis was: Higher resolution DTI techniques would improve tractography mapping by demonstrating more fibers and fibertracts will map closer to the point of interest.

METHODS AND MATERIALS

Patients were recruited from our brain lesion mapping cases (3 vascular lesions, 3 metastatic cases, 6 gliomas). A 3T Ingenia (Philips) system was utilized with a 32 channel head coil. Informed consent was obtained. There are 12 subjects (8Male, 4Female). Average age is 49 years old. Volumetric T1 images pre contrast, T2 FLAIR images and T1 images post-contrast were obtained. DTI parameters: Standard DTI 2x2x2mm zero filled to 1x1x2mm ;16 directions encodes scan time approximately 5 mins, TR=9500, TE=65-70, NSA=2, B-value=800. MB3 DTI 1.5x1.5x1.5mm zero filled to .7x.7x1.5mm, 32 (4 cases) or 64 (8cases) direction encodes, scan time 16 minutes, TR=3900, TE=95, NSA=3, B-value=1000. DTI analysis was performed utilizing Olea Sphere (Olea Medical, France) with FACT technique (Min FA-0.2, Max angle -60 degrees, Min fiber length -10mm). Corticospinal (CS) tractography was performed utilizing 2 main regions of interest (ROIs). Additional ROIs were utilized to remove spurious fibers. ROIs to create the tracts were placed in the same positions on each DTI study. The total fiber count from each CS tract was recorded. The distance between the CS tract and the point of interest was measured. T-tests were employed to evaluate differences between the data sets.

RESULTS

The average CS fiber counts was 433 for the standard DTI and 2021 for the MB3 DTI and were statistically different with a p-value of <0.003. The standard DTI failed in 2 cases and the MB3 failed once. The analysis of distance of CS tract to the point of interest demonstrated average distance of 8.7mm for the standard DTI and for MB3

DTI measured 6.8mm. The The MB3 CS tracts were significantly closer with a p-value <0.003. Two subjects were excluded from this analysis because tract distances could not be measured since the techniques failed.

CONCLUSION

High spatial and angular resolution MB3 DTI allowed for the creation of CS tracts that contained more fibers and demonstrated CS fiber tracts closer to the points of interest in pre-operative brain lesion mapping.

CLINICAL RELEVANCE/APPLICATION

The MB3 DTI technique takes significantly longer to perform but is promising for consistently having better performance in brain lesion mapping cases. This improvement in mapping could result in better pre-operative plans with improved estimation of lesion resection leading to maximal resection with minimization of post-operative deficits.

R5B-SPNR-8 AI ENHANCES DETECTION OF CHALLENGING ACUTE ISCHEMIC STROKE LESIONS ON DIFFUSION-WEIGHTED IMAGE: A READER STUDY

Younbeom Jeong, MD (*Presenter*)
Wi-Sun Ryu (*Abstract Co-Author*)
Byungse Choi, MD,PhD (*Abstract Co-Author*)
Jae Hyoung Kim (*Abstract Co-Author*)
Leonard Sunwoo, MD (*Abstract Co-Author*)

PURPOSE

To assess the impact of artificial intelligence (AI) assistance on the diagnostic performance of human readers in detecting challenging acute ischemic stroke (AIS) lesions on diffusion-weighted imaging (DWI), focusing on small and hyperacute lesions that are often missed in clinical practice.

METHODS AND MATERIALS

This retrospective, single-center, randomized crossover study included 3,986 patients (mean age, 68 ± 14 years; 2,383 men) who underwent DWI between February 2017 and November 2021. From this cohort, 250 cases (130 challenging AIS, 120 controls) were selected for a multi-reader study. Challenging cases were defined as infarcts < 0.5 mL in posterior circulation or < 1.0 mL in anterior circulation within 3 hours of symptom onset. Five readers, including radiology and neurology residents and a neuroradiologist, interpreted the cases with and without AI assistance (JLK-DWI). Diagnostic performance was assessed using AUC, sensitivity, specificity, and Dice similarity coefficient (DSC).

RESULTS

AI assistance significantly improved AUC from 0.85 (95% CI: 0.82-0.90) to 0.93 (95% CI: 0.90-0.95; $p < 0.01$). Pooled sensitivity increased from 74.6% (95% CI: 69.8-79.4) to 90.6% (95% CI: 87.4-93.7; $p < 0.01$), with a notable sensitivity gain of 20.9% in challenging cases. DSC improved from 0.523 to 0.742 ($p < 0.01$), indicating enhanced lesion segmentation accuracy. Specificity slightly decreased from 88.8% (95% CI: 85.1-92.3) to 84.0% (95% CI: 78.5-89.5; $p = 0.05$). AI identified 79.6% (43/54) of false-negative stroke cases missed in clinical reports, including 27 of 38 challenging cases.

CONCLUSION

AI-assisted interpretation significantly improved diagnostic accuracy and lesion segmentation in challenging AIS cases on DWI, reducing missed diagnoses while slightly decreasing specificity. Enhanced sensitivity and lesion detection may aid in earlier stroke identification and more accurate treatment planning.

CLINICAL RELEVANCE/APPLICATION

Integrating AI into stroke imaging workflows may assist radiologists in detecting subtle AIS lesions that are challenging to identify, potentially reducing diagnostic errors and facilitating timely intervention.

R5B-SPNR-9 RELATIONSHIP BETWEEN SPINAL STENOSIS AREA ON MRI AND IMMEDIATE CLINICAL OUTCOME FOR PATIENTS PRESENTING TO THE EMERGENCY DEPARTMENT (ED) WITH SUSPECTED CAUDA EQUINA COMPRESSION (CEC)

Mahsa Alborzi Avanaki, MD (*Presenter*)
Pritesh J. Mehta, MD (*Abstract Co-Author*)
Sepideh Abdi, MD (*Abstract Co-Author*)
Donnella S. Comeau, MD,PhD (*Abstract Co-Author*)
Yu-Ming Chang, MD, PhD (*Abstract Co-Author*)
Rafeeque A. Bhadelia, MD (*Abstract Co-Author*)

PURPOSE

Severe spinal stenosis on lumbar spine MRI in patients presenting to ED with symptoms of CEC may lead to immediate clinical outcome such as surgery. However, accurate diagnosis of severe stenosis depends on experience and training of a radiologist (or in-training radiologist). We hypothesized that measurement of stenosis area may improve the utility of MRI in clinical decision making. Our purpose was to measure the area of spinal stenosis on lumbar spine MRI in patients presenting to ED and correlate it with immediate clinical outcome (surgery or conservative management).

METHODS AND MATERIALS

We retrospectively reviewed approximately 1,000 MR Code Cord cases performed between January 1, 2019, and December 31, 2023. We identified 218 cases with emergency lumbar spine MRI performed for suspicion of CEC. Here we present the preliminary results of first 61 measurements of lumbar stenosis. We excluded thoracic cord compression, fractures, infection, and cancer to focus on degenerative lumbar stenosis. AP and transverse diameters were measured by an experienced neuroradiologist and spinal canal area was calculated using the ellipsoid formula. Patients were classified into two groups based on lumbar spinal canal cross-sectional area: mild/moderate stenosis (=70 mm^2) and severe stenosis (<70 mm^2). Clinical outcomes were surgery or conservative management determined at the time of presentation to ED. Only cases which underwent surgery within 72-hours were included.

RESULTS

The mean age of 61 patients was 54.76 years and 35 were female. Based on the area measurement, 28/61 patients had severe stenosis (<70 mm 2) and 33/61 patients had mild or moderate stenosis ((=70 mm^2). 16/28 patients with severe stenosis and 3/33 patients with mild to moderate stenosis had immediate surgical outcome. This outcomes were significantly different among the groups ($p<0.001$). Patients with mild/moderate stenosis more frequently underwent conservative management (90.9%), whereas patients with severe stenosis were more likely to undergo surgery (57.1%).

CONCLUSION

Our findings show that measurement of spinal stenosis area is an objective method of evaluation which highly correlates with immediate clinical outcomes in patients presenting with suspected cauda equina compression to the ED. Additional data are needed to further refine diagnostic thresholds and support clinical decision-making.

CLINICAL RELEVANCE/APPLICATION

Spinal canal area on MRI can guide early triage in cauda equina compression, with severe cases more likely to require urgent surgery.

R5B-SPNR-11 ASSOCIATION OF PLASMA INTERLEUKIN-6 WITH CEREBRAL AMYLOID AND TAU DEPOSITION AND ADIPOSITY IN A MIDLIFE COHORT AT RISK FOR ALZHEIMER'S DISEASE

Amanollahi (*Presenter*)

Paul K. Commean, BA (*Abstract Co-Author*)
Farzaneh Rahmani, MD, MPH (*Abstract Co-Author*)
Caitlyn Nguyen (*Abstract Co-Author*)
Lakisha Lloyd (*Abstract Co-Author*)
Mahshid Naghashzadeh, MSc, PhD (*Abstract Co-Author*)
Sara Hosseinzadeh Kassani (*Abstract Co-Author*)
Bettina Mittendorfer (*Abstract Co-Author*)
Claude B. Sirlin, MD (*Abstract Co-Author*)
Tammie S. Benzinger, MD, PhD (*Abstract Co-Author*)
Joseph E. Ippolito, MD, PhD (*Abstract Co-Author*)
John C. Morris, MD (*Abstract Co-Author*)
Cyrus A. Raji, MD, PhD (*Abstract Co-Author*)

PURPOSE

Recent studies have demonstrated the impact of elevated BMI and visceral adipose tissue (VAT) in the development of Alzheimer's disease (AD) related pathology. Herein, we aim to study the potential mediating route of this effect by studying the association between plasma interleukin-6 (IL-6), a pro-inflammatory cytokine, and cerebral amyloid and tau deposition measured by PET imaging in a middle-aged cohort of overweight and obese participants.

METHODS AND MATERIALS

Fifty-four participants (mean age 50.2 ± 6.3 years; mean BMI 32.50 ± 7.39; 59.3% male) underwent amyloid PET imaging and plasma IL-6 quantification and were included in the centiloid analysis. Additional analyses examining the relationship between IL-6 and adiposity measures (BMI, VAT, SAT) included 68 participants with available data. Tau PET was assessed in a subset of participants across four selected regions.

RESULTS

Higher IL-6 was significantly associated with greater amyloid burden (ß = 1.92, p = 0.009). Although associations between IL-6 and tau PET SUVRs did not remain significant after FDR correction (FDR-p = 0.067), nominal associations were observed in the lateral occipital and inferior temporal regions. IL-6 correlated with BMI (? = 0.538, p < 0.0001), SAT (? = 0.521, p < 0.0001), and VAT (? = 0.377, p = 0.0016).

CONCLUSION

Plasma IL-6 is positively associated with amyloid deposition and adiposity in midlife, supporting inflammation's role in AD pathology in early stages. However, the exact relationship warrants further investigation on larger sample sizes.

CLINICAL RELEVANCE/APPLICATION

IL-6 may serve as a peripheral biomarker associated with radiological indicators of cerebral amyloid pathology and potentially early tau changes in preclinical AD. It may also act as a mediator linking BMI and visceral adiposity to AD-related pathology.

R5B-SPNR-12 EXPLORING EVIDENCE FOR VERTICAL RECURRENCE OF GLIOBLASTOMA USING DYNAMIC CONTRAST-ENHANCED MRI

Minchul Kim, MD, PhD (*Presenter*)
Kyu Sung Choi, MD, PhD (*Abstract Co-Author*)

PURPOSE

The role of the subventricular zone (SVZ) in glioblastoma progression is acknowledged, yet the detection of its mutated cells through imaging remains elusive. This study utilizes dynamic contrast-enhanced (DCE) MRI to explore changes in the SVZ in patients with recurrent glioblastoma followed by gross total resection, aiming to uncover mechanisms behind tumor recurrence.

METHODS AND MATERIALS

Sixty-three recurred GBM patients after gross total resection (mean age=58±14 years) were evaluated using presurgical DCE. Regions of interest were obtained on the ipsilesional and contralesional SVZ. The volume transfer constant (K trans) and plasma volume fraction (V p) values were assessed using Bayesian one-way repeated measures ANOVA.

RESULTS

Using Bayesian hypothesis testing, we show that the present data substantially favor the null model of no differences between ipsilesional and contralesional SVZ for the DCE pharmacokinetic parameters. The inclusion Bayes factor (BF 10) of SVZ laterality (ipsilesional, contralesional) ranged from 0.186 to 0.328.

CONCLUSION

Together, these findings suggest DCE pharmacokinetic metrics lacking in the ability to prove evidence for "vertical recurrence" and provide the need for a more sensitive metric.

CLINICAL RELEVANCE/APPLICATION

We report that no DCE pharmacokinetic evidence of TERTp mutation in GBM recurrence, suggesting that DCE pharmacokinetic metrics lacking in the ability to prove evidence for "vertical recurrence". In addition, we provided a comprehensive analysis method to investigate SVZ using publicly available FreeSurfer and MATLAB code. As GBM arises from the SVZ, there is a definite unmet need to investigate SVZ in GBM patients. Future researchers may follow our method that analyzes SVZ in multiple shell types as well as layer by layer.

R5B-SPNR-13 THE VALUE OF BLACK-BLOOD MRI IN CEREBRAL VENOUS THROMBOSIS DIAGNOSIS: A SYSTEMATIC REVIEW AND META-ANALYSIS

Ali Akhavi Milani (*Presenter*)

PURPOSE

To evaluate the diagnostic performance of black-blood MRI (BB-MRI) in detecting cerebral venous thrombosis (CVT).

METHODS AND MATERIALS

This study was registered in PROSPERO [ID: blinded]. The PubMed/MEDLINE, Web of Science, Scopus, and Embase databases were searched for studies evaluating the performance of BB-MRI in diagnosing CVT. Studies were selected based on predefined eligibility criteria. The risk of bias was assessed using the QUADAS-2 tool. Meta-analysis was performed using a bivariate random-effects model to calculate pooled sensitivity, specificity, and area under the curve (AUC).

RESULTS

Nine studies fulfilled the eligibility criteria and were included in the review; however, two studies insufficiently reported quantitative data. Thus, seven studies involving 176 CVT patients and 217 controls, encompassing 610 thrombosed and 3,279 normal cerebral venous segments were included in the meta-analysis. The studies

demonstrated a high risk of bias in the patient selection and reference standard domains. The pooled sensitivity and specificity of BB-MRI were 96% [95% CI: 92%-98%] and 96% [95% CI: 93%-98%] on a patient-based level, and 92% [95% CI: 87%-95%] and 98% [95% CI: 92%-99%] on a venous segment-based level, respectively. The AUC was 0.98 for patient-based data and 0.96 for venous segment-based data.

CONCLUSION

BB-MRI demonstrates a significant potential as a diagnostic method for CVT. However, further comparative studies are needed to define its role in the diagnostic workup of patients suspected of having CVT.

CLINICAL RELEVANCE/APPLICATION

BB-MRI provides better diagnostic accuracy for detecting CVT, particularly in small-diameter veins and anatomical locations near bony structures.

R5B-SPNR-14 TIME-SERIES MRI HISTOGRAM ANALYSISIN PREDICTING BRAIN INVASION IN MENINGIOMAS: A PRELIMINARY STUDY

Xianwang Liu, MD (*Presenter*)

PURPOSE

To investigate the utility of time-series histogram parameters (including absolute time-series histogram parameters (AtHP) and relative time-series histogram parameters (RtHP)) in predicting brain invasion in meningiomas.

METHODS AND MATERIALS

One hundred and twelve patients with meningiomas (non-invasion group:68, invasion group:44) who underwent MRI examination (including T1-weighted (T1) and contrast-enhanced T1-weighted images (T1C)) were enrolled in this retrospective study. Histogram parameters (HP) of T1 and T1C were extracted. MRI morphological features, AtHP (AtHP=T1CHP-T1HP), and RtHP (RtHP=(T1CHP-T1HP)/T1HP) were recorded and compared, respectively. Binary logistic regression analysis was used to obtain the combined performance of the significant parameters. Diagnostic performance was identified by the receiver operating characteristic (ROC) analysis.

RESULTS

In MRI morphological features, the invasion group was more likely to have peritumoural edema and irregular margins (all $p<0.05$). In time-series histogram parameters, the invasion group exhibits a higher mean, Perc.01, Perc.25, Perc.50, and variance of AtHP, maximum, mean, Perc.25, and Perc.50 of RtHP, compared with the non-invasion group (all $p<0.00357$). The optimal predictive performance was obtained by combining MRI morphological features and time-series histogram parameters with an AUC of 0.878.

CONCLUSION

Time-series MRI histogram analysis could predict brain invasion in meningiomas, when combined with MRI morphological features yielding superior predictive performance.

CLINICAL RELEVANCE/APPLICATION

Brain invasion in meningiomas correlates with higher recurrence rates and poorer prognosis. This study demonstrates that time-series MRI histogram analysis can predict brain invasion in meningiomas and, when combined with MRI morphological features, further improves predictive performance, which may help to select the appropriate surgical approach and predict prognosis.

R5B-SPNR-17 ORBITAL MRI AFTER CLINICALLY ISOLATED SYNDROME: DIAGNOSTIC PERFORMANCE AND PREDICTION OF VISUAL OUTCOMES

Hana Larassati, MD, MSc (*Presenter*)
Ferran Prados (*Abstract Co-Author*)
Sara Collorone (*Abstract Co-Author*)
Baris Kanber (*Abstract Co-Author*)
Marios Yiannakas (*Abstract Co-Author*)
Giuseppe Pontillo, MD (*Abstract Co-Author*)
Frederik Barkhof, MD, PhD (*Abstract Co-Author*)
Olga Ciccarelli, PhD,MD (*Abstract Co-Author*)
Indran Davagnanam, MBBCh (*Abstract Co-Author*)
Ahmed Toosy (*Abstract Co-Author*)

PURPOSE

To assess the diagnostic performance of orbital 2D-STIR (short-tau inversion recovery) and brain 3D-FLAIR (fluid-attenuated inversion recovery) in optic nerve lesion detection in CIS and their predictive value for structural and functional visual outcomes at one year.

METHODS AND MATERIALS

A retrospective analysis of a prospective study included 100 CIS patients within four months of onset. All underwent orbital 2D-STIR, visual function assessments, and optical coherence tomography; a subset (N=51) had brain 3D-FLAIR. Optic nerve lesions were identified on both acquisitions by experienced radiologists (HL, ID). Lesion lengths, as absolute values (ALL) and relative values as proportions of optic nerve length (RLL), and swelling were recorded. Diagnostic performance was examined using clinical optic neuritis diagnosis as the reference standard. Visual function (Farnsworth-Munsell 100 hue, high contrast acuity (LogMAR) and low contrast letter acuity (LCLA)) and OCT parameters (pRNFL and GCIPL) at baseline and one year were correlated with the MRI findings.

RESULTS

Forty eyes had clinically confirmed ON. The 2D-STIR had a sensitivity of 100%, a specificity of 85.5% and an accuracy of 91.18%. The 3D-FLAIR had a sensitivity of 100%, a specificity of 88.7% and an accuracy of 93.14%. Agreement in lesion detection was near-perfect (Cohen's Kappa=0.961, $p<0.001$), and lesion length measurements were highly concordant (ICC=0.894). Swelling on 2D-STIR correlated with poorer colour vision, high-contrast and low-contrast acuity at baseline ($p<0.05$). ALL and RLL on 2D-STIR predicted LCLA at one year (B=-0.414, 95%CI [-0.716, -0.112], p=0.008 and B=-19.1, 95%CI [-32.3, -5.97], p=0.005), and the model fit improved when RLL was combined with the presence of nerve swelling (R2 change=6.7%, p=0.009). ALL and RLL on 3D-FLAIR predicted LogMAR (B=0.007, 95%CI [0.001, 0.013], p=0.034 and B=0.332, 95%CI [0.072, 0.592], p=0.015), and LCLA (B=-0.511, 95%CI [-0.965, -0.058], p=0.029 and B=-23.7, 95%CI [-41.8, -5.65], p=0.012) at one year.

CONCLUSION

Orbital MRI showed excellent diagnostic performance in detecting optic nerve lesions in CIS patients. The brain 3D-FLAIR may be a practical alternative for optic nerve assessment in routine brain imaging. Optic nerve lesions on MRI show clinical utility in predicting one-year visual outcomes.

CLINICAL RELEVANCE/APPLICATION

Orbital MRI showed excellent diagnostic performance in detecting optic nerve lesions in CIS. Orbital 2D-STIR and brain 3D-FLAIR showed high concordance for optic nerve lesions, suggesting that either acquisition can be reliably used in clinical practice, offering flexibility in MRI protocols. Optic nerve lesions on MRI show clinical utility in predicting one-year visual outcomes.

R5B-SPNR-18 EXPLORING THE VALUE OF MAGNETIC RESONANCE FINGERPRINTING (MRF) AND DIFFUSION-WEIGHTED IMAGING(DWI) FOR PREOPERATIVE PREDICTION OF GLIOMA GRADE AND METHYLATION OF THE MGMT PROMOTER

Liyun Sun
(*Presenter*)
Sike Fu (*Abstract Co-Author*)
Wei Wei (*Abstract Co-Author*)
Yaping Wu (*Abstract Co-Author*)
Yan Bai (*Abstract Co-Author*)
Meiyun Wang (*Abstract Co-Author*)

PURPOSE

Predicting glioma grade and whether the MGMT promoter is methylated using T1 and T2 values obtained by MRF with ADC values obtained from DWI to guide surgery and treatment

METHODS AND MATERIALS

The clinical data of 41 patients with glioma confirmed by histopathology who visited our hospital from December 2023 to January 2025 were analyzed (10 cases of WHO grade II, 5 cases of WHO grade III, and 26 cases of WHO grade IV). All patients underwent preoperative MRF and DWI scans. The optimal region of interest (ROI) was delineated on the tumor using 3D Slicer software, and the Mann-Whitney U test was used to compare the MRF T1, MRF T2 values and ADC values between the two groups. The receiver operating characteristic (ROC) curve was used to calculate the area under the curve (AUC) and logistic regression analysis was used to evaluate the diagnostic efficacy of the related parameters.

RESULTS

Among the 41 patients, 31 had high-grade glioma and 10 had low-grade glioma. Among them, 22 patients had MGMT promoter methylation status-related gene detection. There were 13 cases in the MGMT promoter methylation group and 9 cases in the non-methylation group. Compared with high-grade glioma, the MRF T1, MRF T2, and ADC values of low-grade glioma were higher ($p = 0.002, 0.003, 0.003$, respectively), and the single-discriminative ability was the highest for MRF T1 (AUC = 0.787), and the combined discriminative ability was the greatest for the three (AUC = 0.816). The MRF T2 value and ADC value of the MGMT promoter methylation group were significantly higher than those of the non-methylation group ($p = 0.022, 0.003$, respectively), and there was no significant difference in MRF T1 value between the MGMT methylation group and the non-methylation group ($p > 0.05$). The AUC of MRF T2 and ADC was 0.761 and 0.846, respectively, and the combined AUC of MRF T2 and ADC was 0.855. The combined diagnostic efficacy of MRF T1, MRF T2, and ADC was the highest (AUC = 0.974), with a sensitivity of 100% and a specificity of 84.6%.

CONCLUSION

This study utilized MRF and DWI to distinguish the grading of gliomas and predict whether the MGMT promoter was methylated. The MRF T1, T2 values and ADC values of low-grade gliomas were significantly higher than those of high-grade gliomas. The MRF T2 value and ADC value of the MGMT-methylated group were significantly higher than those of the MGMT-non-methylated group. The combined diagnostic efficacy of MRF T1, MRF T2 and ADC was the highest.

CLINICAL RELEVANCE/APPLICATION

This study is helpful for predicting the grading of gliomas and whether the MGMT promoter is methylated before surgery, and evaluating the sensitivity of patients to the first-line chemotherapeutic drug temozolomide. Thus, it can guide surgery and chemotherapy.

R5B-SPPD-1 MRI EVALUATION OF IRON DEPOSITION PATTERNS IN NEONATAL HEMOCHROMATOSIS USING MULTI-ECHO GRADIENT-RECALLED ECHO SEQUENCES

Diana Veiga Canuto, PhD, MD (*Presenter*)
Mar Miserachs (*Abstract Co-Author*)
Iram Siddiqui (*Abstract Co-Author*)
Chris Tomlinson (*Abstract Co-Author*)
Govind B. Chavhan, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the ability of multi-echo T2* MRI sequence to differentiate NH from other causes of neonatal liver failure. To compare the iron deposition in different organs, including salivary and thyroid glands, in neonates with and without NH .

METHODS AND MATERIALS

This retrospective single-center study evaluated 26 neonates (=20 weeks of age) who underwent MRI for suspected liver failure between November 2016 and December 2024. All examinations included multi-echo GRE T2* sequences (11 echoes, TE range: 2.52-30.6 ms) performed on either 1.5T (n=14) or 3T (n=12) scanners. Two blinded radiologists independently assessed iron deposition in the liver, spleen, pancreas, kidneys, thyroid, and salivary glands using a standardized semi-quantitative grading system. Interobserver agreement was assessed using Cohen's weighted kappa. Correlation between iron deposition grade and final diagnosis was analyzed using Kendall's tau. Diagnostic performance metrics were calculated using integrated clinical, biochemical, imaging and histopathologic data as the reference standard.

RESULTS

Of 26 patients, 7 had liver failure from NH and 19 from other causes. Interobserver agreement was highest for liver iron assessment (?=0.97), followed by kidney (?=0.87), spleen (?=0.84), thyroid (?=0.80), and pancreas (?=0.73). Significant positive correlations on Kendall Tau analysis between iron deposition grade and NH diagnosis were found in thyroid (p=0.0003), pancreas (p=0.0002), and liver (p=0.0271), while spleen showed a significant negative correlation (p=0.0051). No correlation was found for renal iron deposition (p=0.9472). Among the evaluable submandibular and parotid glands, no iron deposition was identified in either group. MRI demonstrated 100% sensitivity, 89.5% specificity, 77.8% positive predictive value, 100% negative predictive value, and 92.3% overall accuracy for NH diagnosis.

CONCLUSION

Multi-echo GRE T2* MRI provides excellent diagnostic performance for NH with distinct patterns of iron deposition across organs. Increased iron in the thyroid, pancreas, and liver, coupled with relative sparing of the spleen, represents a characteristic pattern highly associated with NH. The high interobserver agreement for iron deposition assessment indicates the reliability of this imaging approach.

CLINICAL RELEVANCE/APPLICATION

MRI with multi-echo GRE T2* sequences offers a non-invasive and accurate method for diagnosing NH in neonates with liver failure. The identification of characteristic iron deposition patterns may obviate the need for invasive diagnostic procedures while facilitating timely treatment decisions. This approach is robust across different MRI field strengths and is not influenced by patient sex or gestational age.

R5B-SPPD-3 ACCURACY COMPARISONS OF 2D AND 3D METHODS IN MEASURING FEMORAL VERSION: A PARAMETRIC POSITIONAL STUDY USING 3D-PRINTED HAPTIC FEMUR MODELS

Ani Maroyan (*Presenter*)
Jade Iwasaka-Neder, MD, MPH (*Abstract Co-Author*)
Pedro Henrique Caldeira Brant Faria, MD (*Abstract Co-Author*)
Andy Tsai, MD, PhD (*Abstract Co-Author*)
Michael B. Millis, MD (*Abstract Co-Author*)
Sarah D. Bixby, MD, MBA (*Abstract Co-Author*)

PURPOSE

Femoral version is typically assessed using 2D methods, based on landmarks such as the femoral head/neck junction (Lee), neck (Reikerås), and lesser trochanter (Murphy). Though recent studies have shown that 3D methods are more reliable than 2D approaches, their accuracy is unknown, precluding their wide clinical adoption. To overcome this barrier, we aimed to compare the accuracies of 2D and 3D methods in measuring femoral version, through the use of 3D-printed haptic femur models positioned in different orientations.

METHODS AND MATERIALS

CT DICOM data of three skeletally mature pediatric patients (2 females, 1 male; age 17.8 ± 0.1 years) with femurs representing normal, severe retroversion, and severe anteversion were used as digital templates to 3D-print three biofidelic haptic femur models. CTs were then acquired of each model in 17 different positions: neutral, flexion, internal rotation, external rotation, abduction and adduction (at 15°, 30°, 45°), in addition to a combination of 30° flexion and 30° external rotation. A blinded radiologist measured the femoral versions of these haptic models using four techniques: Lee, Reikerås, Murphy, and 3D. Ground truth femoral version was established by an orthopedic surgeon using the customary approach of a K-wire and an inclinometer. We used absolute error (AE) to assess the accuracy performance of each method in measuring the femoral version of each haptic model across different positions.

RESULTS

Ground truth femoral version was 28° in the normal femur, -14° in the retroverted femur, and 81° in the anteverted femur. Across the different positions of the normal femur, the AE ranges were 0°-127° with Murphy's, 9°-46° with Lee's, 4°-91° with Reikerås', and 1°-4° with 3D methods. Across the different positions of the retroverted

femur, the AE ranges were 0°-44° with Murphy's, 1°-22° with Lee's, 0°-21° with Reikerås', and 0°-3° with 3D methods. Across the different positions of the anteverted femur, the AE ranges were 6°-67° with Murphy's, 0°-26° with Lee's, 0°-32° with Reikerås', and 0°-4° with 3D methods.

CONCLUSION

Femoral version measurement based on the 3D method is more accurate than traditional 2D techniques, and robust to variable femur positioning.

CLINICAL RELEVANCE/APPLICATION

Accurate measurement of femoral version is important for understanding lower extremity deformities in the pediatric population.

R5B-SPPH-2 THE VALUE OF DEEP LEARNING IMAGE RECONSTRUCTION COMBINED WITH HIGH-RESOLUTION LOW-DOSE CT IN NECK IMAGING: A HUMAN CADAVER-BASED DOSE OPTIMIZATION STUDY

Wenjun Qiao (*Presenter*)
Fang Zhou, MD (*Abstract Co-Author*)
Ge Wen (*Abstract Co-Author*)
Yanbing Li (*Abstract Co-Author*)
Basheng Hu (*Abstract Co-Author*)
Tong Su, MD (*Abstract Co-Author*)

PURPOSE

This study aims to explore the potential of a high-resolution scanning mode integrated with deep learning image reconstruction algorithm (ClearInfinity, DLIR-CI) for neck CT image quality improvement under low-dose conditions using human cadaver specimens.

METHODS AND MATERIALS

A wide-detector CT system (NeuViz Epoch Elite CT) was employed to perform neck CT scans on a human cadaver specimen in both conventional scanning mode: standard-dose standard-resolution mode (SDCT: 120 kV, 112 mA, 0.625 mm collimation,CTDI vol 4.97mGy) and low-dose high- resolution mode (HR-LDCT: 120 kV, 56 mA, 0.3125 mm collimation,CTDI vol 2.49mGy). For SDCT, iterative reconstruction (ClearView, CV40%) was applied, while for HR-LDCT, images were reconstructed using CV40% and a deep learning-based algorithm with varying weight levels (CI), resulting in four datasets: HR-LDCT-CI20%, HR-LDCT-CI40%, HR-LDCT-CI60%, and HR-LDCT-CI80%. The CT values and noise (standard deviation, SD) of the left thyroid gland and semispinalis cervicis muscle were measured, with the muscle SD representing the image noise level. Measurements were taken at five layers centered on the isthmus of the thyroid gland, with each region of interest (ROI) measured three times. The signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) of the thyroid gland were calculated for six image groups.

RESULTS

Image noise (SD) decreased progressively with higher CI strength, whereas SNR and CNR gradually increased. The groups of HR-LDCT-CI60% and HR-LDCT-CI80% exhibited significantly lower SD values compared to SDCT-CV40% (15.74 ± 1.62 vs. 19.52±4.34,$P < 0.001$; 10.27 ± 2.07 vs. 19.52±4.34, $P < 0.001$). The group HR-LDCT-CI60% and HR-LDCT-CI80% demonstrated significantly higher SNR compared to Group SDCT-CV40%(9.14 ±0.82 vs. 7.98±0.78, $P < 0.001$; 13.82±1.39 vs. 7.98±0.78, $P < 0.001$)with 14.53% and 73.18% increase, and The group HR-DCT-CI80% demonstrated a 64.13% higher CNR(7.14±1.45 vs. 4.35±0.92, $P < 0.001$).

CONCLUSION

Integrating a high-resolution scanning mode with the ClearInfinity deep learning reconstruction algorithm (DLIR-CI) significantly enhances neck CT image quality while maintaining diagnostic efficacy at half the standard radiation dose.

CLINICAL RELEVANCE/APPLICATION

The radiation risk to the thyroid gland represents a critical concern in neck CT imaging. This study validates that deep learning-enhanced low-dose CT reduces radiation by 90% while improving thyroid imaging, offering a safer protocol for radiation-sensitive neck CT applications.

R5B-SPPH-6 FEASIBILITY OF ULTRA-LOW-DOSE CT FOR AI-BASED HEPATIC STEATOSIS DETECTION: PERFORMANCE ACROSS RADIATION DOSE

Boyuan Li, BS (*Presenter*)
Justin Tse, MD (*Abstract Co-Author*)
H. Henry Guo, MD, PhD (*Abstract Co-Author*)
Adam S. Wang, PhD (*Abstract Co-Author*)

PURPOSE

Hepatic steatosis affects 1/3 of the world’s population and can progress to cirrhosis and related complications, such as liver cancer. AI-based automated liver segmentation methods can robustly detect hepatic steatosis using standard radiation dose CT (hereafter referred to as full-dose CT). This study investigates the performance of these AI methods across varying radiation dose levels using low radiation dose CT (LDCT), exploring their potential utility for preventive screening.

METHODS AND MATERIALS

Fifty pairs of full and low-dose (10% full dose) 120 kVp non-contrast chest CT examinations from the Mayo LDCT dataset were used to synthesize images at varying dose, followed by AI-based liver segmentation. To simulate LDCT at varying dose levels, a noise-only image (difference between full and low-dose images) is scaled by a dose-dependent factor and added to the full-dose image to match the noise expected at the low-dose level. TotalSegmentator, a pretrained nnU-Net based AI segmentation tool, was used to segment livers in all images. Mean liver HU was calculated, and a threshold of <40 HU was used for moderate hepatic steatosis detection. Dose-dependent bias adjustment of detection thresholds was performed by aligning mean liver HU of all subjects for each dose level relative to full-dose CT images. Detection accuracy was evaluated against full-dose-derived ground truth.

RESULTS

The liver segmentations from moderate low-dose CT images (>10% full dose) were closely aligned to the full-dose CT images (Dice scores >0.95). The AI segmentation tool began to suffer from image noise at lower doses, reducing Dice scores from 0.94 at 5% dose to 0.74 at 1% dose. Using mean liver HU from full-dose segmentation as ground truth and <40 HU as threshold, detection accuracy fell slightly to 96% at 10% dose but dropped sharply to 74% at 1% dose. However, at lower doses, the error was dominated by the HU bias rather than segmentation errors. Adjusting the detection threshold for the HU bias, LDCT with 3% full dose achieved 92% detection accuracy.

CONCLUSION

We investigated the effect of radiation dose on the performance of LDCT-based liver fat quantification with AI-based liver segmentation. AI-based hepatic steatosis detection remains robust at significantly reduced radiation doses (~3%), suggesting the potential feasibility of ultra-low-dose CT protocols for preventive screening of hepatic steatosis.

CLINICAL RELEVANCE/APPLICATION

Early detection of hepatic steatosis can facilitate interventions, mitigating progression to irreversible end-stage liver disease and associated complications. The combination of LDCT and robust AI-segmentation may provide an accessible non-invasive approach for whole liver assessment.

R5B-SPPH-9 COMPARISON OF SPATIAL RESOLUTION AND IMAGE QUALITY AMONG FOUR DIFFERENT SCAN MODES IN PHOTON-COUNTING DETECTOR CT: A PHANTOM EXPERIMENTS

Tomoki Maebayashi (*Presenter*)
Koki Kataoka (*Abstract Co-Author*)
Kazuki Ishikawa (*Abstract Co-Author*)
Akiyo Fukutomi, MS, RT (*Abstract Co-Author*)
Kiyosumi Kagawa (*Abstract Co-Author*)
Takashi Okunaga (*Abstract Co-Author*)
Noriyuki Negi, RT (*Abstract Co-Author*)
Akiko Kusaka, RT (*Abstract Co-Author*)
Keitaro Sofue, MD (*Abstract Co-Author*)
Takamichi Murakami, MD, PhD (*Abstract Co-Author*)

PURPOSE

Photon-counting detector CT (PCD-CT) (NAEOTOM Alpha) now supports an Ultra-High-Resolution (UHR) mode with Flash Spiral scan(FS_UHR). In addition to the previously available scan modes- Normal Spiral (NS), Normal Spiral UHR (NS_UHR), and Flash Spiral (FS)- a total of four scan modes are currently available. This phantom study aimed to compare in-plane and z-axis spatial resolution and image noise characteristics across the four modes.

METHODS AND MATERIALS

All scans were acquired using unified parameters in four scan modes: tube voltage, 120kVp; rotation time, 0.25s/rot; pitch, 0.8 of NS and 3.2 of FS. In-plane (x-y) spatial resolution was evaluated using the Task Transfer Function (TTF) measured with an air-filled cylindrical object submerged in water within a TOS phantom (QC phantom). Images were reconstructed using 120kVp image with FBP, kernels: Bv36/40/44/48, slice thickness of 0.4mm, FOV of 320mm. Fifty images were averaged, and 64×64-pixel region of interest (ROI) was placed in the air module. Z-axis spatial resolution was evaluated using a Type 9 X-ray test chart (Moriyama X-ray Equipments), placed 15 cm from the gantry isocenter. Images were reconstructed with 120kVp image with FBP, kernel: Bv48, slice thickness of 0.2/0.4 mm, FOV of 50 mm. Full width at half maximum (FWHM) and CT value fluctuation (maximum - minimum) were calculated using a 1 LP/mm profile curve on the coronal image. Image noise was analyzed via the Noise Power Spectrum (NPS) measured in a uniform water region of a TOS phantom. Tube current was set at CTDI vol of 6.4mGy, simulating clinical AEC setting (IQ level: 65). Images were reconstructed at monochromatic image at 40-70keV(in 5-keV intervals) with FBP, kernels: Bv36/40/44/48, slice thickness: 0.4mm, FOV: 200mm. NPS was measured within 128×128-pixel ROI, and averaged from ten images.

RESULTS

UHR mode showed superior in-plane resolution across all kernels at 10% TTF. Among them, NS_UHR achieved the highest values, followed by then FS_UHR, particularly for Bv44 and 48. For z-axis resolution, FWHM in UHR mode exceeded 0.4mm, with CT value fluctuation being highest in NS_UHR, followed by FS_UHR NPS was the lowest in NS_UHR, followed by FS_UHR.

CONCLUSION

Among the four available scan modes, NS_UHR mode achieved the best performance in terms of in-plane and z-axis spatial resolution and image noise characteristics followed by FS_UHR mode.

CLINICAL RELEVANCE/APPLICATION

PCD-CT with UHR mode provides improved spatial resolution and reduced image noise. The use of 0.2 mm slice thickness enables high-quality imaging while allowing for potential dose reduction. FS_UHR achieves fast acquisition with higher image quality, potentially suitable for patients with poor breath-hold capacity, pediatric imaging, and organs near the cardiac.

R5B-SPVA-3 DEEP LEARNING ENHANCED ULTRA-LOW DOSE DUAL VASCULAR CTA: PROSPECTIVE VALIDATION OF 55% RADIATION & 21% CONTRAST REDUCTION WITH DIAGNOSTIC NON INFERIORITY

Lin Yang (*Presenter*)
Chao Zheng (*Abstract Co-Author*)
Xin J. Sheng (*Abstract Co-Author*)
Meng Wang (*Abstract Co-Author*)
Min Xu, PhD (*Abstract Co-Author*)

PURPOSE

Current combined coronary-carotid-cerebral CT angiography (C&CC-CTA) protocols risk cumulative radiation/contrast toxicity in vulnerable populations, while isolated dose reductions compromise diagnostic quality. We developed a deep learning-enhanced "dual-low" protocol to simultaneously reduce both radiation and contrast burdens without sacrificing diagnostic accuracy.

METHODS AND MATERIALS

This IRB-approved prospective trial (July 2024-April 2025) randomly assigned 80 patients requiring C&CC-CTA into two groups, utilizing a 320-detector CT scanner (Aquilion ONE Genesis Edition). The dual-low group (n=40) received imaging at 80 kVp with 1.48 mgI/kg contrast, reconstructed using both DLR(L-DLR) and hybrid iterative reconstruction (L-HIR). The regular-dose group (n=40) underwent imaging at 100 kVp with 1.85 mgI/kg contrast, reconstructed solely using HIR(R-HIR). Objective metrics, including vessel-specific CT values, standard deviation (SD), signal-to-noise ratio (SNR), and contrast-to-noise ratio (CNR), were quantitatively analyzed. Subjective image quality assessments were performed independently by two fellowship-trained radiologists (with 15 and 8 years of experience), using a blinded, randomized review approach with and a 5-point Likert scale. Statistical analyses were conducted using SPSS 22. Normality of data distribution was assessed by the Shapiro-Wilk test, employing independent t-tests for normally distributed data and Mann-Whitney U tests for non-normally distributed data.

RESULTS

Compared to the regular-dose group, the dual-low protocol significantly reduced both contrast volume (45.2±2.4 mL vs. 57.4±3.2 mL, 21% reduction) and radiation dose (2.3±0.5 mSv vs. 5.1±1.5 mSv, 55.1% reduction). L-DLR markedly enhanced vascular visualization relative to R-HIR, reflected by significant improvements in CT values across coronary and cerebrovascular territories (all $p < 0.05$). Furthermore, L-DLR showed similar or lower SD values in most vascular areas compared to R-HIR, except for the internal carotid artery (13.9±6.4 vs. 17.4±5.4; $p = 0.007$). Additionally, SNR and CNR for L-DLR images were comparable or superior relative to R-HIR. L-DLR images yieled comparable subjective image scores to R-HIR ($p > 0.05$ for both reader 1 and reader 2)

CONCLUSION

In comparison to the regular-dose protocol, the “dual-low” C&CC-CTA using DLR reconstruction demonstrates relatively better image quality while effectively reducing both radiation dose and contrast agent usage.

CLINICAL RELEVANCE/APPLICATION

We propose a novel deep learning-enhanced "dual-low" coronary-carotid-cerebral CTA protocol, significantly reducing radiation by 55% and contrast by 21% while preserving diagnostic accuracy.

S3A-SPBR-1 PREDICTING FUTURE RISK OF DCIS AND INVASIVE BREAST CANCER USING AI: A MULTI-SITE STUDY IN U.S. AND EUROPEAN SCREENING PROGRAMS

Constance D. Lehman, MD, PhD (*Presenter*)
Mark Scully (*Abstract Co-Author*)
Emily Hipp (*Abstract Co-Author*)
David Miller (*Abstract Co-Author*)
Christiane K. Kuhl, MD, PhD (*Abstract Co-Author*)
Elizabeth A. Morris, MD (*Abstract Co-Author*)
Lora D. Barke, DO (*Abstract Co-Author*)
Louie Enriquez, MD, JD (*Abstract Co-Author*)
Toni W. Vomweg (*Abstract Co-Author*)
Philippe Raffy, PhD (*Abstract Co-Author*)

PURPOSE

Traditional breast cancer risk models, such as the Breast Cancer Risk Assessment Tool (Gail model) and Tyrer-Cuzick (IBIS) model, were developed to estimate the risk of invasive breast cancer. The Gail model does not provide risk estimates for ductal carcinoma in situ (DCIS), and the majority of studies evaluating both models exclude DCIS as an outcome. Given these limitations, we evaluated the performance of an image-based artificial intelligence (AI) risk model in predicting DCIS and invasive breast cancer in a large, multi-site study of screening programs in the U.S. and Europe.

METHODS AND MATERIALS

The AI model was trained on 421,499 mammograms from 27 facilities in Europe, South America, and the U.S., using a deep convolutional neural network and calibrated on an independent test set to output 5-year risk probabilities. We applied the model to a cohort of 163,262 bilateral 2D screening mammograms (154,316 from five U.S. sites; 8,946 from one European site) acquired from 2011-2016. Cancer outcomes and type (pure DCIS vs any invasive breast cancer) were obtained from local tumor registries. Five-year cancer incidence was defined as the number of cancers diagnosed within five years of the index exam divided by the total number of exams. Incidence was calculated separately for DCIS (excluding invasive cases) and for invasive cancers (excluding pure DCIS cases). Model performance was assessed with time-dependent areas under the receiver-operating characteristic curve [AUC(t)] and bootstrapped 95% confidence intervals.

RESULTS

A total of 3,234 cancer-positive exams were identified in the cohort of 163,262 exams (2.0%). Among these, 69.9% were invasive cancer (n = 2,260) and 30.1% were DCIS (n = 974). The overall AUC(t) was 0.71 (95% CI: 0.70-0.72), 0.72 for invasive cancer (95% CI: 0.71-0.73), and 0.68 for DCIS (95% CI: 0.66-0.70) ($p < 0.001$). In the European site, AUC(t) was 0.78 for both invasive cancer and DCIS. In contrast, U.S. sites showed higher performance by AUC(t) for invasive cancer than for DCIS (0.71 vs. 0.68).

CONCLUSION

The image-based AI model demonstrated strong performance in predicting both DCIS and invasive cancer, with significantly higher predictive accuracy for invasive disease. Notably, model performance for DCIS and invasive cancer was similar at the European site, whereas in the U.S., the model demonstrated stronger discrimination for invasive cancer than for DCIS.

CLINICAL RELEVANCE/APPLICATION

AI-based five-year breast cancer risk prediction using mammography alone can effectively identify risk for both invasive breast cancer and DCIS across diverse screening populations, and thus may support more comprehensive personalized screening strategies and risk-reduction interventions.

S3A-SPBR-2 MR T_1/T_2 DUAL-MODAL IMAGING OCCLUDER PERFUSED WITH DILUTED GADOPENTETATE DIMEGLUMINE SOLUTION

Xin Weng, MBBS (*Presenter*)
Pingping Wang (*Abstract Co-Author*)
Baoying Chen (*Abstract Co-Author*)

PURPOSE

Currently, needle artifacts limit MRI-guided interventions, affecting visual size estimation and targeting. Combining the excellence of magnetic resonance imaging (MRI), We attempted to fabricate a novel MR T 1 /T 2 dual-modal imaging occluder perfused with a diluted gadopentetate dimeglumine solution. In this research, the imaging occluder hardly produces susceptibility artifacts under different scanning sequences. Moreover, it is easier to manufacture and has a lower cost compared with the traditional VIsILoC TM occluder, offering new value for optimizing MR-guided vacuum-assisted breast biopsy (VABB).

METHODS AND MATERIALS

Using a 3.0 T MR scanner (MAGNETOM Prisma, A Tim + Dot System) and standard head coil, we scanned five diluted gadopentetate dimeglumine solutions (0.5 - 2.5 mmol/L) with T1 and T2 Mapping. After analyzing data, 1.5 mmol/L was chosen as the best concentration. We simulated punctures on porcine tissues with a tube containing the selected solution and scanned a 10G needle as control, using 6 sequences. The 6 sequences are T1 FLASH, T1 FLASH with water excitation fat suppression, T2-weighted turbo spin echo sequence, T2-weighted turbo spin echo sequence (fat sat), diffusion weighted sequence(b values:0, 1000 s/mm 2). Process the obtained images, analyze the length and width of the actual objects and the imaging artifacts, as well as the needle insertion depth, and then conduct a further comparison.

RESULTS

Among all the solutions, the one at a concentration of 1.5 mmol/L exhibited the best-quality imaging, with a T1 relaxation rate of 6.612 s?¹ and a T2 relaxation rate of 4.951 s?¹. For the tube, in coronal T1-fs scans, it was 111.16 mm long, 3.10 mm in diameter, and 67.22 mm deep. The artifact was 107.80 mm long, 3.39 mm wide, and 67.34 mm deep. The 10G needle was 11.30 mm long, 4.00 mm in diameter, and 38.76 mm deep, with an artifact 36.03 mm wide and 78.31 mm deep. Needle artifact reduction was 99.09% in width and 99.70% in length.

CONCLUSION

In this study, the 1.5 mmol/L solution showed the best imaging, with clear images and fewer artifacts. The novel T 1 /T 2 dual - modal magnetic resonance (MR) developing occluder based on a diluted gadopentetate dimeglumine solution was successfully developed. This innovation effectively overcomes a series of challenges in traditional MR rotary cutting biopsy techniques, such as the severe artifacts generated by titanium alloy needle cores, the high cost of fluorescent developing occluders, and their short shelf-lives.

CLINICAL RELEVANCE/APPLICATION

This innovation offers a new solution for MR biopsy and strengthens MR imaging in clinics. Future research will optimize the technology and conduct clinical validation.

S3A-SPBR-3 RESEARCH ON THE VALUE OF CONTRAST-ENHANCED MAMMOGRAPHY (CEM)-GALACTOGRAPHY IN THE DIAGNOSIS OF NIPPLE DISCHARGE

Juan Tao (*Presenter*)
Wenying Zhu (*Abstract Co-Author*)
Shuyi Peng (*Abstract Co-Author*)
Jie Liu (*Abstract Co-Author*)
Fan Pu (*Abstract Co-Author*)
Fan Yang, MD (*Abstract Co-Author*)

PURPOSE

This study aims to evaluate the diagnostic efficacy of contrast-enhanced mammography (CEM)- galactography for nipple discharge and compare it with ultrasound imaging.

METHODS AND MATERIALS

Patients with nipple discharge first underwent full-field digital mammography (FFDM), followed by injection of an appropriate amount of contrast agent into the discharging nipple and delayed acquisition of CEM- galactography images. Diagnosis was performed by integrating FFDM and CEM- galactography images. A total of 81 patients underwent CEM-galactography, among whom had both pathological and ultrasound data. Images from different imaging modalities were evaluated by three researchers with varying levels of experience in breast diagnostic assistance (10, 11, and 30 years). Using histopathological results as the gold standard, the specificity and sensitivity of CEM- galactography were analyzed, and the radiation dose of CEM examinations was recorded. Mann-Whitney U tests were used for analyzing differences in average glandular dose (AGD).

RESULTS

The mean age of the 81 patients was 47.3 years. Their evaluations were compared with the histopathological assessment of the surgical specimens resected from the 81 patients. Pathological findings included 13 cases of intraductal carcinoma, 21 cases of ductal carcinoma in situ, 39 cases of intraductal papilloma, and 8 cases of ductal dilation. CEM- galactography demonstrated a sensitivity of 98% and a specificity of 89% in diagnosing nipple discharge-related diseases, with a contrast agent dosage of approximately 1-2 ml. Ultrasound imaging showed a sensitivity of 90% and a specificity of 81%. The average radiation dose during CEM- galactography was 1.65 mSv, significantly lower than the safety limit of 3 mSv per single mammography examination set by the International Commission on Radiological Protection (ICRP).

CONCLUSION

CEM- galactography ensures that contrast agent dosage and radiation exposure remain within safe ranges during nipple discharge diagnosis. Compared with ultrasound imaging, it offers notable advantages. A single exposure can provide low-energy and subtraction images. It can not only replace galactography obtained under the traditional FFDM technology, but also provide diagnostic images of higher quality for visualizing the contrast medium-filled ducts through the subtraction images. Thus, it serves as a crucial, safe, and reliable reference for clinical diagnosis of nipple discharge.

CLINICAL RELEVANCE/APPLICATION

CEM- galactography offers clinicians a more reliable diagnostic option, enriches the diagnostic strategies for nipple discharge, promotes the optimization of diagnostic procedures, and ultimately improves patient outcomes and prognosis.

S3A-SPBR-4 TRANSFORMER-BASED MULTIMODAL AI RISK MODEL FOR LONG-TERM BREAST CANCER RISK ESTIMATION: PERFORMANCE AND EXTERNAL VALIDATION

Felicia Pasadyn, MA, BA (*Presenter*)
Yanqi Xu (*Abstract Co-Author*)
Jungkyu Park, MS (*Abstract Co-Author*)
Linda Moy, MD (*Abstract Co-Author*)
Laura Heacock, MD, MS (*Abstract Co-Author*)
Krzysztof J. Geras (*Abstract Co-Author*)
Yiqiu Shen, PhD, BSc (*Abstract Co-Author*)

PURPOSE

This study evaluates the performance and generalizability of the Multimodal Transformer (MMT), an AI model for long-term breast cancer risk prediction using FFDM, DBT, and ultrasound (US) across diverse populations and imaging protocols.

METHODS AND MATERIALS

The IRB-approved MMT was developed and validated on a longitudinal dataset comprising 1,442,572 screening and diagnostic FFDM, DBT, and US from 299,024 patients collected from 2010-2020. Internal testing was performed on a matched case-control cohort (n=936) consisting of 468 breast cancer cases (within 5 yrs) and 468 controls matched by age, race/ethnicity, and breast density. External validation included two cohorts: a Polish dataset with 454 patients (916 screening episodes, 40 cancers within 2 yrs; no DBT, 60.0% with prior FFDM, 3.17% with US) and a U.S. dataset with 9,681 patients (50% Black, 9,681 screening episodes, 1,011 cancers within 5 yrs; no DBT, 100% with prior MMG, 0.73% with US). MMT predicts 1- to 5-yr breast cancer risk using modality-specific neural networks, a temporal transformer, and a risk prediction layer. Model performance was assessed using 2- and 5-year AUCs and 2-5-yr concordance indices (C-index). Statistical significance was assessed via bootstrapping and permutation testing. We compared MMT's performance to Tyrer-Cuzick (T-C) and MIRAI on the internal test set and to MIRAI on the external datasets.

RESULTS

On the internal matched test set (mean age 60.5, 60.3% dense breasts, 71.6% white, 8.3% Black, 2.6% Hispanic, 4.5% Asian), MMT achieved higher C-index 0.758 (95% CI: 0.737-0.779) and demonstrated better performance in 2-yr AUC (0.869, 95% CI: 0.841-0.895) and 5-yr AUC (0.875, 95% CI: 0.850-0.897) compared to MIRAI, an FFDM-based AI risk predictor (C-index: 0.657, 95% CI: 0.634-0.679, p<0.001), and T-C (C-index: 0.605, 95% CI: 0.580-0.633, p<0.001). On external dataset 1, MMT had a higher C-index (0.857, 95% CI: 0.740-0.963) compared to MIRAI (0.777, 95% CI: 0.592-0.947, p<0.001). On external dataset 2, MMT achieved a C-index of 0.699 (95% CI: 0.668-0.730), outperforming MIRAI (0.680, 95% CI: 0.650-0.710, p<0.001). For 2-year risk, MMT had AUC of 0.803 (95% CI: 0.751-

0.851), compared to MIRAI (0.783, 95% CI: 0.733-0.831). For 5-yr risk, MMT had AUC of 0.700 (95% CI: 0.667-0.732) compared to 0.684 (95% CI: 0.652-0.714) for MIRAI.

CONCLUSION

MMT consistently outperformed both MIRAI and T-C models in long-term breast cancer risk prediction on internal and external datasets.

CLINICAL RELEVANCE/APPLICATION

More accurate breast cancer risk models like MMT allow for earlier, targeted preventive interventions. This potentially reduces overscreening in low-risk patients and allows resource re-allocation to high-risk patients.

S3A-SPBR-5 DOUBLE-READING MAMMOGRAPHY FOR BREAST CANCER SURVIVORS: A GATEWAY TO SCREENING-BASED FOLLOW-UP

Giulia Vatteroni, MD (*Presenter*)
Rubina Manuela Trimboli (*Abstract Co-Author*)
Federica Fici (*Abstract Co-Author*)
Paola Nardi (*Abstract Co-Author*)
Nicolo Turri (*Abstract Co-Author*)
Elisa Salpietro (*Abstract Co-Author*)
Giulia Pinna (*Abstract Co-Author*)
Isabella Bolengo, MD (*Abstract Co-Author*)
Daniela Bernardi, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the rate and timing of breast cancer (BC) recurrences and to assess the diagnostic performance of double-reading mammography, structured according to a population-based screening model, in the long-term surveillance of women with a personal history of breast cancer (BC).

METHODS AND MATERIALS

This retrospective study included women submitted to BC surgery in 2013 and followed up for 10 years at a tertiary cancer centre in Italy. Recurrence rates and time to relapse were evaluated across molecular subtypes using chi-square and Kruskal-Wallis tests. Available mammograms were independently reviewed by 3 blinded radiologists using a positive/negative binary scale. Pathology served as reference standard. Sensitivity, positive predictive value (PPV) and inter-reader agreement (Cohen's and Fleiss' ?) were calculated. Simulated double reading was analyzed using McNemar's test.

RESULTS

Overall, of the 505 women were included in the study, 46/505 (9.1%) women developed BC recurrences: 19/271 (7%) in Luminal A, 6/84 (7%) in Luminal B, 3/28 (10.7%) in Triple Negative (TN), 7/57 (12,3 %) in HER2+ and 11/65(16.9%) in Ductal Carcinoma In Situ (DCIS) cancers (p = 0.0024). Subtype analysis showed highest recurrence rates in DCIS (16.9%) and HER2+ tumors (12.3%). Median time to relapse ranged from 4.7 years (IQR: 3.1-7.0) for TN and 5.2 years for HER2+(IQR: 3.4-8.0) to 8.1 years (IQR 6.0-9.5) for Luminal A (p=0.190). For the radiological revision, 31 women had available mammograms and were included in the radiological revision. Individual reader sensitivity ranged from 67.7% (95% CI: 50.1%-81.4%) to 74.2% (95% CI: 56.7%- 86.2%) rising to 77.4% (95% CI: 60.2%-88.6%) - 83.9% (95% CI: 67.4%-92.9%) with double reading. PPVs ranged from 95.4% (95% CI: 78.2%-99.1%)-100% (95% CI: 85.6%-99.9%) (single) to 96.0% (95% CI: 80.4%-99.2%) -96.2% (95% CI: 81.7%-99.3%)(double). Differences in sensitivity and PPV were not statistically significant (p=1.0). Five recurrences (16.1%) were mammographically occult and detected by clinical examination. Inter-reader agreement was moderate to good (Cohen's ? = 0.38-0.69; Fleiss' ? = 0.57).

CONCLUSION

Double-reading mammography, modeled on population screening, demonstrates robust diagnostic performance even in the follow-up of women with a prior breast cancer diagnosis. These findings support its integration into structured surveillance protocols and suggest it may reduce reliance on additional imaging modalities

CLINICAL RELEVANCE/APPLICATION

Screening-based double reading mammography is a reliable tool for post-treatment BC surveillance. Incorporating this approach into follow-up strategies can enhance detection rates and ensure effective use of clinical and imaging resources.

S3A-SPBR-6 WHAT AI SEES - AND WHAT IT DOESN'T: EVALUATING THE DETECTION OF BREAST CANCER SUBTYPES ON SCREENING DIGITAL BREAST TOMOSYNTHESIS

Manisha Bahl, MD, MPH (*Presenter*)
Saul Langarica (*Abstract Co-Author*)
Synho Do, PhD, MS (*Abstract Co-Author*)

PURPOSE

Artificial intelligence (AI)-based computer-assisted detection and diagnosis (CADe/x) algorithms are increasingly being used in clinical practice, but there is relatively limited data about AI-based CADe/x for digital breast tomosynthesis (DBT) and the subtypes of breast cancer that are more likely to be detected versus missed by AI. The purpose of this study was to compare the characteristics of breast cancers detected versus not detected by a commercial AI-based CADe/x algorithm for DBT.

METHODS AND MATERIALS

The study institution's breast imaging reporting system was searched for consecutive true-positive (n=334), true-negative (n=333), and false-positive (n=333) screening digital breast tomosynthesis (DBT) examinations from January 2016 until the target sample size was reached (total n=1000). The 1000 DBT examinations were retrospectively analyzed by an AI-based CADe/x algorithm for DBT (INSIGHT DBT v1.1.0.0; Lunit, Inc.). True-positive examinations that were considered positive by AI (score of 10 or higher out of 100) were reviewed by a breast imaging radiologist to determine whether the AI marks corresponded to the site of the subsequently diagnosed breast cancer. Imaging and clinicopathological features were compared between true-positive cases detected versus not detected by AI with standard statistical tests.

RESULTS

The AI algorithm detected and correctly localized 84.4% (282/334) of true-positive (screening-detected) cases. It was more likely to detect cancers presenting as masses (42.9% [121/282] vs 25.0% [13/52], p =0.002) and less likely to detect cancers presenting as calcifications (31.9% [90/282] vs 59.6% [31/52], p =0.002). The AI algorithm was more likely to detect invasive ductal carcinoma (61.0% [172/282] vs 34.6% [18/52], p <0.001) and less likely to detect ductal carcinoma in situ (DCIS) (23.0% [65/282] vs 51.9% [27/52], p <0.001). There were no significant differences in tumor grade, size, hormone receptor status, or lymph node status between invasive cancers detected versus not detected by AI. Using the same threshold (with scores of 10 or higher considered positive), AI correctly categorized 85.9% (286/333) of true-negative and 73.3% (244/333) of false-positive cases as negative.

CONCLUSION

A commercial AI-based CADe/x algorithm for DBT detected and correctly localized 84.4% of true-positive cancers. It was more likely to detect cancers presenting as masses on DBT and less likely to detect cancers presenting as calcifications.

CLINICAL RELEVANCE/APPLICATION

Our study provides insights into the strengths and limitations of a commercial AI-based CADe/x algorithm for DBT. These findings underscore the need for continued refinement and validation of AI algorithms to maximize their clinical utility.

S3A-SPBR-7 LONG RANGE HISTORY OF PRIOR MAMMOGRAMS FOR BREAST CANCER RISK PREDICTION

Zhengbo Zhou (*Presenter*)
Dooman Arefan, PhD, MSc (*Abstract Co-Author*)
Jules H. Sumkin, DO (*Abstract Co-Author*)
Margarita L. Zuley, MD (*Abstract Co-Author*)
Shandong Wu, PhD (*Abstract Co-Author*)

PURPOSE

Predicting the risk of developing breast cancer using mammogram images has shown promising effects when using deep learning-based models. Existing models however are mostly limited to the use of a single mammogram exam, while in reality, many women have multiple longitudinal prior screening exams that may span for a long range of many years, with varying temporal intervals among exams. The goal of this study is to develop a risk model to account for long-range priors with irregular inter-exam intervals.

METHODS AND MATERIALS

Two retrospective datasets were used: Cohort A (n = 590, 293 biopsy-proven breast cancer and 297 normal controls, max 8 priors, inter-exam interval: 12 to 24 months) from a mammogram screening cohort of a single institution; the CSAW-CC (Karolinska Case-Control) dataset (n = 6459, 406 biopsy-proven breast cancer and 6,053 normal controls, max 4 priors, inter-exam interval: 12 to 36 months). We proposed a Spatio-Temporal Mamba(STM) risk model that (1) handles in theory an unlimited number of priors, (2) encodes inter-exam intervals directly in the Mamba structure, and (3) uses temporal contrastive learning to align representations across irregular temporal intervals of exams. CC and MLO views were combined. Patient-wise five-fold cross validation was conducted to report (format: average ±std) C-index and time-specific AUCs of from 1- to 5-year risk prediction. Model performance was assessed using up to 4 and 8 priors, with comparisons to the Mirai model (using a single exam).

RESULTS

STM model on Cohort A (4 priors): C-index 0.737±0.02; 1-/2-/3-/4-/5-yr AUC 0.734/0.729/0.709/0.687/0.665 ± 0.02-0.03. STM on Cohort A (8 priors): C-index 0.739±0.02; AUC 0.748/0.745/0.733/0.709/0.682 ± 0.02-0.04. STM on CSAW-CC (4 priors): C-index 0.737±0.02 and AUC 0.734/0.729/0.709/0.687/0.665 ± 0.02-0.03. Mirai on Cohort A: C-index 0.685±0.02 and AUC 0.685/0.660/0.670/0.655/0.653 ± 0.02-0.03. Mirai on CSAW-CC: C-index 0.687±0.02 and AUC 0.705/0.680/0.664/0.664/0.630 ± 0.02-0.03.

CONCLUSION

The STM model shows substantially improved performance when comparing to state-of-the-art risk model using a single exam. Using more priors appears to be more predictive.

CLINICAL RELEVANCE/APPLICATION

STM model can handle and benefit from multiple prior exams with irregular inter-exam intervals of a long-range screening history to more accurately predict breast cancer risk in real-world scenarios.

S3A-SPCA-1 LEFT VENTRICULAR HEMODYNAMIC FORCE PARAMETERS IN OBESITY: A NEW APPROACH TO ASSESS EARLY MYOCARDIAL DYSFUNCTION

Wenjun Liu (*Presenter*)
Lele Cheng, DPhil, MD (*Abstract Co-Author*)
Jian Yang (*Abstract Co-Author*)
Zhijie Jian (*Abstract Co-Author*)

PURPOSE

Obesity is a well-established risk factor for cardiovascular diseases (CVDs), contributing to metabolic abnormalities, myocardial remodeling or heart failure. Hemodynamic force (HDF) analysis, utilizing cardiac magnetic resonance imaging (CMR), quantifies changes in the intraventricular pressure gradient within the left ventricle (LV) throughout the cardiac cycle, offering a promising tool for the early detection of myocardial abnormalities in patients with obesity. This study aims to evaluate the early effects of obesity on LV myocardial mechanics through HDF analysis and explore its role in detecting myocardial dysfunction.

METHODS AND MATERIALS

We retrospectively analyzed HDF parameters at various cardiac stages in individuals with obesity and comparing them to healthy controls. Relationships between HDF parameters and body mass index (BMI), myocardial morphology, function and strain indices were assessed. Hierarchical cluster analysis was performed to identify different HDF curve patterns in obesity group.

RESULTS

A total of 238 individuals [39.79±11.8 years, 134 male (56.30%)] including 125 obesity were enrolled. Significant alterations in HDF parameters were observed in obesity individuals, particularly in HDF longitudinal (A-B) and main transversal direction (L-S) values during the systolic/diastolic transition and diastolic deceleration phases. HDF parameters were positively correlation with myocardial dysfunction and strain abnormalities, with the correlation being more pronounced at the A-B level than L-S level. Five distinct HDF curve patterns were identified in the obesity group, reflecting potential types of myocardial dysfunction or maladaptation.

CONCLUSION

HDF analysis is an effective method for detecting early myocardial dysfunction in obesity, providing valuable insight for risk stratification and personalized management of obesity-related cardiovascular disease.

CLINICAL RELEVANCE/APPLICATION

This study highlights the potential of hemodynamic force (HDF) analysis, by measuring changes in the intraventricular pressure gradient within the left ventricle (LV), offers a sensitive method for detecting early alterations in myocardial mechanics in obese individuals. This approach not only provides a more accurate tool for evaluating myocardial function in obesity but also has the potential to serve as a novel diagnostic adjunct for assessing obesity-related heart disease in clinical practice, aiding in risk stratification, prevention, and personalized treatment.

S3A-SPCA-3 ASSESSMENT OF NON-ALCOHOLIC FATTY LIVER DISEASE IN SUSPECTED CORONARY HEART DISEASE PATIENTS: PROGNOSTIC VALUE AND INCREMENTAL PREDICTIVE UTILITY OVER CARDIOVASCULAR RISK FACTORS AND CCTA

Jiang Changqin (*Presenter*)

PURPOSE

This study evaluated the prognostic value of non-alcoholic fatty liver disease (NAFLD) in predicting major adverse cardiovascular events (MACE) among patients with suspected coronary artery disease (CAD), using coronary computed tomography angiography (CCTA) and CT-derived fractional flow reserve (CT-FFR). Time-dependent predictive performance and risk stratification were also examined.

METHODS AND MATERIALS

In this retrospective study, patients with suspected CAD who underwent both CCTA and non-contrast CT scans (liver and spleen) at XX University XX Hospital between January 2017 and December 2018 were included. NAFLD was diagnosed using CT imaging and clinical history. MACE was defined as a composite of cardiovascular/cerebrovascular death, all-cause mortality, myocardial infarction, unstable angina hospitalization, unplanned revascularization, and stroke. Patients were stratified into NAFLD and non-NAFLD groups. Cox regression analyses assessed the association between NAFLD and MACE, with adjustments for cardiovascular risk factors, CCTA metrics, and CT-FFR. Subgroup and time-dependent C-index analyses evaluated prognostic value across populations and over time.

RESULTS

Among 2,981 patients (737 with NAFLD), 408 experienced MACE over a median follow-up of 68 months. The NAFLD group had significantly higher CAD-RADS scores, high-risk plaque prevalence, segment involvement and stenosis scores, coronary calcification, and CT-FFR positivity (all $p < 0.05$). NAFLD remained an independent predictor of MACE in multivariate analysis (adjusted HR: 1.39; 95% CI: 1.15-1.73; $p < 0.001$). The association was particularly strong in males, smokers, hypertensive and non-diabetic patients, and those with non-obstructive CAD or normal CT-FFR. Models incorporating NAFLD showed superior predictive accuracy across all time points (C-index at 60 months: 0.753 vs. 0.727 and 0.695; $p < 0.001$).

CONCLUSION

NAFLD is an independent and robust predictor of MACE in patients with suspected CAD. Its inclusion in prognostic models enhances risk prediction beyond traditional clinical and imaging markers, especially in specific high-risk subgroups.

CLINICAL RELEVANCE/APPLICATION

NAFLD is an independent cardiovascular risk factor in patients with suspected CAD and is significantly associated with increased risk of MACE, independent of traditional risk factors and imaging findings.Incorporating NAFLD into existing CAD risk models improves predictive accuracy beyond conventional CCTA and CT-FFR parameters, supporting its use in integrated cardiovascular risk assessment.

S3A-SPCA-4 LATE GADOLINIUM ENHANCEMENT IN CARDIAC MRI AS A NOVEL BIOMARKER FOR PERSONALIZED RISK ASSESSMENT IN MULTI-VESSEL CORONARY ARTERY DISEASE

Zhaoxin Tian (*Presenter*)
Ting Liu (*Abstract Co-Author*)
Minjie Minjie, PhD (*Abstract Co-Author*)

PURPOSE

Multi-vessel coronary artery disease (MVD) is a major cause of morbidity and mortality, making accurate risk assessment essential for clinical decision-making. The SYNTAX score II (SSII) is widely used to guide treatment strategies such as percutaneous coronary intervention (PCI) and coronary artery bypass grafting (CABG), but it has limitations in assessing myocardial injury. Cardiac magnetic resonance (CMR) imaging provides a more detailed and quantitative evaluation of myocardial damage, offering a potential improvement in risk stratification.

METHODS AND MATERIALS

In this multicenter cohort study, we retrospectively included 715 MVD patients who underwent contrast-enhanced CMR. The cohort was divided into a development group and an external validation group, with MI% being quantitatively measured using late gadolinium enhancement (LGE) techniques. We then developed a prognostic model to evaluate its predictive performance for cardiac death and major adverse cardiovascular and cerebrovascular events (MACCE). Cox proportional hazards models were used for stratified survival analysis across three clinical interventions: medical therapy, PCI, and CABG.

RESULTS

MI% was independently associated with both cardiac death and MACCE. Integrating MI% with SSII significantly improved the performance of the clinical prediction model, as indicated by enhancements in the area under the receiver operating characteristic curve (AUC), C-index, and net reclassification index (NRI). Survival analysis showed that revascularization strategies, compared to medical therapy alone, significantly improved patient survival outcomes. CMR-derived MI% not only optimized risk stratification in MVD patients but also provided valuable guidance for personalized treatment decisions.

CONCLUSION

Incorporating MI% into risk assessment models substantially enhances prognostic accuracy in MVD patients, offering additional value beyond traditional clinical scores like SSII. These findings support integrating MI% into routine clinical practice to guide treatment decisions, which is crucial for personalized management and improving outcomes in MVD patients.

CLINICAL RELEVANCE/APPLICATION

Incorporating MI% into revascularization decision-making better identify patients who would benefit from PCI over CABG, particularly when infarct burden is extensive (>20%). CMR-derived infarct quantification offers a noninvasive approach to refine heart team strategies and personalize therapy selection in complex coronary artery disease.

S3A-SPCA-6 STUDY ON THE APPLICATION OF FREE BREATHING, LOW TUBE VOLTAGE COMBINED WITH DEEP LEARNING AND FREEZING TECHNOLOGY IN CORONARY CTA IMAGING FOR OBESE PATIENTS

Yang Cheng (*Presenter*)

PURPOSE

To evaluate the efficacy of a 100-kVp free-breathing protocol combined with deep learning image reconstruction (DLIR) and motion-freeze technology in coronary CT angiography (CCTA) for obese patients (BMI=28 kg/m²), assessing its ability to maintain or improve image quality while reducing radiation dose.

METHODS AND MATERIALS

In this prospective study, 100 obese patients undergoing CCTA were randomly assigned to: Group A (n=50): Standard protocol (120-kVp, breath-hold, 120-HU trigger threshold, 4s delay) Group B (n=50): Experimental protocol (100-kVp, free-breathing, 250-HU threshold, 2s delay) Both groups utilized Smart-mA modulation and iopamidol contrast (350 mgI/mL; dose=BMI×1.5; 12s injection). Images were reconstructed using ASiR-V50%, DLIR-M, and DLIR-H algorithms. Objective measurements (CT values, noise) were obtained at aortic root (Ao) and proximal coronary segments (RCA, LMA, LAD, LCx), with calculation of contrast-to-noise ratio (CNR) and signal-to-noise ratio (SNR). Subjective image quality was assessed using a 5-point Likert scale.

RESULTS

The groups were well-matched in baseline characteristics (P>0.05). Key findings: No significant differences in CT values across vascular segments (P>0.05) DLIR-H demonstrated: 23-28% lower noise (SD) vs. ASiR-V/DLIR-M (P<0.005) 15-20% higher SNR/CNR (P<0.005) Group B showed: 12-15% higher vascular enhancement (P<0.005) 28% higher subjective scores (P<0.05) Radiation dose reduction: Group B: 3.1±1.0 mSv (vs 4.3±1.4 mSv in Group A, P<0.001) 27.9% effective dose reduction

CONCLUSION

The 100-kVp free-breathing protocol with DLIR and motion-freeze technology significantly improves distal vessel enhancement (15-20%) and branch delineation while reducing radiation exposure by 28% in obese patients. DLIR-H reconstruction provides optimal noise reduction and image quality, offering a safer and more effective CCTA solution for this challenging population.

CLINICAL RELEVANCE/APPLICATION

Free breathing, low tube voltage 100KV combined with deep learning reconstruction algorithm and freezing technique for obese patients with coronary artery CTA test, make the distal vascular enhancement, vascular branches clearer, and with the deep learning reconstruction algorithm noise reduction level increase, can further reduce the image noise, image quality to meet the demand of clinical diagnosis.

S3A-SPCA-7 MYOCARDIAL OXYGENATION IS COMPROMISED ONLY IN SEVERE FIBROTIC REGIONS IN PATIENTS WITH ISCHEMIC HEART FAILURE

Jinhan Qiao, MD (*Presenter*)
Keyan Wang (*Abstract Co-Author*)
Ran Li, MD, PhD (*Abstract Co-Author*)
Cihat Eldeniz, PhD (*Abstract Co-Author*)
Liya Dai (*Abstract Co-Author*)
Caleb Berberet, BS (*Abstract Co-Author*)
Qi Huang, PhD,MSc (*Abstract Co-Author*)
Yang Yang, PhD (*Abstract Co-Author*)
Jie Zheng, PhD (*Abstract Co-Author*)

PURPOSE

Many studies used positron emission tomography to assess the changes in myocardial oxygen metabolism in patients with myocardial ischemia. We are leveraging our new cardiovascular MR (CMR) technique in quantification of myocardial oxygen extraction fraction (mOEF) to evaluate oxygen metabolic changes in patients with ischemic heart failure.

METHODS AND MATERIALS

Twenty three patients (Age: 62 ± 12 years, 16 Male, left ventriclular ejection fraction or LVEF: 35 ± 14%) with ischemic heart failure were prospectively recruited after signing consent forms. Additional 10 subjects (Age: 40 ± 13 years, 9 Male, LVEF: 63 ± 10%) without any cardiovascular disease/history were recruited as a control group. The CMR were performed on a 3T MR scanner (Siemens, Skyra). Myocardial extracellular volume (ECV) and late gadolinium enhancement (LGE) were quantified. Rate pressure product (RPP) was obtained by multiplying systolic blood-pressure with heart rate. Myocardial mOEF maps were reconstructed by a supervised deep learning network model. Segmental measurements on maps based on 16-segment AHA model was performed for statistical analysis.

RESULTS

In patients, myocardial global mOEF correlates moderately with RPP ($r = 0.42$, $p = 0.04$), where ECV and native T1 are not related to RPP. This indicates mOEF may be the only index related to myocardial oxygen consumption. Compared to the controls, patients with heart failure had lower mOEF (0.52 ± 0.1 vs. 0.59 ± 0.05, $p < 0.001$) and higher ECV (34 ± 9% vs, 25 ± 2%, $p < 0.001$). Between mOEF and ECV in these patients, no correlation was observed when ECV < 40%, but a mild negative correlation exists when ECV = 40% ($r = -0.34$, $p = 0.002$). This is similar to the observation with the LGE presence (mOEF: 0.54 ± 0.08, LGE< 50% vs. 0.43 ± 0.12, LGE = 50% $p < 0.001$). Myocardial segmental mOEF is significantly lower subtended by obstructive coronary artery stenosis (= 50%) than those by non-obstructive stenosis (< 50%), regardless of 1-, 2-, or 3-vessel obstruction. Using a model combining mOEF, native T1, and myocardial strain values, the non-contrast imaging can predict LGE > 50% with AUC = 0.85 and sensitivity/specificity = 83% / 79%.

CONCLUSION

The novel non-contrast mOEF technique reveals that relatively severe myocardial fibrosis with ECV larger than 40% induces reduced oxygen metabolism in ischemic heart failure. This altered cardiac oxygenation appears to be related to severity of stenosis, but not to number of stenotic coronary arteries.

CLINICAL RELEVANCE/APPLICATION

The non-contrast mOEF technique can be complementary for evaluation of oxygen metabolic changes in patients with cardiac ischemia. Assessment of mOEF may allow series of assessment in treatment response of patients with heart failure in clinical practice.

S3A-SPCA-8 SYNERGISTIC IMPACT OF MULTIPLE DOSE REDUCTION STRATEGIES COMBINED WITH SUBTRACTION CORONARY CT ANGIOGRAPHY IN HIGH-CALCIFICATION PATIENTS

Mengqiang Xiao, MMEd (*Presenter*)
Jun Chen (*Abstract Co-Author*)
Rulin Xu (*Abstract Co-Author*)

PURPOSE

To evaluate the efficacy of combining multiple dose reduction strategies with subtraction coronary CT angiography (S-CCTA) in reducing radiation exposure while enhancing diagnostic accuracy for patients with high coronary artery calcium scores (CACS = 400).

METHODS AND MATERIALS

Fifty patients with severe coronary calcification (CACS = 400) underwent S-CCTA using a protocol integrating narrowed acquisition windows (70-80% R-R interval), reduced tube voltage (80 kV), isocentric scanning, and minimized tube current. Subjective and objective image quality (IQ) metrics, radiation dose, and diagnostic accuracy were compared between conventional CCTA (C-CCTA) and S-CCTA. Coronary segments were evaluated according to the 15-segment model, and stenosis severity was classified using the Coronary Artery Disease Reporting and Data System (CAD-RADS). Invasive coronary angiography (ICA) was used as the reference standard to compare the diagnostic performance of C-CCTA and S-CCTA.

RESULTS

The mean effective radiation dose was 1.08 ± 0.29 mSv. S-CCTA demonstrated comparable subjective IQ (3.71 ± 0.50 vs. 3.67 ± 0.53, $P = 0.10$) and objective metrics (noise, SNR, CNR; $P > 0.05$) to C-CCTA. Among 768 segments, S-CCTA significantly outperformed C-CCTA in sensitivity (87.50% vs. 78.52%) and specificity (92.58% vs. 82.42%, $P < 0.001$). Diagnostic accuracy improved markedly in severely calcified segments (74.56% vs. 49.12%, $P < 0.001$), moderately calcified segments (82.41% vs. 57.41%, $P < 0.001$), and mildly calcified segments (85.56% vs. 65.56%, $P = 0.002$). S-CCTA reduced overestimation of stenosis severity (CAD-RADS) compared to C-CCTA ($P = 0.001$).

CONCLUSION

The integration of multiple dose reduction techniques with subtraction coronary CT angiography substantially lowers radiation exposure while enhancing the diagnostic accuracy for assessing coronary stenosis in patients with high calcification scores.

CLINICAL RELEVANCE/APPLICATION

This advanced imaging protocol offers a promising noninvasive approach for patients with extensive coronary calcifications. By significantly reducing radiation dose without compromising image quality, the method enhances the reliability of coronary stenosis evaluation, thereby improving clinical decision-making and patient management in high-risk cardiovascular populations.

S3A-SPCA-9 CARDIOVASCULAR MAGNETIC RESONANCE T1ρ MAPPING FOR DIAGNOSIS OF ACUTE MYOCARDITIS

Lucia Danny Beissel, MD (*Presenter*)
Alexander Isaak, MD (*Abstract Co-Author*)
Narine Mesropyan, MD (*Abstract Co-Author*)
Dmitrij Kravchenko, MD (*Abstract Co-Author*)
Taraneh Aziz-Safaie, MD (*Abstract Co-Author*)
Leon Bischoff, MD (*Abstract Co-Author*)
Alois M. Sprinkart, PhD (*Abstract Co-Author*)
Christoph Katemann (*Abstract Co-Author*)
Oliver M. Weber (*Abstract Co-Author*)
Claus C. Pieper, MD (*Abstract Co-Author*)
Daniel Kuetting, MD (*Abstract Co-Author*)
Julian A. Luetkens, MD (*Abstract Co-Author*)

PURPOSE

Cardiovascular magnetic resonance (CMR) is an essential pillar in the non-invasive diagnosis of acute myocarditis and can obviate the need for endomyocardial biopsy in clinically stable patients. Although the implementation of T1 and T2 mapping to the Lake Louise criteria (LLC) was of incremental value, limitations and diagnostic uncertainties remain as field strength, sequence, heart rate, age or sex can confound relaxation times. T1? is a novel quantitative parameter that - unlike T1 and T2 mapping - can directly detect changes of the extracellular matrix. The aim of this study was to assess the diagnostic value of T1? mapping in acute myocarditis.

METHODS AND MATERIALS

In this prospective study, patients with acute myocarditis and controls underwent CMR at a 1.5 Tesla. The scan-protocol included 2018 LLC sequences (T2-weighted imaging, T1 and T2 mapping, late gadolinium enhancement) and T1? mapping. Receiver operating characteristic analysis compared the diagnostic performance of single and combined parameters of multiparametric CMR including T1?. The reference standard was defined as clinical evidence of acute myocarditis. Statistics included Mann-Whitney U-test, unpaired Student‘s t, DeLong test and intraclass correlation coefficient (ICC)).

RESULTS

25 patients with acute myocarditis (10 female; mean age: 45.1 ± 23.4 years) and 26 controls (15 female; mean age: 44.5 ± 19.0 years) were included. T1? relaxation time was significantly prolonged in acute myocarditis (98.0 ± 10.3 ms vs. 85.3 ± 5.0 ms, p < 0.01) and in segments with focal myocardial inflammation compared with remote myocardium (104.4 ± 11.3 ms vs. 93.2 ± 11.9 ms, p = 0.02). The area under the curve for T1? (0.89; 95% CI: 0.77-0.96) was comparable to that of T1 (0.93; 95% CI: 0.82-0.98, p=0.35) and T2 (0.86; 95% CI: 0.73-0.94, p=0.52). The diagnostic performance of the 2018 LLC was significantly enhanced by inclusion of T1? mapping (AUC 0.93; 95% CI 0.82-0.98 vs. 0.84 (95% CI: 0.71-0.93), p = 0.02;). The ICC for intra-reader reproducibility (ICC 0.99, 95 % CI 0.98 - 1.00) and inter-reader reproducibility (ICC 0.98, 95 % CI 0.97 - 0.99) were excellent.

CONCLUSION

T1? relaxation times are significantly prolonged in acute myocarditis can differentiate between patients with acute myocarditis and controls. T1? might further improve the diagnostic performance of multiparametric CMR in acute myocarditis.

CLINICAL RELEVANCE/APPLICATION

T1? could be a promising candidate to enhance the diagnostic performance of multiparametric CMR in acute myocarditis. A timely and accurate diagnosis is of special relevance because it can avoid clinical complications that might have an impact on patient outcome.

S3A-SPCA-14 SUPER-RESOLUTION DEEP LEARNING RECONSTRUCTION FOR CORONARY CT ANGIOGRAPHY:IMPROVED CORONARY STENOSIS ASSESSMENT AND CAD-RADS RECLASSIFICATION

Limiao Zou (*Presenter*)
Min Xu, PhD (*Abstract Co-Author*)

PURPOSE

Coronary CT angiography (CCTA) is well-established for non-invasive assessment of significant coronary stenosis, with overall high accuracy against invasive coronary angiography (ICA), and provides guidance for subsequent patient management. However, accurate stenosis assessment remains challenging, mainly due to its limited spatial resolution. By utilizing data from ultra-high-resolution CT as training target, a novel super-resolution deep learning reconstruction (SR-DLR) technique has been developed for CCTA and emerged as a promising tool. Therefore, the aim of this study was to compare SR-DLR against conventional hybrid iterative reconstruction (HIR) in coronary stenosis assessment, using ICA as a reference, and explore the possible impact on patient-level Coronary Artery Disease-Reporting And Data System (CAD-RADS) classification.

METHODS AND MATERIALS

From September 2023 to November 2024, patients who underwent clinically indicated CCTA and ICA within 2-month interval were prospectively enrolled. CCTA images were reconstructed with both HIR (Adaptive Iterative Dose Reduction [AIDR]3D, FC43 kernel) and SR-DLR (Precise IQ Engine [PIQE], Cardiac kernel) and percentage diameter stenosis (PDS) of calcified, noncalcified, and mixed plaques were quantified and compared. Using ICA as a reference, diagnostic performances of HIR and SR-DLR in detecting significant stenosis were compared with the area under the receiver operating characteristic curve (AUC). Patient-level CAD-RADS categories were determined based on the highest-grade stenosis and changes across HIR and SR-DLR were also recorded.

RESULTS

204 patients (mean age, 64.3 years ± 9.1 [SD]; 137 male patients) were included and 605 plaques (175 calcified, 140 noncalcified, and 290 mixed) were identified. Compared with HIR, the median PDS for calcified plaques decreased with SR-DLR (63% [IQR, 53%-85%] vs. 58% [IQR, 44%-71%], P < .001), increased for noncalcified plaques (41% [IQR, 27%-68%] vs. 50% [IQR, 28%-80%], P < .001), whereas no significant difference was found in mixed plaques (P = .12). Moreover, SR-DLR outperformed HIR in detecting significant stenosis, as determined by ICA, on both the per-lesion level (AUC: 0.97 vs. 0.88, P < .001) and per-patient level (AUC: 0.93 vs. 0.84, P < .001). While 163 patients remained constant between the two reconstruction methods, SR-DLR led to 41 patients being assigned a different CAD-RADS category relative to HIR, 25 downgraded and 16 upgraded.

CONCLUSION

SR-DLR outperformed HIR for coronary stenosis assessment and led to 20% patient-level CAD-RADS reclassification.

CLINICAL RELEVANCE/APPLICATION

SR-DLR holds great promise in enhancing the role of CCTA in the diagnosis and patient management of coronary artery disease.

S3A-SPCH-1 EVALUATION OF THE ACCURACY OF QUANTITATIVE PARAMETERS OF LUNG FUNCTION UNDER DIFFERENT CONVOLUTION KERNELS IN CHEST CT

Xu Wang (*Presenter*)
Caiyun Mou (*Abstract Co-Author*)
Hao Chen (*Abstract Co-Author*)

PURPOSE

To explore the effects of different convolution kernels on quantitative parameters of CT lung function.

METHODS AND MATERIALS

A total of 60 patients who completed chest CT and pulmonary function test (PFT) in one week were retrospectively collected from our hospital. Chest CT images with different convolution kernels (lung algorithm Lung20, standard algorithm F20, bone algorithm F60) were transferred to Neusoft NeuMiva Cloud platform, and the slow obstructive pulmonary screening software was utilized to obtain quantitative lung parameters, including the percentage of low-density in the lungs (LAA% -950, -910), and the ratio of the wall area of the airway analysis results (WA% Br0~4).The parameters of PFT examination included the volume of first-second expiratory volume with exertion, the volume of first-second expiratory volume with exertion, and the ratio of wall area with exertion. The PFT parameters included the ratio of first second force expiratory volume (FEV1) to forceful lung volume (FVC) (FEV1/FVC), and FEV1 as a percentage of predicted value (FEV1%). The Friedman test was used to compare the differences in the quantitative lung function parameters between the three reconstruction matrices. Spearman's rank correlation was used to analyze the correlation between CT quantitative parameters and PFT indexes.

RESULTS

The differences in lung quantitative parameters under different convolutional kernels were statistically significant (all P>0.05), except for WA% Br3 (P=0.190), of which LAA%-950 and -910 were the highest at Lung20 and the lowest at F20, and WA% Br0~4 were the highest at F20 and the lowest at F60. LAA%-950 and -910 were negatively correlated with both FEV1 and FEV1/FVC under different convolutional nuclei (both P < 0.001), with LAA%-950 correlating most highly with PFT parameters under F20 (P = -0.628, -0.508).

CONCLUSION

Different convolution kernels affect the accuracy of quantitative CT parameters of lung function, and it is recommended to use the standard algorithm F20 to assess lung function, which has the best correlation with the PFT index.

CLINICAL RELEVANCE/APPLICATION

Different convolution kernels affect the accuracy of quantitative CT parameters of lung function, and it is recommended to use the standard algorithm F20 to assess lung function, which has the best correlation with the PFT index.

S3A-SPCH-2 K-EDGE LUNG PERFUSION IMAGING ENABLED BY SPECTRAL PHOTON-COUNTING CT WITH A PHASE 2 THERANOSTIC AGENT

Salim Si-Mohamed, MD, PhD (*Presenter*)
Agnieszka Gutwinska (*Abstract Co-Author*)
Tristan Doussineau (*Abstract Co-Author*)
Jean-baptiste Langlois (*Abstract Co-Author*)
Vincent Cottin, MD, PhD (*Abstract Co-Author*)
Antoine Robert (*Abstract Co-Author*)

PURPOSE

Computed tomography (CT) technology can evaluate a surrogate marker of lung perfusion, so called pulmonary blood volume (PBV), using iodinated agents. But these agents are neither specific nor suitable for theranostic purposes. Only the concomitant development of color K-edge imaging, a method enabled by spectral photon-counting CT (SPCCT), and dedicated agents may overcome these limitations. In the present study, a gadolinium-based nanoparticle under clinical phase 2, has been tuned towards lung applications. Therefore, we assessed its feasibility for PBV imaging.

METHODS AND MATERIALS

Lung angiographies were performed on a clinical SPCCT prototype (Philips®) 4 s after injection in 2 rabbits (i.e., peak signal in the pulmonary trunk), and 6 s after injection in 1 rabbit (i.e., peak signal in the aorta). 7 mL of GBCA (300 mg/mL, 0.27M $Gd^{3?}$; NH TherAGuIX®) and 7 mL of Xenetix® (iobitridol, 350 mg/mL; Bracco®) were injected at separate times. Conventional (HU), spectral iodine (mg.I/mL), and gadolinium K-edge (mg.Gd/mL) images were reconstructed using voxel size of 0.35 mm^3. Lung segmentation using ISP 15 (Philips®) enabled measurement of global and regional PBV, defined as the ratio between lungs' signal over pulmonary trunk's signal. Spearman correlation analysis was performed.

RESULTS

Ratios of pulmonary trunk to left auricle's signals were inferior to 1 for the first 2 rabbits, i.e., a pulmonary phase, and superior to 1 for the last rabbit, i.e., an aortic phase. Last rabbit presented highest global PBV (18% vs 9%±0 on gadolinium image, 22% vs 9%±2 on iodine image), showing dependence in the acquisition time, as expected by the bolus biodistribution of agents from right to left cardiac cavities. Regional PBV increased from anterior to posterior regions, by 462% and 648% respectively on iodine and gadolinium images, for all rabbits. This highlights the expected gravitational dependence of blood perfusion in the lungs and underscores the substitutive relationship between PBV and perfusion. Excellent correlation of regional PBV was found between both agents (r=0.97, P<0.001), highlighting an excellent agreement.

CONCLUSION

Color K-edge lung perfusion imaging enabled by SPCCT with gadolinium-based nanoparticle is feasible in healthy animals.

CLINICAL RELEVANCE/APPLICATION

Lung perfusion imaging is feasible using dedicated color K-edge agents and spectral PCCT, translatable to disease animal models and potential clinical translation, opening to new theranostic approaches in lung vascular imaging.

S3A-SPCH-3 CT LUNG DENSITOMETRY : INTERGROUP COMPARISON OF QUANTITATIVE PARAMETERS TO ASSESS IMPACT OF AIR POLLUTION

Nitin P. Ghonge, MD, MBBS (*Presenter*)
Nidhi Goyal, MD, FRCR (*Abstract Co-Author*)

PURPOSE

The study examined the hypothesis that prolonged exposure to poor air quality may cause structural lung changes in asymptomatic Delhi-NCR population which may be detected using CT lung densitometry-based [CTLD].

METHODS AND MATERIALS

A prospective cross-sectional study was conducted at the Department of Radiology, Indraprastha Apollo Hospital, New Delhi in two groups [Delhi-NCR patients and elsewhere]. Patients with history of smoking or lung diseases along with pediatric and elderly patients were excluded. CTLD was performed using Osirix-MD to calculate Total lung volume [TLV]; Mean lung attenuation [MLA]; Low Attenuation Area [LAA]; High Attenuation Area [HAA]; Lung attenuation histograms [skewness and kurtosis]. CTLD parameters were compared in two groups. Level of statistical significance was $p<0.05$.

RESULTS

A total of 120 patients were studied with 60 patients in each group. MLA was -862 +/- 26.7 HU in Delhi-NCR and -857 +/- 26.4 HU in the elsewhere group (p-value 0.365). LAA were seen in 63.3 % patients in Delhi-NCR as compared to 38.3% patients in elsewhere group (p-value of 0.006); which is statistically significant. Delhi-NCR group showed mean LAA volume below -950 HU [RA950] of 266.1 cm 3 , as compared to 241.3 cm 3 in the elsewhere group (p value 0.621). HAA, mean HAA volume and CTLD histogram-based skewness and kurtosis does not revealed statistically significant difference.

CONCLUSION

Early 'silent' structural lung changes may be seen with exposure to bad air quality in Delhi-NCR. CTLD-based quantitative parameters are likely to play important role in early detection and surveillance of these lung changes.

CLINICAL RELEVANCE/APPLICATION

Early structural lung changes due to persistent bad air quality are a cause of significant concern and are detectable on CT lung densitometry. These 'silent' changes in the lung may gradually progress to significant structural damage with potential decline in the lung functions and may cause respiratory symptoms. These changes may cause wide range of adverse health effectsCT lung densitometry-based quantitative parameters, particularly low attenuation areas [LAA] are likely to play important role in early detection and surveillance of these lung changes.

S3A-SPCH-4 SARCOPENIA DIAGNOSED BY CHEST CT PREDICTS LONG-TERM MORTALITY IN CRITICALLY ILL PATIENTS WITH EXACERBATION OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Xinyu Dai (*Presenter*)
Ning Lang, MD (*Abstract Co-Author*)

PURPOSE

Sarcopenia is a prevalent extrapulmonary comorbidity in patients with chronic obstructive pulmonary disease (COPD), associated with adverse outcomes. Chest CT is routinely conducted to assess the pulmonary condition of COPD patients. We aimed to investigate the impact of sarcopenia diagnosed by chest CT on the mortality in critically ill patients with exacerbation of COPD (ECOPD).

METHODS AND MATERIALS

This retrospective study enrolled a total of 148 patients hospitalized in intensive care unit (ICU) due to ECOPD from January 2018 to November 2023. Sarcopenia was defined by the skeletal muscle index (SMI) measured at 12 th thoracic vertebra (T12) level on chest CT. Patients were categorized into the sarcopenia and non-sarcopenia groups. Hospital and ICU length of stay, short-term (30-day and 90-day) and long-term (1-year and overall) COPD-related mortality and all-cause mortality were compared between the two groups. Cox regression analyses were further conducted to recognize the risk factors for mortality and a sarcopenia-based nomogram was developed to predict long-term survival.

RESULTS

Eighty-four patients (56.76%) with sarcopenia were found through chest CT measurement. No significant differences were observed in the hospital and ICU length of stay, or short-term mortality between sarcopenia and non-sarcopenia groups ($p > 0.05$). The 1-year COPD-related and all-cause mortality, as well as overall COPD-related and all-cause mortality were significantly higher in sarcopenia group than the non-sarcopenia group (19.05% vs. 4.69%, $p = 0.010$; 28.57 % vs. 6.25%, $p = 0.001$; 33.33% vs. 15.63%, $p = 0.015$; 47.62% vs. 29.69%, $p = 0.027$, respectively). Multivariate Cox regression revealed chest CT-defined sarcopenia as a risk factor for both 1-year (hazard ratio =3.981, 95% CI [1.137,13.938], $p = 0.031$) and overall all-cause mortality (hazard ratio =2.308, 95% CI [1.310, 4.065], $p =0.004$). The sarcopenia-based nomogram demonstrated favourable prognostic performance.

CONCLUSION

Sarcopenia evaluated at T12 level on chest CT may serve as a prognostic factor for predicting long-term mortality among critically ill ECOPD patients. And a sarcopenia-based nomogram may provide prognostic value in clinical practice.

CLINICAL RELEVANCE/APPLICATION

This study expands the value of chest CT, revealing that chest CT can provide more information beyond the pulmonary evaluation for ECOPD patients, which contributes to the comprehensive management for patients.

S3A-SPCH-5 DIRECT EVALUATION OF PERIPHERAL AIRWAYS USING AN ULTRA-HIGH-RESOLUTION 24 X-RAY SOURCES STATIONARY CT SYSTEM

Mu Lin, PhD (*Presenter*)

PURPOSE

Accurate visualization of small airways (<2 mm) is essential for diagnosing diseases such as COPD and bronchiolitis but is limited by the resolution of conventional helical CT (512×512 matrix, =0.5 mm slice thickness). This study evaluated whether a high-resolution stationary CT prototype with 3072×3072 matrix improves peripheral airway visualization and quantification compared to standard helical CT, using both phantom and in-vivo imaging.

METHODS AND MATERIALS

The stationary CT prototype utilizes a dual-ring architecture with 24 fixed X-ray sources and a full detector ring, offering bore size of 83 cm and field of view of 50 cm. Unlike conventional systems, it eliminates the need for slip-ring and mechanical gantry rotation by electronically activating the 24 X-ray sources in sequence. The system achieves ultra-high spatial resolution of 165 μm. A custom airway phantom composed of eleven tubes (internal diameters: 0.9-2.7 mm; wall thicknesses: 0.3-0.4 mm) was scanned using the stationary CT. Measurement accuracy was determined by comparing the measured lumen area to known dimensions. For in-vivo evaluation, 30 subjects underwent chest imaging with both standard helical CT (512×512, 0.6 mm-thickness, 120 kVp, 100 mAs, 50-cm FOV) and the prototype stationary CT (3072×3072, 0.33 mm-thickness, 120 kVp, 100 mAs, 50-cm FOV). A thoracic radiologist reviewed axial images to identify the most distal visible bronchial generation in the right upper lobe, using the right main bronchus as the first-order branch. Maximum generation counts of all subjects were recorded and compared between two CT systems using the Wilcoxon signed-rank test, with significance defined as $p < 0.01$.

RESULTS

In phantom scans, lumen area measurement errors were within -10% for all tubes =1.2 mm in diameter. For smaller tubes, errors increased to -15.2% for 1.1 mm, -22.6% for 1.0 mm, and -38.0% for 0.9 mm tubes. For in-vivo evaluation, stationary CT enabled improved visualization of small airways. The median visible bronchial generation was significantly higher on stationary CT than helical CT (9 vs. 7; $p < 0.001$), with maximum visibility reaching 12 vs. 9 generations, respectively. These results indicate enhanced peripheral airway tracking with stationary CT.

CONCLUSION

The stationary CT prototype demonstrated significantly enhanced visualization and quantification of peripheral small airways compared to conventional helical CT, supporting its potential utility for advanced airway assessment in both clinical and research settings.

CLINICAL RELEVANCE/APPLICATION

By enabling detection and measurement of subtle airway abnormalities, the stationary CT prototype may facilitate early diagnosis of COPD, bronchiolitis, asthma and other small airway diseases.

S3A-SPCH-6 SPAIDNET: A DEEP LEARNING-BASED IMAGING CLASSIFICATION FRAMEWORK FOR INTERSTITIAL LUNG DISEASE

Hongyi Wang (*Presenter*)
Min Liu (*Abstract Co-Author*)
Huaping Dai (*Abstract Co-Author*)

PURPOSE

Interstitial lung diseases (ILDs) are a group of significantly heterogeneous conditions, where diagnosis relies on high-resolution chest computed tomography (HRCT) imaging. This study aims to develop and validate a deep learning (DL) model for the automated classification diagnosis of ILD based on HRCT enabling improved diagnostic consistency.

METHODS AND MATERIALS

Our multicenter study prospectively included 2,901 ILD patients (1496 women, median age: 64) undergoing who underwent 5,213 high-resolution chest computed tomography (HRCT) scan from July 2016 to June 2023, The study was registered at ClinicalTrials.gov (NCT04370158). Patients were divided into 4 cohorts for model development and internal validation, and two independent cohorts for external validation. SPAIDNet, a DL framework using the pre-trained ResNet18 model, was developed, leveraging multi-instance learning techniques to detect spatial pattern enhancing ILD diagnosis. SPAIDNet-assisted radiologist was compared with radiologists and evaluated in both internal and external validation cohorts. Performance metrics included macro-average under the receiver operating characteristic curve (AUC) for multiclass classification. We employed a multivariate Cox proportional hazards regression model to assess the prognostic association between diagnostic probability and all-cause mortality risk.

RESULTS

SPAIDNet model achieved macro-average AUCs of 1.000 [1.000-1.000], 0.905 [0.856-0.944], and 0.870 [0.798-0.932] for multiclass classification in the internal validation cohort, external validation cohort I, and external validation cohort II, respectively. The model outperformed a junior radiologist with 3 years of experience (macro-average AUC: 0.737 [0.691-0.784]) and a senior radiologist with 10 years of experience (macro-average AUC: 0.763 [0.713-0.812]). With AI assisting, the junior radiologist achieved an improved macro-average AUC of 0.817 [0.779-0.855] ($p<0.001$) and the senior radiologist also obtained improvement (macro-average AUC: 0.787 [0.739-0.835], $p<0.001$). A higher probability of usual interstitial pneumonia was strongly associated with increased mortality risk across all models, with adjusted hazard ratios remaining significant at 2.19 (95% CI: 1.91-2.51, $p<0.001$).

CONCLUSION

The multi-instance SPAIDNet model demonstrated high accuracy and robustness in the imaging-based diagnosis of common ILD subtypes, with strong generalizability and potential clinical utility.

CLINICAL RELEVANCE/APPLICATION

This model has the potential to significantly enhance the diagnostic capabilities of clinicians, providing a valuable tool for more accurate diagnosis and prognosis of ILD in clinical practice.

S3A-SPCH-9 TIME SERIES MODEL BASED ON CLINICAL DATA, LABORATORY INDICATORS, AND CHEST X-RAY PNEUMONIA QUANTIFICATION SCORES TO PREDICT PSEUDOMONAS AERUGINOSA PULMONARY INFECTION AND COLONIZATION

Zhi Zhang (*Presenter*)
Yaya Guo (*Abstract Co-Author*)
Zilong He (*Abstract Co-Author*)
Jiefang Wu (*Abstract Co-Author*)
Zhaodong Zeng (*Abstract Co-Author*)
Zeng Fengxia (*Abstract Co-Author*)
Lixuan Jia (*Abstract Co-Author*)
ZHIJUN FAN (*Abstract Co-Author*)
Yue Tan (*Abstract Co-Author*)
Genggeng Qin, MD, PhD (*Abstract Co-Author*)
Weiguo Chen (*Abstract Co-Author*)

PURPOSE

To establish a time-series model based on clinical data, multi-timepoint laboratory indicators, and multi-timepoint chest X-ray pneumonia quantification scores to predict the infection and colonization status of Pseudomonas aeruginosa in the lungs.

METHODS AND MATERIALS

This study retrospectively analyzed 143 patients who met the inclusion criteria.Clinical information, laboratory markers at three time points, and chest X-ray pneumonia quantification scores at these three time points were collected from the patients.The time points are as follows: T1: within 1 day after admission; T2: 3 or 7 days prior to specimen submission; T3: the day of specimen submission.Four time series models were constructed: Model_1 (including clinical baseline information, T3 laboratory data, and chest X-ray pneumonia quantification scores), Model_2 (adding ?T3-T1 change values), Model_3 (adding ?T3-T2 change values), and Model_4 (adding both ?T3-T2 and ?T3-T1 change values).Each model was based on seven machine learning algorithms, and the optimal classifier was selected by evaluating the area under the

ROC curve (AUC).The final four time series models were evaluated using AUC, sensitivity, specificity, accuracy, and other metrics. The Shapley additive explanation method was used to analyze key factors and interpret the model's decision-making process.

RESULTS

The optimal classifiers corresponding to the four time series models were XGBoost, logistic regression, random forest, and logistic regression, respectively.The multivariate time series model (Model_4) performed the best, with an AUC of 0.936 (95% CI: 0.818-0.988), accuracy of 0.907, sensitivity of 0.895, and specificity of 0.917, significantly outperforming the basic model that only includes a single time point (Model_1, AUC = 0.717).The features with higher model contribution include the short-term change in pneumonia score (?T3-T2), pneumonia score at T3, short-term change in CRP (?T3-T2), long-term change in pneumonia score (?T3-T1), and long-term change in platelet count (?T3-T1).

CONCLUSION

The time series model constructed based on clinical data, laboratory indicators from three time points, and chest X-ray pneumonia quantification scores can accurately distinguish Pseudomonas aeruginosa lung infections from colonization. It provides guidance for clinical antibiotic use, improves patient prognosis, and further promotes precision treatment for pneumonia.

CLINICAL RELEVANCE/APPLICATION

This study develops the first machine learning model for distinguishing Pseudomonas aeruginosa pulmonary infection from colonization, offering reliable decision support for clinicians and providing new insights into the diagnosis and treatment of bacterial pneumonia.

S3A-SPCH-10 CORRELATION BETWEEN LYMPHATIC ABNORMALITIES AND GROUND-GLASS OPACITIES IN CHYLOPTYSIS-RELATED PLASTIC BRONCHITIS: FINDINGS FROM CT LYMPHANGIOGRAPHY

Chunyan Zhang (*Presenter*)
Ling Li (*Abstract Co-Author*)
Meng Huo (*Abstract Co-Author*)
Yunlong Yue, MD (*Abstract Co-Author*)

PURPOSE

To investigate the correlation between lymphatic abnormalities and ground-glass opacities (GGOs) using CT lymphangiography (CTL) in chyloptysis-related plastic bronchitis (PB).

METHODS AND MATERIALS

This retrospective study included 19 PB patients with branching bronchial casts. CTL was performed by injecting Lipiodol into foot lymphatic vessels after methylene blue dye localization. Dynamic imaging assessed lymphatic regurgitation (bronchial submucosal [BSLR], peripulmonary hilar [PHLR], subpleural) and pulmonary signs (GGOs, septal thickening, etc.). Two radiologists evaluated CTL findings, with inter-reader agreement analyzed via kappa statistics.

RESULTS

BSLR was present in 15 patients (78.9%), with strong agreement to bronchial wall thickening (kappa > 0.999, P < 0.001). GGOs occurred in 16 patients, 14 (93.3%) of whom had BSLR (84.2% concordance; kappa = 0.477, P = 0.035). PHLR was observed in 16 patients (84.2%), 15 (93.8%) of whom had BSLR and GGOs (89.5% concordance; kappa = 0.604, P = 0.01). Three patients without PHLR lacked GGOs in two cases.

CONCLUSION

CTL effectively detects lymphatic abnormalities in PB, demonstrating substantial concordance between BSLR, PHLR, and GGOs, supporting its role in comprehensive PB evaluation.

CLINICAL RELEVANCE/APPLICATION

CTL provides critical insights into lymphatic dysfunction underlying PB-associated GGOs, aiding diagnosis and guiding targeted therapies. A figure illustrating lymphatic-pulmonary correlations is recommended for review.

S3A-SPCH-11 DLCT-BASED MACHINE LEARNING MODEL FOR PREDICTING EGFR MUTATION STATUS IN NON-SMALL CELL LUNG CANCER

Haojie Zhang (*Presenter*)
Yuhan Zhou, MD (*Abstract Co-Author*)
Fan Feng (*Abstract Co-Author*)
Rui Chen (*Abstract Co-Author*)

PURPOSE

To develop a machine learning model using dual-layer detector spectral CT (DLCT) parameters, conventional imaging features, and clinical data for non-invasive prediction of EGFR mutation status in non-small cell lung cancer (NSCLC).

METHODS AND MATERIALS

This IRB-approved retrospective study included 342 patients with pathologically confirmed NSCLC (193 EGFR-mutant, 149 wildtype) who underwent preoperative DLCT between January 2021 and December 2023. Patients from our institution (n=204) formed the training cohort, while patients from two external centers (n=138) constituted the validation cohort. We extracted quantitative DLCT parameters (iodine concentration, water concentration, effective atomic number, and virtual monoenergetic values at 40-200 keV), conventional imaging features (size, margins, density, location), and clinical parameters (age, sex, smoking history). Feature selection was performed using LASSO regression, and a random forest model was developed. Performance was evaluated using AUC, accuracy, sensitivity, and specificity.

RESULTS

The final model incorporated 12 features: 8 spectral CT parameters (primarily iodine concentration, Z-effective values, low-keV measurements), 2 conventional imaging features (tumor margin, density), and 2 clinical parameters (age, smoking status). In the external validation cohort, the model achieved an AUC of 0.87 (95% CI: 0.81-0.92), accuracy of 82.6%, sensitivity of 84.3%, and specificity of 80.1%. This significantly outperformed models based solely on clinical parameters (AUC=0.66, p<0.001) or conventional CT features (AUC=0.72, p<0.001). Iodine concentration measurements and low-keV (40-70 keV) values contributed most significantly to prediction performance.

CONCLUSION

The DLCT parameter-based machine learning model demonstrates strong generalizability with high accuracy for non-invasive EGFR mutation prediction in NSCLC patients across different institutions. This approach leverages spectral CT's material decomposition capabilities without requiring complex radiomic feature extraction, potentially reducing reliance on invasive biopsies.

CLINICAL RELEVANCE/APPLICATION

This externally validated approach offers a promising non-invasive strategy for precision oncology by facilitating accurate prediction of EGFR mutation status. The model's reliance on standardized spectral CT parameters rather than complex radiomics enhances its clinical applicability and potential for wider implementation across institutions.

S3A-SPCH-12 LOBAR IMPAIRMENTS IN MULTI-VOLUME CT-DERIVED RESPIRATORY AIRWAY MECHANICS IN COPD

Alejandro Comellas, MD (*Abstract Co-Author*)
Punam K. Saha, PhD (*Abstract Co-Author*)

PURPOSE

Impaired airflow is the hallmark of chronic obstructive pulmonary disease (COPD). Differential radiographic signals of lung health impairments in COPD have been observed at different lobes. We retrospectively study associations of multi-volume CT-based respiratory airway mechanical biomarkers with demographics, smoking, and COPD severity.

METHODS AND MATERIALS

Our automated algorithms were applied to inspiratory and expiratory CT images to compute breathing-related radial expansion (? air-R) and along-the-length stretching (? air-S) of airways (Figure 1(a)). ? air-R is computed as the change (%) in cross-sectional area (CSA) at a matching airway between two lung volumes. ? air-S is computed as the change (%) in airway geodesic path-length from the carina to a specific matching airway between two lung volumes. Mean values of ?-metrics at segmental airways were computed at upper and lower lobes. The method was applied on multi-volume CT scans of participants of the Genetic Epidemiology of COPD (COPDGene) study Iowa cohort at baseline and of those with 5-year follow-up visits to compute baseline and 5-year longitudinal changes in airway ?-metrics respectively; exclusion criteria: never-smokers, body mass index (BMI) < 20 kg/m 2 or > 35 kg/m 2 , and missing data. Pearson correlation of baseline values of airway ?-metrics with age, sex, BMI, smoking data, and COPD severity was computed.

RESULTS

The correlation (r-values) heat map of lobar airway ?-metrics with age, sex, BMI, smoking data, and COPD severity is presented in Figure 1(b) (n = 853; age (mean±SD): 64.2±8.3 years; 384 females; BMI: 27.9±3.6 kg/m 2). All airway ?-metrics showed significant negative association with COPD severity; the association was stronger for ? air-S compared ? air-R and for lower lobes compared to upper lobes. Aging had significant negative association with ? air-S at both lobes. Females had significantly lower ? air-S at both lobes as compared to males. BMI showed significant positive association for ? air-R at upper lobes and for ? air-S at lower lobes. Smoking status showed significant negative association for ? air-R at lower lobes, while pack-years were found to have significantly negative association for ? air-S at upper lobes.

CONCLUSION

Breathing-related airway mechanical biomarker of along-the-length stretching strongly associates with COPD severity, age, and sex at both upper and lower lobes; differential regional associations of BMI and smoking data with airway mechanical biomarkers were observed.

CLINICAL RELEVANCE/APPLICATION

Understanding regional interactions of breathing-related mechanical properties of airways with different demographic risk factors and smoking in COPD-a disease of compromised airflow and lung function.

S3A-SPER-1 GENERALIZABILITY OF PE DETECTION AI TOOL IN PEDIATRIC CT PULMONARY ANGIOGRAM AND CHEST CT WITH CONTRAST

Seyedehelaheh Hosseini, MD (*Presenter*)
Javier Contreras Yametti, MD (*Abstract Co-Author*)
Keith J. Dreyer, DO, PhD (*Abstract Co-Author*)
Bernardo C. Bizzo, MD, PhD (*Abstract Co-Author*)
Subba R. Digumarthy, MD (*Abstract Co-Author*)
Pallavi Sagar, MBBS (*Abstract Co-Author*)

PURPOSE

Differences between pediatric and adult chest stress the importance of testing generalizability of AI tools in children. We investigated the generalizability of an AI tool for triaging and detecting pulmonary emboli (PE) in pediatric CT pulmonary angiogram (CTPA) and contrast-enhanced routine chest CT (CECT).

METHODS AND MATERIALS

Our IRB-approved study included 395 CTPA and CECT in children (age range 3- 20 years; mean age 15.9 years, female: male 222:173) from 13 US sites in emergency (n=215), inpatient (n=102), and outpatient settings (n=78). We recorded the presence/absence and location of PE. De-identified thin-section CT images of each patient (1-1.25mm slice thickness) were deidentified, exported, and processed with a commercial AI tool (United Imaging Intelligence) for triaging, detecting, and localizing PE (at main, lobar, segmental, and subsegmental levels). A thoracic subspecialty radiologist performed the failure analysis of all discrepancies between AI outputs and radiology reports. We also recorded the AI output of the pulmonary arterial obstruction index (PAOI- based on Qandil scoring system for PE burden). Data were tabulated in EXCEL and analyzed with SPSS to estimate sensitivity, specificity, negative predictive value (NPV), positive predictive value (PPV), F1-score, Area Under the Curve (AUC with 95% confidence interval [95%CI]). We performed DeLong test to assess differences in AI tool performance across different pediatric age groups.

RESULTS

Out of the 395 pediatric exams, 60 (15.2%) were positive for PE, and 335 (84.8%) were negative. The AI's performance for detecting PE in pediatric CT scans showed the following metrics: 90% NPV, 99% PPV, F1-score of 0.65, AUC (95% CI): 0.93 (0.9-0.96), 96% sensitivity, and 90% specificity. There was no significant difference in the AI performance in children =15 years compared with those >15 years (p-value>0.05). The localization of detected PE was correct in all CTPA and CECT exams (main PE: 15/60; lobar PE: 19/60; segmental PE 11/60; subsegmental PE 3/60). The PAOI scores for patients with central PE (main and lobar PE: 32.2) were significantly higher than for peripheral PE (segmental and subsegmental PE:13.66) ($p<0.01$).

CONCLUSION

We demonstrate the generalizability of the AI tool for detecting and localizing PE in children who underwent CTPA and contrast-enhanced routine chest CT.

CLINICAL RELEVANCE/APPLICATION

The assessed AI tool had higher performance in pediatric CTPA and CECT despite the variable dimensions, hyperdynamic circulation, and propensity for motion artifacts in pediatric CT exams.

S3A-SPER-3 DEVELOPMENT AND VALIDATION OF A DEEP-LEARNING MODEL FOR SEGMENTING ACTIVE BLEEDING LESIONS ON ABDOMINOPELVIC CT

Jihwan Kim, BSc, MSc (*Presenter*)
Taehyun Kim (*Abstract Co-Author*)
Sujeong Kwon, BA (*Abstract Co-Author*)
Namkug Kim, PhD (*Abstract Co-Author*)
Gil-Sun Hong, MD, PhD (*Abstract Co-Author*)

PURPOSE

Active abdominopelvic bleeding requires rapid, accurate diagnosis, yet manual interpretation of abdominopelvic CT (APCT) is labor-intensive and error-prone. We developed and externally validated a two-stage, 3D patch-based deep-learning model to detect and segment active bleeding lesions on APCT.

METHODS AND MATERIALS

A total of 1,727 APCT scans obtained between January 2001 and February 2019 were retrospectively collected; active bleeding was present in 57.7% of cases. The scans were randomly divided into training, tuning, and internal-validation sets in an 8:1:1 ratio. External validation involved two cohorts: cohort A, 204 APCT scans from another institution’s emergency department (29.4% bleeding), and cohort B, 514 scans from the public RSNA 2023 challenge dataset (47.1% bleeding). All examinations were reviewed, and bleeding foci were manually annotated by board-certified emergency radiologists with more than 20 years of experience. A two-stage U-Net model with a ResNet encoder was trained on small patches to capture fine-grained features and large patches to reduce false positives. Performance metrics were the Dice similarity coefficient (DSC), lesion-wise sensitivity (LWS), and mean false-positives per scan (FPV), with all metrics reported with confidence intervals (CIs).

RESULTS

LWSs of our two-stage model in the internal set, cohort A, and cohort B, were 95.5% (93.9-97.4), 88.2% (79.4-94.2), and 84.2% (80.1-87.7), with corresponding FPVs of 2.2 (1.9-2.6), 1.3 (1.1-1.5), and 2.0 (1.8-2.2), respectively. Our model achieved DSCs of 66.5% (62.5-70.6), 50.7% (42.8-58.6), and 42.1% (39.8-47.1) for the same datasets.

CONCLUSION

Our proposed model detects and segments active abdominopelvic bleeding with LWSs of at least 84% while maintaining acceptable false positives per scan across both internal and external datasets, suggesting it could accelerate diagnosis and reduce human error in emergency care.

CLINICAL RELEVANCE/APPLICATION

This AI model can facilitate timely diagnosis and rapid clinical decision-making in patients with active abdominopelvic bleeding. By automatically detecting and segmenting bleeding foci, it can help prioritize critical cases, reduce interpretation delays, and assist in early intervention planning, such as embolization or surgery.

S3A-SPGI-1 FROM LIVER TO BRAIN: A 2.5D DEEP LEARNING MODEL FOR PREDICTING HEPATIC ENCEPHALOPATHY USING OPPORTUNISTIC NON-CONTRAST CT IN ACUTE-ON-CHRONIC LIVER FAILURE PATIENTS

Kangyi Pan (*Presenter*)
Xueyun Zhang (*Abstract Co-Author*)
Yuxian Huang (*Abstract Co-Author*)
Shiman Wu, MD (*Abstract Co-Author*)

PURPOSE

To develop a 2.5D ?deep learning framework leveraging ?non-contrast CT scans for early prediction of ?hepatic encephalopathy (HE) in ?acute-on-chronic liver failure (ACLF) patients.

METHODS AND MATERIALS

This prospective study enrolled 228 ACLF patients from two centers, which were divided into training (n=102), internal validation (n=44), and external testing group (n=82). Non-contrast CT scans from six scanner models were preprocessed (1×1×1 mm³ voxels, HU 30-110), with liver ROIs segmented by two radiologists (arbitrated by an expert). The image center on the maximal cross-sectional slice of the ROI and its adjacent slices (central ±1/2/4) were cropped to generate a 2.5D data. Deep learning models, including DenseNet121, DenseNet201, ResNet50, and InceptionV3, were used for features extraction from 2.5D data and were evaluated for their prediction efficacy on slice level. Multi-instance learning (MIL) methods, including probability likelihood histograms and bag-of-words, were used for feature fusion. Machine learning algorithms including Logistic Regression, RandomForest, and LightGBM with 5-fold cross-validation were applied for fusion signature building and classifier model construction for ACLF-HE prediction. Performance was evaluated by the area under the receiver operating characteristic curve (AUC). Gradient-weighted Class Activation Mapping (Grad-CAM) technique was employed for visualizing the recognition region of deep learning model.

RESULTS

The DenseNet121 model exhibited the highest AUC of 0.698 in the validation cohort compared to other models based on slice-level prediction. The LightGBM model based on MILFusion signature demonstrated the best predictive performance with AUCs of 0.969 (training), 0.886 (validation) and 0.829 (external testing), and outperformed other fusion methods. Grad-CAM confirmed anatomically plausible attention to peri-portal fibrotic regions.

CONCLUSION

The MIL-based 2.5D deep learning model can effectively individualize the evaluation of the risk of HE in patients with ACLF using non-contrast CT.

CLINICAL RELEVANCE/APPLICATION

The MIL-based 2.5D deep learning model enables a scalable solution for early HE risk stratification using conventional CT scans, especially in resource-limited environments.

S3A-SPGI-2 STUDY ON THE TREATMENT OF LIVER CIRRHOSIS WITH BONE MARROW MESENCHYMAL STEM CELLS LABELED WITH NAGDF4@ZIF-8

Yuxin Huang (*Presenter*)
Yao Zhenwei (*Abstract Co-Author*)
Shiman Wu, MD (*Abstract Co-Author*)
Xueyun Zhang (*Abstract Co-Author*)
Yuxian Huang (*Abstract Co-Author*)

PURPOSE

This study developed a multifunctional NaGdF4@ZIF-8 nanozyme with tracking and antioxidative stress capabilities. MRI was used to track NaGdF4@ZIF-8-labeled stem cells, while its ROS scavenging ability optimized cell survival and colonization in the cirrhotic microenvironment.

METHODS AND MATERIALS

NaGdF4@ZIF-8 was characterized by using TEM, XRD, and FTIR. Its effects on cell viability, ROS scavenging, and its ability to label stem cells were evaluated through both in vitro and in vivo experiments. In the CoCl 2 -induced cell oxidative stress experiment, its ROS scavenging ability were observed. The colonization, differentiation and regeneration ability of NaGdF 4 @ZIF-8-labeled stem cells in the liver were further verified by magnetic resonance imaging, pathological staining, blood biochemical indicators and fluorescent staining. C57BL/6J mice with carbon tetrachloride-induced cirrhosis were injected with NaGdF4@ZIF-8-labeled stem cells via the superior mesenteric vein. Colonization was assessed by MRI and verified again by fluorescent staining. ROS distribution and liver pathology were analyzed using DHE staining, H&E staining, Masson, and Sirius red staining. Biocompatibility was evaluated through histology, hepatic/renal function, and blood parameters.

RESULTS

NaGdF 4 @ZIF-8 exhibited uniform morphology and high T1 relaxivity without affecting stem cell viability. It effectively scavenged ROS in vitro and in vivo. Laser confocal microscopy imaging showed that NaGdF 4 @ZIF-8 was endocytosed by stem cells and effectively scavenged intracellular ROS. T1WI and T1 mapping sequences revealed that, compared to the control group, the cirrhotic mice injected with NaGdF 4 @ZIF-8-labeled stem cells exhibited higher liver T1 signals on days 1 and 2 post-injection, which returned to baseline levels by day 7. Immunofluorescence co-localization staining confirmed the successful colonization and differentiation of NaGdF 4 @ZIF-8-labeled stem cells into hepatocyte-like cells, promoting liver regeneration. NaGdF4@ZIF-8-labeled stem cells significantly improved liver pathology and blood biochemistry compared to the control group.

CONCLUSION

NaGdF 4 @ZIF-8 exhibits high T1 relaxivity, excellent ROS scavenging ability, and good biocompatibility, making it a valuable tool for assisting stem cell therapy in liver cirrhosis and monitoring the short-term colonization of stem cells after injection.

CLINICAL RELEVANCE/APPLICATION

The antioxidant properties of NaGdF4@ZIF-8 can reduce oxidative stress under liver pathological condition, ensuring the colonization and proliferation of transplanted stem cells. Its T1 relaxation performance also enables MRI tracking of stem cell localization in the liver.

S3A-SPGI-3 DEEP LEARNING-BASED DETECTION OF SMALL BOWEL TUMORS ONNON-CONTRAST CT WITHOUT BOWEL PREPARATION

QIUXIAN WANG (*Presenter*)
Jianbin Zhu (*Abstract Co-Author*)
Dong Zeng (*Abstract Co-Author*)
Ni Zeng, MS (*Abstract Co-Author*)
Caihong Li (*Abstract Co-Author*)
Wen Zhibo, BA (*Abstract Co-Author*)

PURPOSE

Small bowel tumors (SBTs) pose significant clinical challenges due to their nonspecific symptoms. Most patients present with lymph node or distant metastases at diagnosis, leading to poor therapeutic outcomes and substantially worsened prognosis. Early detection is critical for improving survival rates. Although non-contrast CT is widely used, its diagnostic performance for SBTs remains limited, with sensitivity of 0.71 and specificity of 0.75. Moreover, the lack of bowel preparation during CT examination markedly increases the risk of missed SBTs lesions. This study aimed to develop and validate a deep learning (DL) model for small intestine segmentation and SBTs detection on non-contrast CT, thereby enhancing tumor detection rates and diagnostic accuracy.

METHODS AND MATERIALS

We first trained a segmentation DL model on a manually annotated dataset (298 patients vs. 480 normal controls) and tested it using an external validation set (33 patients vs. 54 normal controls). Subsequently, we developed a detection DL model with a multicenter dataset (298 patients vs. 239 normal controls; 5,474 positive slides and 4,320 negative slides). The detection model was further validated with an independent test set (33 patients vs. 54 normal controls).

RESULTS

For the external validation:The segmentation model achieved an AUC of 0.677 (95% CI: 0.642-0.712), with 97.5% sensitivity and 71.8% accuracy.The detection model showed an AUC of 0.745 (95% CI: 0.711-0.779), demonstrating 88.5% sensitivity and 65.5% accuracy.

CONCLUSION

The proposed DL model shows potential as a novel tool for SBTs detection and segementation in low-preparation settings.

CLINICAL RELEVANCE/APPLICATION

This DL model helps mitigate the influence of radiologists' subjective factors, reducing the risks of missed diagnoses. It shows promising potential to improve early diagnosis rates, thereby enhancing patient survival outcomes. Furthermore, the model facilitates optimization of clinical workflows, enabling radiologists to complete diagnostic procedures more efficiently while maintaining diagnostic accuracy.

S3A-SPGI-4 COMPUTED TOMOGRAPHY-BASED DEEP LEARNING MODEL FOR ASSESSING PREOPERATIVE TUMOR DEPOSIT IN COLORECTAL CANCER

Gengyun Miao (*Presenter*)

PURPOSE

Tumor deposits (TDs) are an established adverse prognostic factor in colorectal cancer (CRC). However, their identification currently depends on postoperative histopathologic evaluation, restricting their utility in preoperative risk stratification and treatment planning. This study aimed to develop and validate a deep learning (DL) model based on contrast-enhanced CT for the noninvasive, preoperative prediction of TD status in patients with CRC, with the goal of facilitating personalized therapeutic strategies.

METHODS AND MATERIALS

A deep learning model was trained using retrospective data collected from a single center between 2015 and 2024, with patients randomly assigned to training and internal test sets in a 7:3 ratio. External validation was conducted using data from a tertiary medical center between 2017 and 2024. CNN architectures (ResNet18, ResNet34, and attention-enhanced variants) were trained separately on colon cancer (CC), rectal cancer (RC), and combined CRC cohorts. Model performance was assessed using area under the receiver operating characteristic curve (AUC), sensitivity, specificity, and decision curve analysis.

RESULTS

A total of 441 patients were included (340 in the development cohort: 237 for training, 101 for internal testing; 103 in the external test cohort). The attention-enhanced ResNet18 model consistently demonstrated robust performance in identifying TDs. In the combined CRC cohort, the model achieved AUCs of 0.999 (training), 0.909 (internal validation), and 0.896 (external validation). In subgroup analyses, AUCs for the CC cohort were 0.999, 0.892, and 0.828, respectively, and for the RC cohort were 0.999, 0.931, and 0.889, respectively. DCA showed a favorable net benefit across all cohorts, suggesting potential clinical applicability.

CONCLUSION

This DL-based model leveraging contrast-enhanced CT enables accurate preoperative prediction of TD status in CRC. The proposed approach holds promise for enhancing individualized treatment planning and improving risk stratification before surgery.

CLINICAL RELEVANCE/APPLICATION

ResNet18_Attention-based CT model demonstrated excellent performance in identifying tumor deposit status preoperatively in colorectal cancer, offering a noninvasive tool for clinical decision-making.

S3A-SPGI-5 NON-INVASIVE PREDICTION OF TERTIARY LYMPHOID STRUCTURES AND PERITONEAL RECURRENCE IN GASTRIC CANCER USING A MULTITASK DEEP LEARNING MODEL: A MULTICENTER STUDY

Yuming Jiang, MD, PhD (*Presenter*)

PURPOSE

Tertiary lymphoid structures (TLSs) are markers of antitumor immunity and are associated with favorable prognosis and treatment response in gastric cancer. However, histologic evaluation is invasive and subject to sampling bias. This study aimed to develop and validate a novel deep learning model for non-invasive prediction of TLS subtypes and peritoneal recurrence using CT imaging, with implications for treatment stratification.

METHODS AND MATERIALS

We developed CTransNet , a multitask deep learning model combining a convolutional neural network with Transformer-based self-attention to extract features from pre-treatment CT images. The model was designed to predict TLS subtypes (TLS1-3) and peritoneal recurrence. This retrospective study included 2,569 gastric cancer patients from seven independent cohorts. Patients had annotated CT scans, histologic TLS classification, and clinical follow-up. Model performance was assessed in internal and external validation cohorts. Multitask learning was compared to single-task models using area under the curve (AUC), Kaplan-Meier survival analysis, and multivariate Cox regression.

RESULTS

CTransNet demonstrated high predictive accuracy for TLS classification in the training cohort (AUC: TLS1 = 0.910, TLS2 = 0.925, TLS3 = 0.953), with consistent performance in internal and external validation. High-risk scores predicted by the model were associated with significantly increased 5-year cumulative peritoneal recurrence across cohorts. The model independently predicted recurrence in multivariate analyses. Importantly, in patients with low model scores, adjuvant chemotherapy significantly improved DFS and OS, whereas patients with high-risk scores derived minimal benefit. Multitask learning outperformed single-task models in both TLS classification and peritoneal recurrence prediction.

CONCLUSION

This multitask deep learning model enables non-invasive prediction of TLS subtypes and peritoneal recurrence using CT imaging in gastric cancer. It offers a valuable tool for personalized treatment planning, particularly in identifying patients likely to benefit from adjuvant chemotherapy.

CLINICAL RELEVANCE/APPLICATION

This AI-based imaging model predicts tumor immune microenvironment and recurrence risk, offering a non-invasive method to guide individualized therapeutic decisions in gastric cancer.

S3A-SPGI-7 RADIOMIC FEATURE EXTRACTION IN RECTAL CANCER USING WHOLE-MOUNT HISTOPATHOLOGY AS THE GOLD STANDARD

Joao Manoel M. Santos, PhD (*Presenter*)
Jon S. Heiselman (*Abstract Co-Author*)
Nil Urganci (*Abstract Co-Author*)
Canan Firat (*Abstract Co-Author*)
Hadi Ghahremannezhad (*Abstract Co-Author*)
Rami Vanguri, PhD (*Abstract Co-Author*)
Jayasree Chakraborty (*Abstract Co-Author*)
Julio Garcia Aguilar (*Abstract Co-Author*)
Marc J. Gollub, MD (*Abstract Co-Author*)
Jinru Shia, MD (*Abstract Co-Author*)
Natally Horvat, MD, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate the ability of MRI-based radiomic features to predict treatment response in rectal cancer using co-registered whole- and half-mount histopathology as the gold standard.

METHODS AND MATERIALS

We included 38 patients with rectal adenocarcinoma who underwent neoadjuvant therapy followed by surgery. Whole-mount slides were divided into 3 slices and 4 quadrants each, yielding 456 ROIs. After excluding regions with only healthy tissue and regions with missing ground truth pathology information, 370 regions remained (171 with complete response, 199 with incomplete response). Data were split by patient into training (n = 259) and test (n = 111) sets. T2-weighted MRIs were used for radiomic feature extraction (n = 1,510) within the registered tumor bed using PyRadiomics, with isotropic resampling. After removal of highly correlated features, statistical filtering and mRMR selection were performed. Logistic regression was used for classification.

RESULTS

In the training set, the model achieved an AUC of 0.71 (95% CI: 0.65-0.76), sensitivity of 0.80 (0.75-0.85), specificity of 0.46 (0.40-0.52), PPV of 0.61 (0.55-0.67), and NPV of 0.68 (0.63-0.74).In the independent test set, performance was similar with an AUC of 0.72 (95% CI: 0.63-0.80), sensitivity of 0.84 (0.78-0.91), specificity of 0.45 (0.36-0.55), PPV of 0.63 (0.54-0.72), and NPV of 0.73 (0.64-0.81).

CONCLUSION

MRI radiomic features, validated against co-registered whole- and half-mount histopathology, demonstrate promising predictive performance for assessing treatment response in rectal cancer.

CLINICAL RELEVANCE/APPLICATION

This radiomics-pathology pipeline provides spatially validated, imaging-based biomarkers that may support clinical decision-making regarding nonoperative management in rectal cancer patients.

S3A-SPGI-8 UNMASKING EARLY RENAL DAMAGE: PERFORMANCE OF MECHANICAL MAGNETIC RESONANCE ELASTOGRAPHY IN DETECTING EARLY REMODELING IN KIDNEY DISEASE BEFORE DIALYSIS

Vitali Koch, MD (*Presenter*)
Thomas J. Vogl, MD, PhD (*Abstract Co-Author*)
Leon D. Gruenewald, MD (*Abstract Co-Author*)
Mohamed Alrahmoun (*Abstract Co-Author*)
Katrin Eichler, MD (*Abstract Co-Author*)
Christian Booz, MD (*Abstract Co-Author*)

PURPOSE

Chronic kidney disease (CKD) is a progressive condition characterized by renal fibrosis and loss of function. 3D magnetic resonance elastography (MRE) has emerged as an advanced imaging technique that facilitates more detailed tissue characterization, providing not only biomarkers of renal fibrosis but also inflammation. This study aims to assess the performance of 2D/3D MRE in detecting pre-dialysis CKD stages and renal inflammation.

METHODS AND MATERIALS

A prospective cohort of 60 patients with CKD stages 1-4 and healthy controls underwent both 2D and 3D MRE (low-frequency mechanical vibrations ~40 Hz) during the same imaging session. Inversion algorithms were applied to generate stiffness maps in kilopascals (kPa). Quantitative stiffness values, spatial heterogeneity, and diagnostic sensitivity were compared across modalities. Associations with eGFR, urinary biomarkers, and biopsy-confirmed fibrosis/inflammation (where available) were analyzed.

RESULTS

3D MRE demonstrated superior spatial resolution, better depiction of cortical-medullary contrast, and more consistent detection of focal stiffness elevations compared to 2D MRE. In patients with early-stage CKD and normal imaging morphology, 3D MRE detected stiffness increases in both cortical and perihilar regions, while 2D MRE

often failed to capture these regional changes due to slice positioning limitations. Stiffness values showed a significant inverse correlation with eGFR (P<0.01), and elevated stiffness was observed in patients with histologically confirmed early fibrosis, even in the absence of morphological abnormalities on conventional MRI. Patients with CKD stage 3-4 exhibited up to a 30% increase in cortical stiffness compared to healthy controls. Importantly, 3D MRE detected subclinical changes in patients with preserved renal morphology, offering imaging markers for early fibrotic remodeling. Phase angle (Y) and wave attenuation (a) correlated with progression to dialysis and mortality (both P<0.05).

CONCLUSION

3D MRE offers significant advantages over 2D MRE and provides a non-invasive, quantitative, and reproducible method for assessing renal stiffness, enabling early detection of CKD in pre-dialysis stages and outcome prediction. Its volumetric coverage, enhanced sensitivity, and superior spatial resolution allow for improved detection of early pathological changes.

CLINICAL RELEVANCE/APPLICATION

Our findings support the clinical potential of 3D MRE as a next-generation diagnostic tool in nephrology, warranting further validation in larger, multi-center studies.

S3A-SPGI-9 DEEP LEARNING-BASED VENOUS PHASE CT RADIOMICS COMBINED WITH CLINICAL MODELS PREDICT TUMOR BUDDING GRADING AND 2-YEAR METASTASIS/RECURRENCE IN COLORECTAL CANCER

Dong Bai (*Presenter*)
Zhiqun Wang (*Abstract Co-Author*)

PURPOSE

To develop a deep learning radiomics-clinical fusion model for preoperative prediction of tumor budding (TB) grading in colorectal cancer (CRC) using venous-phase CT and clinical data, and evaluate its prognostic value for 2-year metastasis/recurrence.

METHODS AND MATERIALS

Materials and Methods This multicenter retrospective study included 412 CRC patients (2018-2021) with pathologically confirmed TB grades (low-grade: 246; high-grade: 166). Venous-phase CT images were analyzed using hybrid 3D CNN-Transformer architecture for deep radiomics feature extraction, followed by LASSO regression to select signatures for Rad-score calculation. Clinical variables (age, sex, CEA, CA199, CA724, tumor location/size, vascular invasion, T-stage, neural invasion, liver/lymph node metastasis) were filtered via random forest. A multilayer perceptron integrated Rad-score and clinical features. Model performance was validated through 5-fold cross-validation and external testing (n=156). Prognostic analysis included 2-year metastasis/recurrence follow-up. Statistical methods encompassed AUC/Delong test, SHAP interpretability, and Cox regression.

RESULTS

The integrated model demonstrated superior TB grading performance (training AUC: 0.92 vs. 0.85/0.81 for radiomics/clinical models; validation AUC: 0.88 vs. 0.80/0.76; Delong p<0.05). Key predictors identified by SHAP included venous-phase tumor spiculation (weight=0.32), intratumoral heterogeneity (GLCM_contrast, weight=0.28), and CEA =5 ng/mL (weight=0.21). External validation showed sustained robustness (AUC=0.85). High-grade TB correlated with 2.85-fold increased metastasis/recurrence risk (HR=2.85, 95%CI:1.92-4.23), independent of vascular invasion (HR=1.78) and liver metastasis (HR=3.12), with a prognostic model C-index of 0.79.

CONCLUSION

A CT-based deep radiomics-clinical fusion model effectively predicts tumor budding grading and identifies CRC patients at high risk for early metastasis/recurrence. Tumor budding grading serves as an independent prognostic biomarker, supporting its integration into preoperative risk stratification.

CLINICAL RELEVANCE/APPLICATION

In summary, this model represents a significant step toward integrating advanced imaging analytics with clinical data to improve diagnostic accuracy and prognostic precision in CRC. Its clinical utility lies in enabling early risk stratification, guiding treatment decisions, and optimizing patient management to enhance outcomes.

S3A-SPGU-1 DIAGNOSTIC VALUE OF CONTRAST-ENHANCED ULTRASOUND FOR PREOPERATIVE STAGING OF BLADDER CANCER: A PROSPECTIVE STUDY

Qiyun Ou (*Presenter*)
Weiwei Pan (*Abstract Co-Author*)
Xiaotong Li (*Abstract Co-Author*)
Zexin Fu (*Abstract Co-Author*)

PURPOSE

Bladder cancer is one of the most common malignancies worldwide, ranking ninth in incidence among all cancers. Based on the depth of invasion, it is classified into non-muscle-invasive bladder cancer (NMIBC) and muscle-invasive bladder cancer (MIBC). NMIBC accounts for 75% of cases, with 20%-25% progressing to MIBC. Over 95% of MIBC cases are highly aggressive, malignant, and prone to metastasis, with a poor prognosis and a 5-year survival rate often below 50%. Treatment strategies depend on staging, making preoperative diagnosis critical for guiding therapy. Contrast-enhanced ultrasound (CEUS) offers real-time dynamic imaging of lesions and blood flow, with advantages such as low allergic reactions, minimal nephrotoxicity, and high sensitivity. This study aims to evaluate the diagnostic value of CEUS for preoperative staging of bladder cancer.

METHODS AND MATERIALS

This prospective study included 491 bladder cancer patients diagnosed postoperatively at Sun Yat-sen Memorial Hospital, Sun Yat-sen University from April 2020 to December 2024. Two experienced radiologists independently analyzed 2D ultrasound and CEUS features to assess tumor invasion depth. Ultrasound findings were compared with postoperative pathological staging to calculate diagnostic accuracy, sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV).

RESULTS

Among 491 patients (NMIBC: 413, MIBC: 78), CEUS demonstrated an AUC of 0.79 for differentiating MIBC and NMIBC, with an overall accuracy of 88.0% (95% CI: 85.0%-91.0%), sensitivity of 92.0%, and specificity of 65.0%. Significant CEUS features for muscle invasion ($P<0.05$) included tumor base width (AUC=0.78), pedunculation (AUC=0.80), tumor morphology (AUC=0.78), base continuity (AUC=0.74), and tumor size (AUC=0.73).

CONCLUSION

CEUS shows high diagnostic value in preoperative differentiation of NMIBC and MIBC. Statistically significant imaging features identified in this study may facilitate future risk stratification models for assessing muscle invasion.

CLINICAL RELEVANCE/APPLICATION

CEUS is a non-invasive, reliable tool for preoperative bladder cancer staging, aiding in treatment decision-making and improving patient outcomes.

S3A-SPGU-2 VALUE OF T1 MAPPING IN NON-INVASIVE ASSESSMENT OF THE OXFORD CLASSIFICATION OF IGA NEPHROPATHY

Chaobo Li (*Presenter*)
Shaopeng Zhou, MD (*Abstract Co-Author*)
Haiyi Wang, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the diagnostic value of native T1 mapping in differentiating Oxford classification (MEST-C) scores in IgA nephropathy patients.

METHODS AND MATERIALS

In this prospective study, Patients who underwent both T1 mapping and renal biopsy at our Hospital between April 2023 to October 2024 were consecutively enrolled. Two radiologists performed blinded measurements of renal T1 mapping parameters,including cT1 (cortical T1 value), mT1 (medullary T1 value), ?T1(corticomedullary difference) and T1 ratio(corticomedullary ratio) values. Patients were grouped into five categories based on the Oxford classification (MEST-C). Spearman correlation analysis was applied to evaluate the associations between MEST-C scores and T1 parameters; the diagnostic performance of T1 parameters for discriminating different scores of Oxford classification was analyzed using the receiver operating characteristic (ROC) curve.

RESULTS

A total of 124 patients with IgA nephropathy were included in this study [66 males, 58 females; age 19~70 years (IQR: 30-51)]. Except for the E indicator, M, S, T, and C were significantly correlated with renal T1 values (? = 0.177-0.414, all $P < 0.05$). cT1 showed the best diagnostic efficacy for the S score, with an area under the curve (AUC) of 0.798, with a sensitivity of 0.687 and a specificity of 0.88. The best T1 parameters for differentiating the T score was T1 ratio, with an AUC of 0.687, sensitivity of 0.579 and a specificity of 0.791. The AUC values of T1 parameters for differentiating different scores of M, E, and C indices in patients range from 0.505 to 0.616.

CONCLUSION

Native T1 mapping can be used for non-invasive assessment of the S and T scores in the Oxford classification of patients with IgA nephropathy.

CLINICAL RELEVANCE/APPLICATION

Native T1 mapping demonstrates potential for non-invasive assessment of Oxford MEST-C scores in IgA nephropathy. Cortical T1 (cT1) effectively differentiates S scores (AUC=0.798), while T1% best identifies T scores (AUC=0.687). Correlations with M, S, T, and C scores (?=0.177-0.414) suggest utility in evaluating renal pathology, except for E lesions. This technique may reduce reliance on invasive biopsies for monitoring disease severity in select parameters.

S3A-SPGU-4 THE ROLE OF PALEORADIOLOGY IN THE STUDY OF ANATOMICAL SPECIMENS: A CASE OF FEMALE PSEUDOHERMAPHRODITISM IN A 19TH-CENTURY PRUSSIAN SOLDIER

Martina Afano, MD (*Presenter*)
Anna Russo, MD (*Abstract Co-Author*)
Alfonso Reginelli, MD (*Abstract Co-Author*)
Michele Papa, MD (*Abstract Co-Author*)

PURPOSE

This study aims to perform a morphological and diagnostic analysis of a rare pelvic anatomical specimen preserved at the Anatomical Museum of the University of Campania "Luigi Vanvitelli", using advanced radiological techniques. The goal is to identify signs of sexual development disorders and demonstrate the effectiveness of paleoradiology in the non-invasive investigation of historical specimens.

METHODS AND MATERIALS

The specimen examined is the pelvis of Stefan Rusz, a 28-year-old Prussian soldier from Rosu-Maskas, Transylvania, who died of “chest disease” on February 25, 1817, at the Military Hospital of Sacramento in Naples. His body was used for anatomical training and later examined by Professor Trinchera, who diagnosed female pseudohermaphroditism. In 1851, the specimen was donated to Professor Stefano delle Chiaje, then director of the Anatomical Museum of the Regia University of Naples. The pelvis underwent high-resolution multislice CT and MRI with T1- and T2-weighted sequences. Images were reconstructed in 3D and analyzed with focus on genitopelvic anatomy.

RESULTS

Imaging revealed a blind-ending vaginal-like canal and structures compatible with penile corpora cavernosa, but no identifiable uterus or ovaries. The anatomy supports a diagnosis of female pseudohermaphroditism—a condition in which genetically and gonadally female individuals present masculinized external genitalia, such as hypertrophied clitoris and labia majora resembling a scrotum. No signs of trauma, malformations, or surgical intervention were found. The bones showed normal preservation of trabecular and cortical structures. The gluteal muscles displayed normal MRI signal and preserved trophism.

CONCLUSION

This rare case of disordered sexual development in a historical individual highlights the value of paleoradiology in the diagnostic and preservational study of anatomical specimens. The combined use of CT and MRI enabled detailed reconstruction of pelvic structures, offering insights into poorly documented conditions of the past. The specimen also serves as a significant medico-historical and anthropological record.

CLINICAL RELEVANCE/APPLICATION

This study shows the utility of paleoradiology in diagnosing rare congenital conditions, such as disorders of sexual development (DSD), in historical specimens. CT and MRI allow detailed, non-invasive reconstruction of fragile structures, providing insight into intersex anatomy and supporting interdisciplinary collaboration between radiology, anthropology, and medical history.

S3A-SPGU-5 THE VALUE OF RADIOMICS MODELS BASED ON DTI AND DWI SEQUENCES IN IDENTIFYING CERVICAL ADENOCARCINOMA AND SQUAMOUS CELL CARCINOMA

Hanyue Zhang (*Presenter*)
Shifeng Tian (*Abstract Co-Author*)
Changjun Ma (*Abstract Co-Author*)
Ailian Liu, MD (*Abstract Co-Author*)

PURPOSE

To explore the value of radiomics models based on DTI and DWI sequences in differentiating pathological types of cervical adenocarcinoma and squamous cell carcinoma.

METHODS AND MATERIALS

This retrospective study included 147 cervical cancer patients with MRI in our hospital, including 41 adenocarcinoma and 106 squamous carcinoma. All enrolled patients underwent 1.5T MRI scanning two weeks before surgery, and the scanning sequences included T1WI, T2WI, DWI and DTI sequences.The original DWI and DTI images were transferred to the ADW 4.6 workstation, and the Functool function was applied to generate the ADC,FA and ADCT images. By using ITK-SNAP software , the primary lesions of cervical cancer were mapped manually on ADC images, FA images and ADCT images in full layer as Region of interest (ROI).On the uAI Research Portal platform, 464 radiomics features were extracted from ADC, FA and ADCT images respectively. The image data were randomly divided into the training set and the test set according to the ratio of 7:3. Through minimum Redundancy Maximum Relevance (mRMR), Recursive Feature Eliminationusing Cross Validation (RFECV) and Least absolute shrinkage and selection operator (LASSO) algorithms reduce the dimension of features. Based on the final selected features, partial least squares discriminant analysis(PLS-DA) was used to establish the radiomics models: including ADC, FA, ADCT and combined radiomics models.The area under the receiver operating characteristics curve (AUC), sensitivity, specificity and accuracy of each radiomics model were recorded.

RESULTS

The AUC of ADC radiomics model in the training set and test set were 0.877 (95%CI 0.810-0.946) and 0.825 (95%CI 0.684-0.961), respectively.The AUC of FA radiomics model in the training set and test set were 0.722 (95%CI 0.608-0.839) and 0.647 (95%CI 0.389-0.905),respectively.The AUC of ADCT radiomics model in the training set and test set were 0.725 (95%CI 0.610-0.841) and 0.71 (95%CI 0.481-0.934), respectively. The AUC of combined radiomics model in the training set and test set were 0.895 (95%CI 0.833-0.960) and 0.840 (95%CI 0.682-0.989), respectively.

CONCLUSION

The radiomics models based on DTI and DWI sequences are valuable in differentiating the pathological types of cervical adenocarcinoma and squamous cell carcinoma, and can provide a non-invasive and effective auxiliary method for judging tumor heterogeneity before clinical treatment of cervical cancer.

CLINICAL RELEVANCE/APPLICATION

Radiomics can transform images into data that can be mining, providing a non-invasive and effective auxiliary method for determining tumor heterogeneity before clinical treatment of cervical cancer.

S3A-SPGU-6 IMPROVED VISUALIZATION AND STAGING OF UPPER TRACT UROTHELIAL CARCINOMA USING CORONAL REDUCED FIELD-OF-VIEW DIFFUSION-WEIGHTED IMAGING

Wei Wang (*Presenter*)
Jian-Xing Qiu, MD (*Abstract Co-Author*)
Jingyun Wu (*Abstract Co-Author*)

PURPOSE

To compare image quality and staging performance between coronal reduced field-of-view (r-FOV) DWI and conventional axial full FOV (f-FOV) DWI in upper tract urothelial carcinoma (UTUC) evaluation.

METHODS AND MATERIALS

Sixty patients with confirmed UTUC underwent preoperative 3.0T MRI with both axial f-FOV and coronal r-FOV DWI (b value = 50, 1000 s/mm 2). Two experienced radiologists independently evaluated image quality for both DWI sequences, including image sharpness, distortion, artifacts, and lesion conspicuity using a 4-point scale. Tumor contrast was quantitatively calculated as the signal intensity difference between the tumor and adjacent fat. ADC values of tumors were obtained from ADC maps. Both readers evaluated tumor staging (T1-2 vs. T3-4) based on invasion of adjacent fat or renal parenchyma. Pathological results from radical nephroureterectomy served as the reference standard.

RESULTS

Tumors were in the renal pelvis (n =24), ureter (n =34), or both (n =2). Pathological staging classified 24 cases as T3-4. Coronal r-FOV DWI demonstrated superior image sharpness, reduced distortion, fewer artifacts, and better lesion conspicuity compared to axial f-FOV DWI (all $p < 0.05$). ADC values from f-FOV DWI were significantly lower than those from r-FOV DWI [$(1.02\pm0.25)\times10^{-3}$ mm²/s vs. $(1.17\pm0.33)\times10^{-3}$ mm²/s, $p < 0.001$]. Tumor contrast was higher on r-FOV DWI than on f-FOV DWI (240.95±107.97 vs. 183.95±89.87, $p < 0.001$). For staging UTUC (T3 or higher), coronal r-FOV DWI outperformed axial f-FOV DWI (AUC of Reader 1/2: 0.861/0.833 vs. 0.750/0.722, p =0.045/0.020).

CONCLUSION

Coronal r-FOV DWI provided superior image quality, tumor conspicuity, and staging performance for UTUC compared to axial f-FOV DWI, offering added diagnostic value. Integrating coronal r-FOV DWI into clinical protocols may enhance UTUC evaluation and guide clinical therapeutic strategies.

CLINICAL RELEVANCE/APPLICATION

UTUC often exhibits diverse morphological features with its elongated axis predominantly in the coronal plane, which may not be well visualized on axial DWI. Coronal r-FOV DWI improves visualization of UTUC along its long axis while providing superior resolution compared to f-FOV DWI. This study demonstrates that coronal r-FOV DWI provides better image quality and tumor conspicuity compared to axial f-FOV DWI in UTUC evaluation. Additionally, it improves staging accuracy in distinguishing invasive (T3-4) from non-invasive (T1-2) tumors, aiding therapeutic decision-making. The results support incorporating coronal r-FOV DWI into MRU protocols as an adjunct to conventional sequences, potentially improving diagnostic precision and clinical management for UTUC patients.

S3A-SPHN-2 MRI EDEMA PATTERNS IN ACUTE NECK INFECTIONS: A MULTICENTER AND MULTIDISCIPLINARY INTEROBSERVER STUDY

Jussi Hirvonen, MD, PhD (*Presenter*)
Jari-Pekka Vierula, MD (*Abstract Co-Author*)
Heidi Huhtanen, MD (*Abstract Co-Author*)
Jaakko A. Heikkinen, MD (*Abstract Co-Author*)
Janne Nurminen (*Abstract Co-Author*)

PURPOSE

To assess the diagnostic accuracy and interobserver agreement of radiologists and surgeons in detecting prognostic MRI edema patterns, retropharyngeal (RPE) and mediastinal (ME) edema, in acute neck infections, supporting their clinical integration into emergency imaging workflows. These patterns are known to predict disease severity, yet their reliable identification across specialties remains untested until now.

METHODS AND MATERIALS

In this multicenter observational study, 28 readers (comprising radiology residents, board-certified radiologists, and head and neck surgeons from five academic hospitals) evaluated axial T2-weighted Dixon MRI images from 60 patients with clinically confirmed acute neck infections. Readers, blinded to clinical data such as patient symptoms or laboratory results, assessed images for RPE and ME presence and rated their confidence. Sensitivity, specificity, accuracy, and interobserver agreement (Fleiss' kappa) were calculated against a consensus standard set by two fellowship-trained neuroradiologists. Intraobserver consistency was tested by repeating 10 randomly selected cases, unbeknownst to readers.

RESULTS

Overall sensitivity, specificity, and accuracy were 0.92, 0.80, and 0.87 for RPE and 0.88, 0.86, and 0.85 for ME, with substantial interobserver agreement (?=0.61 for RPE, 0.52 for ME). Radiologists outperformed surgeons in RPE sensitivity (p =0.007), RPE accuracy (p =0.04), ME sensitivity (p =0.01), and ME accuracy (p =0.02), with intraobserver consistency reaching 90%. Confidence was high, averaging 4.3 for RPE and 4.1 for ME, and strongly correlated with accuracy (p<0.001), reinforcing diagnostic reliability.

CONCLUSION

Physicians reliably detect MRI edema patterns across expertise levels, validating their use for risk stratification in acute neck infections and supporting broader adoption in clinical practice where MRI is available.

CLINICAL RELEVANCE/APPLICATION

These findings pave the way for the practical application of MRI-detected retropharyngeal and mediastinal edema patterns in emergency settings to stratify risk in acute neck infections. The high diagnostic reliability across specialties supports the broader use of these markers to guide timely clinical decisions and optimize patient care where MRI is available.

S3A-SPHN-3 IMPROVED VISUALIZATION OF MIDDLE EAR PROSTHESES USING PHOTON-COUNTING-DETECTOR CT COMPARED TO ENERGY-INTEGRATED-DETECTOR CT: A CADAVER STUDY

Maryam Sadeghian Sharafi, BSc, MSc (*Presenter*)
John I. Lane, MD (*Abstract Co-Author*)
John C. Benson, MD (*Abstract Co-Author*)
Paul J. Farnsworth, DO (*Abstract Co-Author*)
Kevin J. Treb, PhD (*Abstract Co-Author*)
Michael R. Bruesewitz, RT (*Abstract Co-Author*)
Joseph R. Swicklik, RT, BS (*Abstract Co-Author*)
Eric Babajanian (*Abstract Co-Author*)
Karl Khandalavala (*Abstract Co-Author*)
Matthew Carlson, MD (*Abstract Co-Author*)
Cynthia H. McCollough, PhD (*Abstract Co-Author*)
Shuai Leng, PhD (*Abstract Co-Author*)

PURPOSE

Middle ear prostheses require high-resolution CT for detailed visualization, which is essential for evaluating postoperative results following ossicular chain reconstruction. This study compared image quality, with a focus on spatial resolution, of photon-counting-detector (PCD) to energy-integrated-detector (EID) CT in a cadaver study.

METHODS AND MATERIALS

Nine types of middle ear prostheses, (six stapes and four ossicular replacement prostheses [two total and two partial]), were implemented in five fresh-frozen (non-fixed) whole head specimens. Each prosthesis was first implanted in the correct anatomic position, then intentionally displaced to mimick common types of prosthesis malposition. The specimens were scanned on both PCD-CT (NAEOTOM Alpha, Siemens) and EID-CT (SOMATOM Force, Siemens) scanners. Clinical temporal bone protocols were used with matched tube potential (120kV), CTDI vol, and field of view (80mm). Images were reconstructed at the thinnest slice thickness available on each scanner: 0.2mm for PCD-CT and 0.4mm for EID-CT, using clinical kernels (Hr84 for PCD-CT and Ur77 for EID-CT). A total of 18 image series were evaluated by two experienced neuroradiologists who were blinded to the scanner type and the prosthesis positioning. Each series was scored for prosthesis position (lateral and medial contact: 1=good contact, 2=tangential contact, 3=no contact), reader confidence, and overall image quality. Inter-reader agreement and agreement with ground truth were assessed and compared between PCD-CT and EID-CT.

RESULTS

PCD-CT consistently outperformed EID-CT in prosthesis visualization and diagnostic confidence. For lateral contact (n=18), PCD-CT correctly detected 14 cases versus 12 with EID-CT; for medial contact (n=18), 12 vs 9, respectively. PCD-CT was particularly superior in detecting loss of contact (score 3). Reader confidence was significantly higher with PCD-CT compared to EID-CT for both contacts. For lateral contact, reader 1 reported a mean confidence of 88.9% vs 79.4% (p=0.0188), and reader 2, 86.9% vs 63.3% (p=0.0001). For medial contact, reader 1 rated 92.5% vs. 76.1% (p<0.0001), and reader 2, 93.3% vs 75.6% (p=0.0033). Inter-reader agreement was also higher with PCD-CT (ICC: 0.88 vs 0.60 and 0.77 vs 0.57 for lateral and medial contact, respectively). For overall image quality, the readers preferred PCD-CT images in 16/18 (88.9%) and 17/18 (94.4%) cases.

CONCLUSION

PCD-CT provided superior image quality and higher diagnostic accuracy and confidence for evaluating the position and contact points of middle ear prostheses compared to EID-CT.

CLINICAL RELEVANCE/APPLICATION

Using PCD-CT for postoperative assessment of ossicular chain reconstruction can improve diagnostic confidence and accuracy.

S3A-SPHN-5 LOGIC-GATED MET-TARGETED NIR-II FLUORESCENCE IMAGING ENABLES SUBMILLIMETER QUANTITATIVE DELINEATION OF ORAL CANCER MARGINS

Jingbo Wang, MD (*Presenter*)
Qifan Ma (*Abstract Co-Author*)
Ying Yuan (*Abstract Co-Author*)
Xiaofeng Tao (*Abstract Co-Author*)

PURPOSE

To validate a novel pH-responsive, MET-targeted near-infrared II (NIR-II, 1000-1700 nm) fluorescent imaging system for precise, quantitative delineation of invasive tumor margins in oral squamous cell carcinoma (OSCC).

METHODS AND MATERIALS

A fluorescent probe (PCPA@oMBP-ICG) targeting MET receptors was synthesized by conjugating MET-binding peptides (oMBP) with indocyanine green (ICG), encapsulated within pH-sensitive polymeric vesicles (PCPA) for tumor-specific fluorescence activation. Orthotopic OSCC mouse models (n=30) underwent real-time NIR-II imaging. Dynamic fluorescence intensity-time curves were quantitatively analyzed. Tumor margins were delineated via threshold-based and morphological segmentation algorithms, generating pixel-level intensity maps. Imaging-derived margins were compared with pathology (HE staining, MET immunohistochemistry). Bland-Altman and Pearson correlation analyses quantified imaging-pathology concordance. Diagnostic accuracy was statistically compared to MRI.

RESULTS

The probe showed enhanced serum stability (82.3±4.5% at 24h vs. 51.2±3.6% control, p<0.001). Tumor-specific fluorescence activation yielded higher tumor-to-background ratios (14.6±2.1 vs. 4.8±0.9; p<0.001). Margin delineation achieved 0.63±0.18 mm accuracy, with strong fluorescence-MET expression correlation (r=0.92, p<0.0001). Bland-Altman analysis showed excellent imaging-pathology agreement (mean difference: 0.27 mm; limits: -0.39-0.93 mm). Imaging-based margins outperformed MRI (sensitivity: 93.2% vs. 74.5%; specificity: 89.7% vs. 70.8%; PPV: 91.3% vs. 69.2%; all p<0.05). No adverse probe effects were observed.

CONCLUSION

This logic-gated MET-targeted NIR-II system quantitatively delineates OSCC margins with submillimeter accuracy, superior to conventional MRI and closely matching pathology.

CLINICAL RELEVANCE/APPLICATION

This molecular imaging method has significant potential to enhance surgical accuracy and reduce positive margin rates in OSCC management.

S3A-SPHN-6 QUANTITATIVE STUDY OF VESTIBULAR ENDOLYMPHATIC HYDROPS IN MENIERE'S DISEASE BASED ON THREE-DIMENSIONAL REAL INVERSION RECOVERY SEQUENCE

Mengqiu Liu (*Presenter*)
Mengqiu Liu (*Abstract Co-Author*)
Jiang Fan (*Abstract Co-Author*)
Ying Liu (*Abstract Co-Author*)
Feier Ding, PhD (*Abstract Co-Author*)

PURPOSE

To quantitatively assess the degree of vestibular endolymphatic hydrops (EH) in patients with Meniere's disease (MD) using a three-dimensional real inversion recovery (3D-real IR)sequence and to analyze the correlation between the degree of EH and specific clinical features.

METHODS AND MATERIALS

A retrospective analysis was conducted on 155 clinically diagnosed MD patients (189 ears) treated at the First Affiliated Hospital of the University of Science and Technology of China between January 2022 and June 2024. For each case, we acquired a range of data, including a detailed medical history, pure tone audiometry, caloric tests, electrocochleography, and gadolinium-enhanced inner ear MRI. Vestibule volume (VV) and the volume of vestibular endolymph (EndV) were outlined on 3D-real IR sequence images, and the volume of vestibular endolymph was calculated by the vestibular endolymphatic ratio (ELR) to evaluate the degree of EH, analyze the correlation between the degree of EH and specific clinical features, hearing and vestibular function, and determine the optimal ELR value to differentiate each degree of effusion by using ROC curve analysis.

RESULTS

The degree of vestibular EH in the affected ear group (155 patients) was significantly correlated with disease stage and pure tone audiometry ($P < 0.001$), age and caloric test results ($P < 0.01$), but not with gender, disease duration, frequency of vertigo episodes, tinnitus, ear fullness or electrocochleography ($P > 0.05$). Both EndV and ELR differed significantly between the affected ear group and the control group ($P < 0.01$), although there was no significant difference in VV between the two groups ($P > 0.05$); the mean VV was 0.08 cm3. ROC curve analysis revealed that ELR cutoff values of 16%, 34% and 47% distinguished no hydrops from grade I, grade I from grade II, and grade II from grade III, with AUC values of 0.905, 0.871, and 0.899, respectively.

CONCLUSION

The degree of vestibular EH detected by 3D-real IR MRI correlated with age, disease stage, pure tone audiometry, and caloric test results in MD patients, but not with gender, disease duration, frequency of vertigo episodes, tinnitus, ear fullness, or electrocochleography results. The VV of the affected ear of patients with Meniere's disease was stabilized at 0.08 cm 3 with the healthy ear. Quantitative assessment of vestibular hydrops by 3D-real IR sequences is feasible, with ELR values of 16%, 34%, and 47% defining different levels of hydrops.

CLINICAL RELEVANCE/APPLICATION

The quantitative assessment of vestibular endolymphatic hydrops (EH) using Three-Dimensional Real Inversion Recovery (3D Real IR) sequence offers transformative potential in the diagnosis and management of Meniere's Disease (MD

S3A-SPHN-8 OPTIMIZING OPTIC NEURITIS DIAGNOSIS: THE ADDED VALUE OF CONTRAST-ENHANCED FAT-SUPPRESSED 3D FLAIR IN ORBITAL MRI

Etsushi Iida, MD (*Presenter*)
Atsuo Inoue (*Abstract Co-Author*)
Takaaki Ueda, MD (*Abstract Co-Author*)
Masahiro Tanabe, MD (*Abstract Co-Author*)
Katsuyoshi Ito, MD (*Abstract Co-Author*)

PURPOSE

This study evaluates whether the addition of contrast-enhanced fat-suppressed 3D FLAIR (CE FS 3D FLAIR) to the standard orbital MR protocol—comprising FS 2D T2WI and CE FS 3D T1WI—enhances lesion detection and diagnostic confidence in optic neuritis.

METHODS AND MATERIALS

A retrospective review of 422 orbital MR examinations identified 48 patients meeting specific clinical criteria for acute optic neuritis. These patients underwent imaging using FS 2D T2WI, CE FS 3D T1WI, and CE FS 3D FLAIR. The standard protocol included FS 2D T2WI and CE FS 3D T1WI, while the advanced protocol incorporated CE FS 3D FLAIR. Five datasets were created, analyzed independently by two blinded radiologists, and evaluated across seven optic nerve segments using a 5-point Likert scale. Scores =4.0 were classified as abnormal. ROC analysis and statistical comparisons assessed diagnostic efficacy.

RESULTS

Among symptomatic optic nerves, CE FS 3D FLAIR detected abnormalities in 31.5% of optic discs, outperforming CE FS 3D T1WI (20.4%) and FS 2D T2WI (0%). Intraorbital optic nerve abnormalities were identified in 24.1% (T2WI and FLAIR) versus 20.4% (T1WI). ROC analysis demonstrated a significantly higher AUC for the advanced protocol (0.926) compared to the standard protocol (0.879). Sensitivity, NPV, and accuracy were significantly improved with the advanced protocol (88.9%, 86.4%, 89.6%) versus the standard protocol (70.4%, 71.4%, 81.3%). Weighted kappa values indicated excellent inter- and intra-rater reliability (0.81-0.99).

CONCLUSION

Adding CE FS 3D FLAIR to the standard orbital MR protocol enhances lesion detection and diagnostic confidence in optic neuritis.

CLINICAL RELEVANCE/APPLICATION

CE FS 3D FLAIR is a valuable imaging sequence for the diagnosis of optic neuritis.

S3A-SPIN-1 AI-POWERED MAP OF THE ABDOMEN COULD HELP FIND CANCER EARLY ON

Yucheng Tang (*Presenter*)
Wenxuan Li, BS (*Abstract Co-Author*)
Alan Yuille, PhD (*Abstract Co-Author*)
Zongwei Zhou, PhD (*Abstract Co-Author*)

PURPOSE

This study explores whether AI trained to segment normal anatomy can better detect cancer by identifying deviations from the normal anatomy. The underlying intuition is that if AI has a deep understanding of what normal anatomy looks like—shaped by consistent structures across thousands of patients—it can more reliably identify abnormalities such as cancer that disrupts anatomical integrity.

METHODS AND MATERIALS

To enable AI to learn from normal anatomy, we voxel-wise annotated 16 anatomical structures in 45,312 CT scans, creating the largest datasets of healthy population. This dataset includes structures from all major abdominal organs and vessels, providing a comprehensive spatial map of human anatomy. The AI was pre-trained to mimic radiologists' segmentation behavior by learning to identify the precise boundaries of each structure. To validate that the AI had learned a generalizable representation of normal anatomy, we evaluated its segmentation performance on an external cohort (n = 5,242). Following successful pre-training, we fine-tuned this anatomy-aware AI on a smaller but richly annotated cancer dataset (n = 3,174), which included 3,577 voxel-wise annotations for pancreatic cancer. Notably, only 562 cases (17.7%) in this set were early-stage cancer (<2 cm), reflecting real-world data scarcity in early cancer CT scans. For evaluation, we assembled a test cohort (n = 1,008), with a focus on early-stage cancers confirmed by pathology (n = 274). We compared the anatomy-aware AI to a model trained from scratch for pancreatic cancer detection.

RESULTS

(1) The pre-trained AI achieved an average DSC of 89.8% across 16 anatomical structures on the external cohort. (2) For pancreatic cancer detection, the anatomy-aware AI achieved a sensitivity/specificity of 97.1/98.7%. In detecting early-stage cancer (<2 cm), this anatomy-aware AI obtained a sensitivity of 95.3%, yielding a 6.3%-point gain over the model trained from scratch. Compared to experienced radiologists, the anatomy-aware AI demonstrated a 27.6/4.4% higher sensitivity/specificity in cancer detection.

CONCLUSION

This work showed that pre-training on large-scale normal anatomy enables AI to generalize better to disease detection tasks through fine-tuning. The learned anatomical features were not only interpretable but also highly transferable, offering a principled approach to building clinically useful AI systems.

CLINICAL RELEVANCE/APPLICATION

Anatomy-aware AI has strong potential for broad clinical applications in early cancer detection and beyond. By using prior knowledge of normal anatomical structure, these models may offer enhanced accuracy, interpretability, and data efficiency for detecting subtle pathological changes in real-world patient populations.

S3A-SPIN-2 16 READILY AVAILABLE RADIOLOGY REPORTS ARE WORTH 1 TIME-CONSUMING VOXEL-WISE ANNOTATION FOR WHOLE-BODY CT TUMOR DETECTION

Zongwei Zhou, PhD (*Presenter*)
Pedro Ricardo Ariel Salvador Bassi (*Abstract Co-Author*)
Wenxuan Li, BS (*Abstract Co-Author*)
Sergio Decherchi (*Abstract Co-Author*)
Andrea Cavalli (*Abstract Co-Author*)
Kang Wang, MD,PhD (*Abstract Co-Author*)
Yang Yang, PhD (*Abstract Co-Author*)
Alan Yuille, PhD (*Abstract Co-Author*)

PURPOSE

To leverage tumor characteristics extracted from radiology reports as large-scale, weak annotations to complement small-scale, but detailed voxel-wise annotations for accurate detection of seven understudied abdominal-pelvic tumors.

METHODS AND MATERIALS

We first applied large language models (LLMs) to extract the tumor characteristics—such as tumor size, location, attenuation, and more— from 40,000 radiology reports across a major U.S. hospital's clinical data repository. To ensure alignment between AI-predicted tumors and radiology report content, we introduced three novel loss functions to guide training: (1) Tumor Size Loss (TSL), (2) Tumor Location Loss (TLL), and (3) Tumor Attenuation Loss (TAL). These loss functions transformed both structured and narrative report content into supervisory signals, enabling the AI to learn tumor characteristics consistent with clinical documentation. This approach enhanced detection of tumor types rarely represented in public datasets, including those in the spleen, gallbladder, prostate, bladder, duodenum, esophagus, and uterus. The model was trained using a small number of voxel-wise annotated CT scans (n = 30 / tumor type) and a large set of weakly annotated scans (n = 6,625), derived from 109 to 1,223 reports per organ. Performance was evaluated on 1,000 CT scans for detecting the seven types of tumors.

RESULTS

Across the seven types of tumors, the model supervised by report and voxel-wise annotations achieved mean sensitivity 71.3% and specificity 77.7%, exceeding the model only supervised by voxel-wise annotations by 19.2% and 5.2%, respectively. The breakdown sensitivity/specificity for each type were 70.3/82.7% for bladder tumors, 71.2/64.7% for duodenum tumors, 75.0/72.9% for esophagus tumors, 65.5/80.5% for gallbladder tumors, 71.1/78.9% for prostate tumors, 72.3/79.7% for

spleen tumors, and 73.7/84.2% for uterus tumors. Efficiency analysis showed that replacing one voxel-wise annotation with 16 report-annotated scans kept sensitivity within 0.5 pp of the voxel-only model, establishing a 16:1 equivalence ratio.

CONCLUSION

Tumor information already present in radiology reports provide supervision equivalent to one voxel-wise annotations for every sixteen reports. Leveraging these weak annotations allows accurate multi-organ tumor detection with as few as 30 detailed masks per organ and creates the first public detectors for seven types of tumors.

CLINICAL RELEVANCE/APPLICATION

Report-enabled weak annotations turn hospital archives into a low-cost resource for developing and updating whole-body cancer AI, reducing annotation labor >90 % and accelerating deployment to different types of tumors where voxel-wise annotations are scarce and expensive.

S3A-SPIN-4 MCR-VQGAN FOR TAU PET IMAGE SYNTHESIS: A SCALABLE AND COST-EFFECTIVE ALTERNATIVE FOR ALZHEIMER'S DISEASE IMAGING

Jin Young Kim (*Presenter*)
Zhen Lin (*Abstract Co-Author*)
Jeremy Hudson (*Abstract Co-Author*)
Hongyu Yuan (*Abstract Co-Author*)
Richard A. Barcus (*Abstract Co-Author*)
Jeongchul Kim, PhD (*Abstract Co-Author*)
Qing Lyu (*Abstract Co-Author*)
Christopher T. Whitlow, MD, PhD (*Abstract Co-Author*)

PURPOSE

To develop a scalable and cost-effective method for synthesizing tau PET images from structural T1-weighted MRI scans to support more robust and accessible Alzheimer's disease (AD) imaging research.

METHODS AND MATERIALS

A modified Vector Quantized Generative Adversarial Network (VQGAN) architecture was developed by integrating ResNet blocks, multi-scale convolutional layers, and Convolutional Block Attention Modules (CBAM). The model includes three downsampling and three upsampling layers. The downsampling path uses multi-scale convolutions (kernel sizes 3, 5, and 7) to capture features at varying spatial resolutions, while the upsampling path employs standard convolutional layers (kernel size 3). The encoder and decoder are connected by six ResNet blocks. CBAM modules are applied throughout the network to enhance spatial and channel-wise attention. The model was trained and evaluated on 222 paired structural T1-weighted MRI and tau PET scans from the Alzheimer's Disease Neuroimaging Initiative 3 (ADNI-3), covering a range of AD clinical stages (CN = 134, MCI = 76, AD = 12). Dedicated preprocessing pipelines were applied separately to MRI and tau PET scans to ensure accurate spatial alignment and quantification. The dataset was randomly split into training (n = 178) and testing (n = 44) subsets. For each subject, 14 axial slices were extracted from the center of each MRI and tau PET volume to standardize model input. Model performance was assessed using RMSE, PSNR, and SSIM.

RESULTS

The proposed pipeline generated realistic tau PET images. The modified VQGAN outperformed other GAN-based models, achieving an SSIM of 0.9002, PSNR of 24.27 dB, and RMSE of 0.005724.

CONCLUSION

The proposed pipeline synthesizes realistic tau PET images from structural T1 MRI and provides a scalable, cost-effective alternative to direct PET imaging. This approach may expand access to tau biomarkers in AD research and improve performance in predictive modeling. A downstream AD clinical classification task will be conducted to further evaluate the utility of the synthesized tau PET images. Preliminary results indicate that synthetic tau PET scans achieve classification performance comparable to real PET scans in differentiating AD clinical stages.

CLINICAL RELEVANCE/APPLICATION

Tau PET is a critical imaging tool for early AD diagnosis due to its radiotracer's specificity for tau proteins, a key pathological hallmark. Longitudinal tau PET studies are often used to monitor disease progression but require repeated scans, which are costly and not always feasible. The proposed synthesis approach may reduce dependence on repeated PET imaging by generating tau PET-like images from more accessible MRI scans, enabling more frequent and scalable monitoring of AD progression.

S3A-SPIN-5 EFFECTIVENESS OF LIVER TUMOR SCREENING USING NON-CONTRAST CT: A LARGE-SCALE MULTI-CENTER STUDY

Wei Liu, MSc (*Presenter*)
ZHANG XIAOMING (*Abstract Co-Author*)
Xiaoli Yin (*Abstract Co-Author*)
Yuan Gao, MSc, PhD (*Abstract Co-Author*)
Chunli Li (*Abstract Co-Author*)
Ling Zhang (*Abstract Co-Author*)
Yu Shi, MD (*Abstract Co-Author*)
Ke Yan (*Abstract Co-Author*)
Xu Han (*Abstract Co-Author*)

PURPOSE

We developed a deep learning framework, LiSAR (Liver tumor Screening And Recognition), for early detection of liver tumors using non-contrast CT (NCCT) scans and validated its effectiveness on multi-center data.

METHODS AND MATERIALS

Our development cohort includes 7,709 patients with liver tumors and 7,376 non-tumor subjects from two hospitals. Of these, 1,600 cases were used for internal validation, and the rest for training. We further collected three external test sets: (a) 926 tumor cases, (b) 498 tumor cases, and (c) 363 tumor and 388 non-tumor cases. The study covers the full spectrum of liver tumors including hepatocellular carcinoma (HCC), intrahepatic cholangiocarcinoma, metastasis, hemangioma, focal nodular hyperplasia, cysts, other malignant/benign neoplasms and calcifications. Control cases include diffuse liver diseases like steatosis and cirrhosis. LiSAR comprises three key components: (1) a lesion branch dedicated to lesion segmentation and classifiation. (2) a patient branch focused on image-level diagnosis. (3) a fusion branch that integrates information from the lesion branch and the patient branch. This fusion mechanism enhances prediction accuracy by leveraging complementary information while mitigating potential misalignments between them.

RESULTS

LiSAR achieved a screening AUC of 0.994, sensitivity of 0.948 and specificity of 0.99. The average sensitivities for malignant and benign tumors were 0.967 and 0.867, respectively. For HCC stratified by Barcelona-Clinic Liver Cancer (BCLC) staging, LiSAR demonstrated sensitivities of 0.846 (BCLC=0), 0.975 (BCLC=A), and 1.0 (BCLC=B), surpassing the performance of routine screening methods (e.g., ultrasound+AFP) reported in previous literature. In the subset with severe diffuse liver diseases, LiSAR maintained robust performance, achieving a screening AUC of 0.972, with a sensitivity of 0.912 and specificity of 0.926. Moreover, LiSAR demonstrated strong generalizability across three external testing cohorts, achieving the following results: (a) sensitivity of 0.945, (b) sensitivity of 0.938, and (c) sensitivity of 0.891 and specificity of 0.995.

CONCLUSION

Extensive evaluation on internal and external cohorts highlights LiSAR's effectiveness in detecting liver tumors, outperforming existing routine methods, with consistent performance across diverse patient populations, including challenging cases.

CLINICAL RELEVANCE/APPLICATION

NCCT is a useful tool for early liver tumor screening, especially when contrast agents are contraindicated. LiSAR outperformed ultrasound + AFP in HCC screening, offering an accurate potential approach for routine surveillance or opportunistic discovery of hepatic lesions.

S3A-SPIN-6 CREATING TRIPLET DATASETS FOR MULTIOMIC AND MULTICENTER RADIOLOGY AI EXPLOITING CT IMAGES, ANATOMICAL SHAPES, AND RADIOLOGY REPORTS

Zongwei Zhou, PhD (*Presenter*)
Pedro Ricardo Ariel Salvador Bassi (*Abstract Co-Author*)
Alan Yuille, PhD (*Abstract Co-Author*)

PURPOSE

To create a multicenter database of 9,262 pairs of CT images, anatomical shapes, and radiology reports.

METHODS AND MATERIALS

We developed a large public triplet dataset, with 9,262 triplets of 3D CT scans, shapes (organs & tumors), and radiology reports. First, we gathered 9,262 abdominal CTs from public sources (138 institutions, 19 countries). Most of them lacked shape annotations for many organs and tumors. Thus, our radiologists created shapes (contour) for tumors in the liver, kidney and pancreas in these public CTs. Organ shapes were created by AI and refined by radiologists. Then, a novel AI framework faithfully converted the shapes into reports, which the radiologists revised. The study involved 12 radiologists, and the dataset has reports and shapes for 929 liver, 344 pancreatic and 1,674 kidney tumor CTs. Reports can indicate organ enlargement, steatosis and tumor type, diameter, volume, location, vessel interaction and T stage.

RESULTS

Our AI-assisted framework allowed radiologists to annotate 9,262 CT scans in six months. With our dataset, we evaluated AI models for radiology report generation. We evaluated 5 state-of-the-art AI models (CT-Chat, CT2Rep, M3D, RadFM & Merlin)—trained with the CTs and reports—and our shape-based AI. The shape-based AI surpassed the 5 state-of-the-art models. On external validation, the shape-based AI reports had sensitivity and specificity of 76.9% and 76.6% for pancreatic tumors, 94.65% and 78.3% for kidney tumors, and 84.5% and 73.3% for liver tumors. The best not shape-based AI, CT-CHAT, had reports with sensitivity and specificity of 27.5% and 73.1% for pancreatic tumors, 27% and 74.6% for kidney tumors, and 4.7% and 94% for liver tumors.

CONCLUSION

Learning from shapes strongly improves AI performance in report generation. This highlights the importance of our triplet dataset, which has shapes and reports. Moreover, our dataset increases the number of annotated tumors in public datasets: in the public domain, these 9,262 CT scans had only 944 tumor shapes; now, we provide 2,947 tumor reports and shapes for them.

CLINICAL RELEVANCE/APPLICATION

The AI's ability to accurately detect and measure tumors enhances the precision and efficiency of radiological services, allowing healthcare professionals to focus on more complex cases. Our triplet dataset with CT, shapes and reports can help the community create AI models for diverse tasks, including tumor detection, contouring and staging.

S3A-SPIN-7 A UNIFIED MODEL FOR SYNTHETIC MULTIPLANAR REFORMATION OF MULTIPLE KNEE MRI SEQUENCES

Thomas C. Arnold, PhD (*Presenter*)
Long Wang (*Abstract Co-Author*)
Lawrence N. Tanenbaum, MD (*Abstract Co-Author*)
Ajit Shankaranarayanan (*Abstract Co-Author*)

PURPOSE

Knee MRI protocols typically consist of a limited number of 2D sequences acquired in multiple orientations (axial, sagittal, coronal) and sequence types (e.g., T1w, T2w, T2w fat-sat, PD, PD fat-sat), constrained by scan time. Previously, we demonstrated that deep learning can synthesize high-resolution multiplanar reformations (MPR), enabling more comprehensive exams or faster protocols. However, the diversity of sequence combinations across sites poses a challenge for generalizing such methods. To address this, we developed a unified deep learning model capable of synthesizing 2D sequences from various combinations of paired input images, leveraging complementary contrast and plane information.

METHODS AND MATERIALS

We retrospectively analyzed 245 knee MRI exams, yielding 708 possible synthesis sets (i.e., target image, sequence match, plane match) across 26 unique sequence/plane combinations. Forty-two sets from 26 subjects (spanning 9 combinations and 3 targets: Sag PD FS, Sag T2 FS, Cor PD FS) were held out for testing. The remaining data was used for training and validation with no subjects overlapping. A patch-based neural network was trained to synthesize target images using two input images (i.e. one sequence match, one plane match). Performance was assessed using peak signal-to-noise ratio (PSNR) and structural similarity index (SSIM) against ground truth images.

RESULTS

Synthesized images preserved tissue and pathology features and showed strong similarity to standard-of-care (SOC) images, outperforming basic 2D reformats. Across all combinations, the average PSNR was 24.8±3.0 dB and SSIM was 0.81±0.05. Among individual sequence targets, Sag T2 FS achieved the highest scores (PSNR: 27.2±3.1 dB, SSIM: 0.85±0.04), followed by Sag PD FS (PSNR: 24.4±2.8 dB, SSIM: 0.81±0.06) and Cor PD FS (PSNR: 23.3±1.9 dB, SSIM: 0.79±0.04).

CONCLUSION

We demonstrate that a single model can synthesize 2D knee MRI sequences across diverse protocol combinations, offering flexibility to match site-specific imaging protocols. The model showed strong quantitative performance across 9 input combinations for 3 different target sequences. Clinically, this enables a generalized image synthesis approach that supports existing protocol combinations, eliminating the need for sites to modify their protocols to fit algorithm input requirements.

CLINICAL RELEVANCE/APPLICATION

This study presents a deep learning model that can synthesize high-quality 2D knee MRI sequences from varied input combinations, enabling clinical sites to enhance or accelerate exams without altering their existing protocols. The approach supports flexible deployment across diverse imaging practices while maintaining diagnostic image quality.

S3A-SPIN-8 AI REGULATION IN HEALTHCARE AROUND THE WORLD: WHAT IS THE STATUS QUO?

Felix Busch, MD (*Presenter*)
Raym Geis, MD (*Abstract Co-Author*)
Cheng-Yuan Wang (*Abstract Co-Author*)
Jakob Nikolas Kather (*Abstract Co-Author*)

Marcus R. Makowski (*Abstract Co-Author*)
Daniel Truhn, MD (*Abstract Co-Author*)
Warren Clements (*Abstract Co-Author*)
Lisa C. Adams, MD, PhD (*Abstract Co-Author*)
Keno K. Bressem, MD (*Abstract Co-Author*)

PURPOSE

The rapid adoption of artificial intelligence (AI) in healthcare presents challenges related to ethics, safety, equity, and governance. In many jurisdictions, AI-driven medical devices are currently covered by existing medical device frameworks; however, novel AI-specific legislation may be required to address emerging complexities.

METHODS AND MATERIALS

We conducted an expert review focusing on frameworks and legislation explicitly tailored to AI as of December 2024. This review synthesized information from research literature, government and intergovernmental framework programs, and online media coverage to compile a global overview of AI-specific regulation or strategies in healthcare.

RESULTS

Among 197 countries or territories examined, 15.2% (n=30) had enacted legally binding AI-specific legislation, including the 27 member states of the European Union (EU) following the adoption of the EU AI Act. An additional 9.1% (n=18) had drafted legislation, and 28.4% (n=56) had issued non-binding guidelines. Notably, 47.2% (n=93) did not have any AI-specific framework or legislation in place. Disparities emerged between the Global North and South, with 60.3% (n=82/136) of Global South countries or territories lacking such frameworks or legislation, compared to 18% (n=11/61) in the Global North.

CONCLUSION

Despite some progress, nearly half of the countries or territories worldwide lack AI-specific regulation or strategies in healthcare. These findings highlight significant disparities in regulatory adoption and underscore the need for enhanced intergovernmental and regional cooperation to ensure equitable, effective governance of AI in healthcare.

CLINICAL RELEVANCE/APPLICATION

Addressing these regulatory gaps is critical for mitigating risks associated with AI in healthcare, particularly in regions with limited resources. Strengthened collaboration, harmonized standards, and forward-thinking policies will be essential to safeguard patient welfare and harness AI's transformative potential.

S3A-SPIN-9 MULTI-MODAL GUIDED CROSS-DOMAIN ADAPTATION FOR ESOPHAGEAL SQUAMOUS CELL CARCINOMA DETECTION ON NON-CONTRAST CT USING DEEP LEARNING

funing Chu (*Presenter*)
Jin Rong Qu, MD (*Abstract Co-Author*)
Binbin Han (*Abstract Co-Author*)
Zhaoqi Wang (*Abstract Co-Author*)
Bingmei Bai (*Abstract Co-Author*)

PURPOSE

To develop and validate a deep learning framework using multi-modal guidance (contrast-enhanced CT [CECT], MRI) and cross-domain adaptation to improve Esophageal Squamous Cell Carcinoma (ESCC) detection on non-contrast CT (NCCT), overcoming absent contrast and domain shift issues.

METHODS AND MATERIALS

This retrospective single-center (2018-2023) IRB-approved study included 480 ESCC patients with co-registered NCCT, CECT, and MRI acquired within 14 days. Data underwent normalization and expert segmentation. A multi-modal guided cross-domain adaptation framework was built: 1) A dual-encoder teacher network (using 3D ResNet-34/Inception-DenseNet) was pretrained on CECT/MRI. 2) CycleGAN adapted CECT features to the NCCT domain unsupervisedly. 3) A lightweight nnU-Net student network, enhanced with anatomical priors and consistency regularization, was trained specifically for NCCT detection via knowledge distillation using NCCT labels and teacher pseudo-labels. The dataset was split into training (n=336), validation (n=48), and independent test (n=96) sets. Performance metrics (Dice, 95th percentile Hausdorff distance [HD95], sensitivity, false positives/scan [FP/scan]) were compared against baseline models (NCCT-only U-Net, direct fusion, Mean Teacher semi-supervised) using paired Wilcoxon tests (Bonferroni corrected $p<0.05$). Radiologist agreement was assessed (Cohen's ?).

RESULTS

On the independent test set (n=96), the proposed framework significantly outperformed baselines. It achieved a mean Dice of 0.79 (±0.11 SD), compared to 0.66 (±0.14) for NCCT-only U-Net ($p<0.001$), 0.70 (±0.13) for direct fusion ($p<0.001$), and 0.72 (±0.12) for Mean Teacher ($p<0.001$). The framework showed superior boundary accuracy (mean HD95: 5.8 mm vs 10.3 mm for NCCT-only, $p<0.001$) and higher sensitivity (86% vs 74% for NCCT-only, $p=0.002$) at a comparable false positive rate (mean 1.7 vs 2.0 FP/scan for NCCT-only, $p=0.18$). Good agreement with radiologists was observed (mean ? = 0.76).

CONCLUSION

Leveraging CECT/MRI knowledge via dedicated cross-domain adaptation and anatomical priors significantly enhances deep learning performance for ESCC detection on NCCT, surpassing models trained solely on NCCT or using simpler fusion/semi-supervised techniques.

CLINICAL RELEVANCE/APPLICATION

This AI framework improves the diagnostic utility of accessible NCCT for ESCC detection, potentially facilitating earlier diagnosis, enabling better screening, and reducing the need for contrast or resource-intensive imaging in specific clinical situations.

S3A-SPIN-10 LOCAL RADIOMICS PROBABILITY MAPS AND AUTOMATED PATIENT CLASSIFICATION FOR EARLY DETECTION OF PANCREATIC DUCTAL ADENOCARCINOMA

Florent Tixier, PhD (*Presenter*)
Emir Syailendra, MD (*Abstract Co-Author*)
Felipe Lopez-Ramirez, MD (*Abstract Co-Author*)
Alejandra Blanco (*Abstract Co-Author*)
Mohammad Yasrab (*Abstract Co-Author*)
Hajra Arshad, MD (*Abstract Co-Author*)
Zahra Rahmatullah, MD (*Abstract Co-Author*)
Linda C. Chu, MD (*Abstract Co-Author*)
Satomi Kawamoto, MD (*Abstract Co-Author*)
Elliot K. Fishman, MD (*Abstract Co-Author*)

PURPOSE

To develop and evaluate a local radiomics approach that generates voxel-wise probability maps of pancreatic ductal adenocarcinoma (PDAC) and automatically classifies patients, with the goal of improving early detection and providing decision support for radiologists.

METHODS AND MATERIALS

We retrospectively enrolled 850 patients with histologically confirmed PDAC (IQR: 2.99-5.31 cm) and 711 control subjects who underwent contrast-enhanced abdominal CT in the venous phase. Manual segmentations of the pancreas were used to generate over 60,000 volumetric patches (1000 voxels or 1 cm^3 each), from which first-order and texture radiomics features were extracted. Patches were randomly divided into training (80%) and testing (20%) sets using stratified sampling to preserve the PDAC-to-normal class ratio. A random forest classifier was trained to distinguish PDAC from normal pancreas patches and then applied across the entire segmented volume to generate voxel-wise probability maps, computing each voxel's probability as the mean of the probabilities assigned to all patches containing that voxel. Patient-level classification was defined by the presence of at least one contiguous cluster of voxels exceeding a probability threshold and corresponding to a volume = 1 cm^3.

RESULTS

On the test set, the patch-level classifier achieved 96.6% accuracy. Patient-level predictions yielded a ROC-AUC of 0.97. Using the optimal probability threshold for detecting =1 cm^3 clusters, the model correctly classified 286 (91.4%) of the 313 patients in the testing set, with a sensitivity of 0.92, and a specificity of 0.90. Voxel-wise probability maps were generated, with high-probability regions aligning with the segmented pancreatic volume, facilitating visual reclassification of PDAC cases missed by the patient-level model.

CONCLUSION

This local radiomics approach improves predictive accuracy for early PDAC detection and generates voxel-wise probability maps highlighting tumor location.

CLINICAL RELEVANCE/APPLICATION

This model not only outperforms conventional radiomics approaches but also generates voxel-wise probability maps that can be overlaid on the original CT images to localize regions of high PDAC probability, adding spatial information typically absent from radiomics models. This approach enhances radiologists' confidence in the predictive model and accelerates accurate diagnosis in patients suspected of PDAC.

S3A-SPIN-11 ORIENTATION-CONSISTENT PATCH SAMPLING METHOD BASED ON CENTERLINE FOR COLON SEGMENTATION IN CT

Ze Jin, PhD (*Presenter*)
Yanhong He (*Abstract Co-Author*)
Yafei Ou (*Abstract Co-Author*)
Pengyu Dai (*Abstract Co-Author*)
Yuqiao Yang, MS (*Abstract Co-Author*)
Kenji Suzuki, PhD (*Abstract Co-Author*)

PURPOSE

Patch-based deep learning methods have become highly effective for segmentation tasks. However, the anisotropic shapes and varying orientations of the colon introduce patch inconsistencies among patches, which slow down model learning and limit segmentation accuracy. We developed an orientation-consistent patch sampling method that mitigates this issue by sampling patches from a straightened volume generated via curved planar reformation (CPR) along the centerline of the colon in the CT volume. By sampling from straightened volumes, anatomical variations among patches are reduced, thereby enhancing model learning ability and segmentation performance.

METHODS AND MATERIALS

We used the WORD dataset for colon segmentation, which includes 68 cases without severe adhesion. All scans were acquired without appearance enhancement, with each volume comprising 159-330 slices at an in-plane resolution of 0.976 mm and a slice thickness of 2.5-3.0 mm. For each volume, the colon centerline was extracted to guide the curved planar reformation (CPR), processing into a straightened volume. Orientation-consistent (OC) patches were then sampled from the straightened volume with less anatomical and orientation variability. These OC patches were used for model training, validation, and inference. After inference, segmentation results were mapped back to the original volume space for metric computation and visualization to ensure clinical usability.

RESULTS

We evaluated our proposed orientation-consistent patch sampling method on three widely adopted segmentation models: SegResNet, Swin-UNETR, and UNETR. Significant improvements ($P < 0.05$) were consistently observed across all models, with average Dice scores increase of 2.07%, 6.35%, and 9.31% on SegResNet, Swim-UNERT, UNETR, respectively.

CONCLUSION

We developed an orientation-consistent patch sampling method for colon segmentation to address patch inconsistency caused by variations in colon orientation. The proposed method improved segmentation accuracy across three major segmentation models, offering an effective and generalizable solution for colon related tasks.

CLINICAL RELEVANCE/APPLICATION

While CPR is widely used clinically for stent planning and plaque measurement, our study introduced CPR into the pre-processing pipeline, enabling anatomically consistent patch sampling and thereby improving colon segmentation accuracy.

S3A-SPIN-12 ANNOTATION-EFFICIENT SEMI-SUPERVISED DEEP LEARNING SEGMENTATION OF FETAL LUNGS AND LIVER IN MRI

Leo Joskowicz, PhD (*Presenter*)
Aaron Olender (*Abstract Co-Author*)
Aviad Rabinowich (*Abstract Co-Author*)
Jayan Khawaja, MD (*Abstract Co-Author*)
Dafna Ben Bashat, PhD (*Abstract Co-Author*)

PURPOSE

Volumetric evaluation of the fetal lungs and liver in MRI holds potential for diagnosing various fetal conditions, e.g. pulmonary hypoplasia, congenital diaphragmatic hernia, and liver-related anomalies. However, manual annotation is impractical and automatic deep learning methods required high-quality annotated data for training, which requires expertise and is resource and time intensive. Our aim was to evaluate the performance of a new annotation-efficient semi-supervised deep learning method for accurate segmentation of the fetal lungs and liver using MRI.

METHODS AND MATERIALS

We retrospectively collected 1,085 participants who underwent fetal whole-body TruFISP MRI scanning at 30-38 weeks' gestation. We used the semi-supervised Uncertainty-guided Collaborative Mean-Teacher framework to automatically segment the fetal lungs and liver with reduced radiologists' annotation burden. It uses a multi-class 3D V-Net architecture in which a teacher network generates pseudo-labels used to train two student networks. Cross pseudo supervision was used to regularize the student networks and uncertainty-guided region mix was used for augmentation.The network was initially trained on 80 scans with manual annotations combined with 920 unlabeled scans in a semi-supervised approach. For validation, an expert reviewed and corrected the network's segmentations on the remaining 85 scans. The final model was trained using expert-validated segmentations along with 1,000 unlabeled scans, with the dataset split into 45/5/30% scans for training/validation/testing respectively. Two experts independently annotated 10 additional scans to quantify interobserver variability. Segmentation accuracy was evaluated using both the Dice score and the Average Symmetric Surface Distance (ASSD).

RESULTS

The mean inter-observer variability for the fetal lungs and fetal liver yielded a Dice of 0.86±0.02 and 0.86±0.04, and ASSD of 1.0±0.3 mm and 1.5±0.4 mm, respectively. The automatic segmentation on the test set for the fetal lungs and fetal liver yielded a Dice of 0.96±0.02 and 0.91±0.07, and ASSD of 0.3±0.2 mm and 1.3±1.0 mm, respectively.

CONCLUSION

Training an automatic segmentation using a semi-supervised model surpasses the inter-observer variability while substantially reducing the annotator time and effort. Results are demonstrated on the fetal lungs and liver. The method may be applicable to other structures.

CLINICAL RELEVANCE/APPLICATION

The method may speed up the development and deployment of deep learning models for the automatic detection and segmentation of fetal structures in MRI.

S3A-SPIR-1 QUANTITATIVE THREE-DIMENSIONAL (3D) ASSESSMENT OF THE DISTRIBUTION OF ABLATIVE MARGIN IN HEPATOCELLULAR CARCINOMA AS A PREDICTOR OF COMPLETE PATHOLOGIC NECROSIS

Mahmoud Odeh, MD (*Presenter*)
Adeel R. Seyal, MD,MBBS (*Abstract Co-Author*)
Muneeb Ahmed, MD (*Abstract Co-Author*)
Ammar Sarwar, MD (*Abstract Co-Author*)

PURPOSE

To compare quantitative 2D and 3D ablation margin assessment models in their predictive ability for complete pathologic necrosis (CPN) after percutaneous thermal ablation of hepatocellular carcinoma (HCC).

METHODS AND MATERIALS

This single-center retrospective HIPAA compliant study was approved by IRB. 128 tumors in 101 patients treated with percutaneous thermal ablation that subsequently underwent liver transplantation were evaluated. All target HCC lesions on the contrast-enhanced pretreatment imaging (CT or MRI) and ablation zones on the intraprocedural post-ablation contrast-enhanced CT were segmented and registered using 3D software (MIM - Columbus, OH). The 3D distribution of ablation margin was quantified by computing the exact tumor to ablation surface Euclidean distances. Conventional side-by-side 2D assessment of the ablation margin was also performed. Multivariable logistic regression analysis with generalized estimating equations was used to create 2D and 3D models to predict CPN. The discriminating power and optimal cutoff values for predicting CPN were calculated using receiver operatic characteristic (ROC) analysis.

RESULTS

CPN was reported in 85 out of 128 tumors (66%). A baseline multivariable logistic regression model that included patient and tumor characteristics yielded tumor diameter as the only significant variable associated with CPN [OR = 0.44 (95%CI: 0.25,0.79), p = 0.006]. Adding 2D ablation margin assessment to the baseline model resulted in a slight improvement in the discriminating power [AUC (95% CI), 2D model: 0.69 (0.59, 0.8) vs. baseline: 0.68 (0.57, 0.78)]. ROC analysis yielded optimal 3D quantitative ablation margin of = 1 mm with an optimal threshold of = 66% of the tumor surface (AUC = 0.64). Addition of optimal 3D quantitative ablation margin to the baseline model yielded 3D model as superior to 2D model [AUC: 0.72 (95%CI: 0.63, 0.82); p < 0.001] in predicting CPN.

CONCLUSION

3D ablation margin of = 1 mm with at least 66% tumor surface coverage is the strongest predictor for CPN after percutaneous thermal ablation of HCC.

CLINICAL RELEVANCE/APPLICATION

3D ablation margin quantification suggests that the entire 3D circumference of the tumor does not require 5 mm margins in order to predict complete pathologic response.

S3A-SPIR-2 MR GUIDED CATHETER-BASED INTERSTITIAL BRACHYTHERAPY OF LIVER TUMOURS - INTRAPROCEDURAL IMAGE QUALITY AND LOCAL RECURRENCE RATES

Matthias P. Fabritius, MD (*Presenter*)
Max Seidensticker (*Abstract Co-Author*)
Olaf Dietrich, PhD (*Abstract Co-Author*)
Jens Ricke, MD, PhD (*Abstract Co-Author*)
Daniel Puhr-Westerheide, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the intraprocedural image quality and early local recurrence rates following MR-guided catheter-based high-dose-rate interstitial brachytherapy (HDR-BT) of primary and secondary liver tumours.

METHODS AND MATERIALS

In this subanalysis of a prospective single-center study (MR BRIGHT trial), 31 patients with a total of 48 liver lesions were analysed. All patients were treated between June 2023 and April 2024 using MR-guided catheter-based HDR-BT with IR192 due to primary or oligometastatic secondary liver cancer. All procedures were performed under conscious sedation using a 1.5T MRI system (Magnetom Solafit, Siemens Healthineers) with a 15 cm loop coil and real-time gradient-echo sequences (TE 3.4 ms, TR 7.3 ms, FA 30°) for needle navigation. Gadoxetic acid was administered intravenously for lesion visualization. After coaxial needle placement, brachytherapy catheters were inserted via a 6F sheath. 3D T1-weighted sequences were acquired and sent to the treatment planning system in the radiation department for BT with a IR192 HDR afterloading unit. and 3D T1-weighted datasets were transferred for treatment planning. Tumor coverage and catheter position were evaluated based on image quality during the procedure. Follow-up imaging was performed at 1, 3, 6, and 12 months to assess local control. Intraprocedural image quality was evaluated using a 5-point Likert scale (1 = no visibility of the lesion, 5 = excellent visibility during the procedure). MR-guided procedures were compared to a propensity score-matched cohort of patients who underwent CT-guided brachytherapy.

RESULTS

Local control rate was 97.9 % after 12 months. The analysis of the intraprocedural image quality revealed a significantly superior lesion visibility in the MR-guided group, with a median Likert score of 5 compared to 1 in the CT-guided group (p < 0.001).

CONCLUSION

MR-guided catheter-based interstitial HDR brachytherapy of liver tumours provides excellent intraprocedural lesion visibility and enables precise catheter placement, resulting in a high local control rate at 12 months.

CLINICAL RELEVANCE/APPLICATION

The superior image quality of MRI during HDR brachytherapy procedures supports its use as a highly effective guidance modality for local tumour control in primary and secondary liver cancer, particularly when accurate lesion targeting is critical

S3A-SPIR-3 ULTRASOUND-GUIDED THERMAL ABLATION VERSUS SURGICAL RESECTION OF T10N0M0 PAPILLARY THYROID CARCINOMA: A META-ANALYSIS

Karabo Marole, MD (*Presenter*)

PURPOSE

To compare and contrast the efficacy of ultrasound-guided thermal ablation with surgical resection in treatment of T1N0M0 papillary thyroid carinoma

METHODS AND MATERIALS

We performed a comprehensive literature search in PubMed, Embase, and Scopus for studies comparing thermal ablation (TA) and surgical resection (SR) in patients with T1N0M0 papillary thyroid carinoma (PTC). Data was extracted from published journal articles, and quality assessment was performed per Cochrane recommendations. Odds ratios (ODs) with 95% CI were pooled across studies with dichotomous outcomes, and mean differences were used for continuous outcomes. We assessed the heterogeneity using the I^2 statistics. The primary outcomes of interest were disease progression, recurrence, complication rates, and health-related quality of life. The study was registered on PROSPERO under the identifier CRD42024546144.

RESULTS

This study incorporates findings from twelve retrospective cohort studies and included 3767 patients. Patients who underwent thermal ablation (TA) showed a similar risk of disease progression (OR 1.10; 95% CI 0.70 -1.72; p = 0.69) and disease recurrence (OR 1.61; 95% CI 0.85 -3.04; p = 0.15) to surgical resection (SR). Additionally, the risk of lymph node metastasis was reduced in the TA group (OR 0.43; 95% CI 0.22 -0.88; p <0.05). The complication rates were significantly lower in the TA group than in the SR group (OR 0.33; 95% CI 0.25 -0.44; p <0.05). Health-related quality of life was assessed using THYCA-QoL scores, which showed an overall pooled standard mean difference of -0.09 (95% CI: -0.24 -0.06; p =0.25).

CONCLUSION

Thermal ablation represents a minimally invasive alternative to surgical resection. Here, we show that TA is comparable to SR in terms of disease progression, recurrence, lymph node metastasis, and quality of life assessed with THYCA-QoL in low-risk PTC. Furthermore, TA has a reduced risk of complications compared to SR.

CLINICAL RELEVANCE/APPLICATION

Surgical resection of low-risk T1N0M0 papillary thyroid carcinoma remains a common practice despite the American Thyroid Association guidelines recommending active surveillance. However, patient factors such as anxiety often encourage patients with T1N0M0 PTC to seek more invasive surgery such as lobectomy and thyroidectomy. Here, TA represents a robust and minimally invasive alternative to surgery in the management of T1N0M0 papillary thyroid cancer.

S3A-SPIR-4 A NATIONWIDE TARGET TRIAL EMULATION ON THE TREATMENT OF PATIENTS WITH HCC AND MAIN TRUNK PVTT USING ^{125}I IRRADIATION STENTS AND COMBINED THERAPEUTIC APPROACHES (PATENCY II)

Junhao Mei (*Presenter*)
Kaizhi Jia (*Abstract Co-Author*)
Jian Lu (*Abstract Co-Author*)
Gaojun Teng (*Abstract Co-Author*)

PURPOSE

This study aimed to evaluate the safety and efficacy of combining transcatheter arterial chemoembolization (TACE) following irradiation stent placement (ISP) combined with immune checkpoint inhibitors (ICIs) plus targeted therapy (TT), compared to ICIs plus TT alone in patients with hepatocellular carcinoma (HCC) and Vp4 portal vein tumor thrombosis (PVTT).

METHODS AND MATERIALS

Retrospective cohort study with target trial emulation (TTE) framework was conducted across thirty-one centers in China. All patients with HCC and Vp4 PVTT who underwent either ISP-TACE or ICIs-TT between January 2020 and May 2023 were screened. The clone-censor-weighting (CCW) approach was utilized as the primary analysis, while overlap propensity score weighting, multi-regional cluster propensity score matching, landmark analyses, traditional Cox proportional-hazards model and traditional propensity score matching were served as sensitivity analyses to enhance the robustness of our findings. E-values were calculated across all sensitivity analyses to evaluate the influence of unobserved confounders on the treatment-outcome association. The primary endpoint was overall survival (OS), with secondary endpoints including progression-free survival (PFS) and safety.

RESULTS

Among the 444 participants (The mean (SD) age was 57.0 (10.8) years, 396 (89.2%) were male), 131 patients were enrolled in the ISP-TACE group and 313 in the ICIs-TT group. Using CCW methodology for emulated target trial analyses revealed superior survival outcomes in the ISP-TACE cohort: median OS extended to 356 days (95% CI 309-420) versus 258 days (ICIs-TT group, 95% CI 235-287), demonstrating a 35% risk reduction (HR 0.65, 0.52-0.81; log-rank P<0.0001). PFS assessments showed consistent advantages through dual criteria - 150 vs. 96 days by RECIST 1.1 (HR 0.71, 0.59-0.87; log-rank P=0.0075) and 144 vs. 93 days by mRECIST (HR 0.74, 0.61-0.90; log-rank P=0.0030). Sensitivity analyses confirmed the robustness of these primary findings. Grade =3 treatment-related adverse events were reported in 42.0% (55/131) of the ISP-TACE group participants, compared to 33.5% (105/313) in the ICIs-TT cohort (P = 0.091).

CONCLUSION

The findings of this cohort study indicate that TACE following ISP, in combination with ICIs and TT, presents a promising and well-tolerated therapeutic strategy for patients with HCC and Vp4 PVTT.

CLINICAL RELEVANCE/APPLICATION

This study presents an innovative treatment protocol for HCC patients suffering from Vp4 PVTT. The irradiation stent placement significantly enhances liver functionality and markedly prolongs patient survival. Furthermore, the therapy maintains a manageable safety profile.

S3A-SPIR-5 TEN-YEAR OUTCOMES AFTER PARTIAL NEPHRECTOMY, HEAT-BASED ABLATION, AND CRYOABLATION OF RENAL CANCER: RETROSPECTIVE COHORT STUDY OF OVER 10,000 PATIENTS

Madison Stamper, BS (*Presenter*)
Jennifer Collins (*Abstract Co-Author*)
Ronald S. Arellano, MD (*Abstract Co-Author*)
Frank Annie (*Abstract Co-Author*)
Samuel Deem (*Abstract Co-Author*)

Matthew Desanto (*Abstract Co-Author*)
Amy R. Deipolyi, MD, PhD (*Abstract Co-Author*)

PURPOSE

To compare peri-procedural outcomes and 10-year survival, metastasis risk, and reintervention rates in patients undergoing partial nephrectomy versus image-guided ablation (cryoablation and heat-based ablation) for renal cell carcinoma (RCC).

METHODS AND MATERIALS

This IRB-approved, retrospective cohort study utilized TriNetX, a multi-institutional database of deidentified electronic health records. Adult patients with RCC who underwent partial nephrectomy, cryoablation, or heat-based thermal ablation between 2004 and 2025 were identified. Exclusion criteria included prior renal procedures, malignancies, and degenerative diseases. Propensity score matching (PSM) balanced cohorts for age, comorbidities, renal function, and BMI. Outcomes assessed peri-procedural complications, ICU admission, transfusion, hospital length of stay, reintervention, long-term survival and treatment for metastatic disease. Statistical analyses included Kaplan-Meier survival curves and chi-square tests for categorical variables.

RESULTS

The cohort included 9,374 partial nephrectomy, 2,169 cryoablation, and 1,003 heat-based ablation patients. After PSM, partial nephrectomy was associated with longer hospital stays (1.2 vs. 0.4 days for cryoablation and 0.3 days for heat-based ablation; $p<0.01$), increased intensive care unit admissions (4.0% vs. 1.4% and 1.0%; $p<0.01$), and higher blood transfusion rates (4.3% vs. 1.4% and 0.9%; $p<0.01$). Ablation was associated with increased reintervention rates at 10 years (cryoablation: 13.0%; heat-based ablation: 9.6%) compared to partial nephrectomy (1.3%; $p<0.01$). Ten-year survival rates were similar across groups (partial nephrectomy: 89.4%, cryoablation: 89.2%, heat-based ablation: 87.8%; $p>0.05$).

CONCLUSION

Partial nephrectomy and image-guided ablation demonstrated comparable 10-year survival and metastasis rates for RCC. Image-guided ablation confers lower procedural morbidity but higher reintervention rates. Findings support patient-specific treatment selection considering comorbidities and procedural risks.

CLINICAL RELEVANCE/APPLICATION

This analysis provides comparative data relevant to the evolving management of RCC by analyzing matched controls to assess procedural outcomes. Using this method allows for deeper understanding of therapy alternatives suitable in the clinic setting. While the current gold standard, partial nephrectomy, was found to have lower 10-year reintervention rates, ablation resulted in fewer peri-procedural complications. Despite higher reintervention rates, ablation achieved comparable 10-year survival. These findings reinforce the importance of individualized treatments to achieve optimal outcomes.

S3A-SPIR-6 RADIOFREQUENCY ABLATION FOR PATIENTS WITH PRIMARY HYPERPARATHYROIDISM: A MULTICENTER, NON-RANDOMIZED, OPEN-LABEL, SINGLE-ARM PROSPECTIVE CLINICAL TRIAL

Eun Ju Ha, MD (*Presenter*)

PURPOSE

To evaluate the efficacy, safety, and factors influencing the response to radiofrequency ablation (RFA) in patients with primary hyperparathyroidism (PHPT) in a prospective multicenter trial.

METHODS AND MATERIALS

Between September 2022 and June 2024, 34 patients with 35 parathyroid lesions who either refused surgery or were ineligible for it underwent RFA for treatment of PHPT across three hospitals. Nodule size, volume, and biochemical data were compared before and after treatment (at 2 hours, 1 week, and 1, 3, 6, and 12 months). Complications were assessed during and after treatment. Factors influencing the treatment response to RFA for PHPT were analyzed.

RESULTS

Significant reductions in nodule size and volume, as well as improvements in serum parathyroid hormone (PTH) and total calcium levels, were noted at the 3-, 6-, and 12-month follow-ups after RFA (all $p < 0.05$). Out of the 34 patients, 17 experienced a complete response with normalized serum PTH and calcium levels (50.0%), whereas 17 showed a partial response (50.0%) (median number of sessions 1). The initial serum PTH level was a key factor associated with the treatment response to RFA, with an area under the receiver operating characteristic curve of 0.853 using a PTH cutoff value of = 118 pg/mL. Transient voice change (n=1) and hypocalcemia (n=1) were reported after the procedure.

CONCLUSION

In selected cases, RFA is a safe and effective treatment option for patients with PHPT. The initial PTH level of < 118 pg/mL is associated with achieving a biochemical cure after a single treatment.

CLINICAL RELEVANCE/APPLICATION

1. RFA has been proposed as a treatment option for patients with PHPT who refuse or are ineligible for surgery, but limited evidence requires further investigation. 2. In this prospective multicenter study, the complete response rate was 50.0%, with 79.4% showing normocalcemic changes. Baseline serum PTH level influenced treatment response.

S3A-SPMK-1 PROXIMAL HUMERUS FRACTURES IN CHILDREN: DISTRIBUTION AND PREDICTORS OF SURGERY

Julian Forero, MD (*Presenter*)
Vandan Patel, BS (*Abstract Co-Author*)
Jie C. Nguyen, MD, MS (*Abstract Co-Author*)
Samuel S. Hailu, MD (*Abstract Co-Author*)
Lewis Fanney (*Abstract Co-Author*)

PURPOSE

Proximal humerus fractures (PHFs) account for about 2% of all pediatric fractures, most commonly affecting children aged 10-14, typically due to falls onto an extended, externally rotated arm. While most PHFs in children are managed nonoperatively, indications for surgical management remain debated. Thus, the purpose of this study was to characterize clinical and radiographic findings of pediatric PHFs to identify findings that are associated with surgical management.

METHODS AND MATERIALS

This IRB-approved retrospective study included children (=18 years) with radiographically confirmed PHFs, who were treated at our tertiary care children's hospital (2014-2024). Age, sex, BMI percentile, mechanism of injury, and treatment were collected. Radiographs were reviewed to collect information on skeletal maturity, physeal involvement, fracture angulation, and displacement. Demographic and imaging findings were compared between surgical and non-surgical groups using t-tests, Mann-Whitney U, and Kruskal-Wallis tests. Logistic regression models were used to identify predictors of surgery.

RESULTS

418 patients (mean age 10.5 ±7.2 years; 47% male; 350, 83.7% skeletally immature) were included. Injuries from falls were more common among younger and sports injuries among older children (8.8 vs. 12.5 years, $p<0.01$). Physeal involvement occurred in 13.4% (47/350); Salter-Harris II was the most common (85.1%, 40/47). 10.1% (42/418) underwent surgery, more likely among fractures with greater angulation (<10°: 3.0%, >70°: 50%) and displacement (0% for nondisplaced, 61.8% for 100% translation). =40° angulation, >100% translation, physeal involvement, male sex, and increasing age significantly associated with surgery. In multivariate analysis, only =40° angulation (OR 6.51; $p<0.001$), >100% translation (OR 14.01; $p<0.001$), and age (OR 1.09; $p=0.027$) were independent predictors, while falls remained protective (OR 0.20; $p=0.004$).

CONCLUSION

Angulation (=40°), translation (>100%), and age (but not physeal involvement) were independent predictors of surgery. Key clinical and imaging findings identified in this study may assist in guiding treatment decisions and prioritizing early surgical consultation for high-risk pediatric patients.

CLINICAL RELEVANCE/APPLICATION

Most pediatric proximal humerus fractures are treated nonoperatively, but certain features warrant surgical consideration. This study identifies age, =40° angulation, and >100% translation as independent predictors of surgery. Recognizing these factors early can guide decisions and prioritize surgical consultation for high-risk patients.

S3A-SPMK-3 EVALUATION OF VERTEBRAL TRABECULAR STRUCTURE USING A 24-SOURCE STATIONARY CT SYSTEM: EX VIVO AND IN VIVO FINDINGS

Mu Lin, PhD (*Presenter*)

PURPOSE

Deterioration of vertebral trabecular microstructure is a critical factor contributing to spinal fracture. Accurate visualization and quantification of trabecular microstructure are essential for assessing bone strength and fracture risk. This study aimed to (1) evaluate the accuracy of a high-resolution stationary CT prototype for assessing vertebral trabecular microstructure on vertebral specimen using micro-CT as a reference and (2) assess its feasibility for in vivo application.

METHODS AND MATERIALS

The stationary CT prototype features a dual-ring architecture with 24 X-ray sources and 64 detector modules, providing a bore size of 83 cm, a 50-cm FOV, and an isotropic voxel size of 165 μm. For ex-vivo validation, 20 dried human vertebral specimens were scanned using both the stationary CT and micro-CT (18-μm resolution). For each specimen, images from the two systems were spatially registered, and ROIs defined on micro-CT was then mapped to stationary CT image. Trabecular bone within each ROI was segmented using adaptive thresholding. Microstructural parameters, including bone volume fraction (BV/TV), trabecular thickness (Tb.Th), trabecular separation (Tb.Sp), and trabecular number (Tb.N), were extracted using custom Python script. Spearman correlations were calculated to evaluate agreement with micro-CT. For in-vivo feasibility, lumbar spine scans were acquired from 20 patients using the stationary CT system (3072×3072 matrix, 0.165-mm slice thickness, 120 kVp, 100 mAs). Parameters were calculated and compared between two age groups (<50 vs. =50 years) using Mann-Whitney U tests. A significance level of $p < 0.01$ was applied.

RESULTS

For ex-vivo validation, the stationary CT demonstrated strong correlations with micro-CT across all trabecular parameters (Spearman's $r = 0.8$). BV/TV and Tb.Th were slightly overestimated, while Tb.N was underestimated. This could be explained by partial volume effects, where thin trabeculae may be missed and adjacent trabeculae appear merged. In vivo, age-stratified analysis revealed significant trabecular deterioration in the older group ($p<0.001$): participants =50 years had lower BV/TV (19.3% vs. 21.1%), reduced Tb.Th (0.32 mm vs. 0.35 mm), decreased Tb.N (1.05/mm vs. 1.16/mm), and increased Tb.Sp (0.78 mm vs. 0.71 mm), compared to those <50 years.

CONCLUSION

The stationary CT prototype provides accurate ex-vivo quantification of vertebral trabecular microarchitecture and demonstrates feasibility in detecting age-related trabecular microstructure changes in human spine.

CLINICAL RELEVANCE/APPLICATION

By enabling in-vivo assessment of vertebral trabecular microstructure, the stationary CT system may support early detection of osteoporosis and improved prediction of fracture risk.

S3A-SPMK-4 FLAT BONE FIBROUS DYSPLASIA: CORTICAL DISCONTINUITY—RED FLAG OR BENIGN FINDING?

Samia Sayyid (*Presenter*)
Leen Alkukhun, MD (*Abstract Co-Author*)
Hakan Ilaslan, MD (*Abstract Co-Author*)

PURPOSE

To assess the imaging characteristics of pathology-proven fibrous dysplasia (FD) in flat bones and compare them to long bones, with a specific focus on the prevalence of cortical discontinuity—a feature that may raise concern for malignant transformation or low-grade central osteosarcoma.

METHODS AND MATERIALS

Following IRB approval, a musculoskeletal radiologist and a musculoskeletal radiology fellow reviewed the imaging of pathology-confirmed fibrous dysplasia (FD) cases in flat bones over the past 20 years. Imaging modalities analyzed included radiographs, computed tomography (CT), magnetic resonance imaging (MRI), and bone scintigraphy. Lesions were assessed in the sternum, ribs, scapula, clavicle, pelvic girdle, and vertebral bodies, incorporating both monostotic and polyostotic cases. Craniofacial FD cases were excluded due to their distinct radiologic and clinical features. A total of 100 biopsy-proven FD cases were reviewed, evenly distributed between flat and long bones (50 cases each). For each case, anatomical location, lesion size, presence of cortical discontinuity, and presence of an associated soft tissue component were systematically documented.

RESULTS

Fibrous dysplasia (FD) in flat bones exhibited a higher incidence of cortical interruption compared to long bones, though without an associated soft tissue mass. Furthermore, lesions exceeding 5 cm demonstrated a greater likelihood of cortical disruption, with larger lesions more frequently presenting cortical irregularities.

CONCLUSION

Fibrous dysplasia (FD) in flat bones more commonly exhibits cortical discontinuities compared to long bones, especially in larger lesions. These findings may mimic aggressive pathology or suggest malignant transformation. Recognizing these imaging characteristics is crucial to prevent misdiagnosis and ensure appropriate clinical management.

CLINICAL RELEVANCE/APPLICATION

Fibrous dysplasia in flat bones can sometimes have features that may be confused as aggressive and may alter management accordingly.

S3A-SPMK-5 DEEP-LEARNING DERIVED OPPORTUNISTIC MEASURES OF PARASPINAL MUSCLE COMPOSITION PREDICTS THORACIC VERTEBRAL BONE LOSS USING NONCONTRAST CHEST CT: THE MULTI-ETHNIC STUDY OF ATHEROSCLEROSIS

Quincy A. Hathaway, MD, PhD (*Presenter*)
Elena Ghotbi, MD (*Abstract Co-Author*)
Tommy Pan, MD, BA (*Abstract Co-Author*)
Sara Momtazmanesh, MD (*Abstract Co-Author*)
Eduardo J. Mortani Barbosa JR, MD, MBA (*Abstract Co-Author*)
Graham Barr, MD (*Abstract Co-Author*)
David A. Bluemke, MD, PhD (*Abstract Co-Author*)
Joao A. Lima, MD (*Abstract Co-Author*)
Wendy Post (*Abstract Co-Author*)
Matthew J. Budoff, MD (*Abstract Co-Author*)
Shadpour Demehri, MD (*Abstract Co-Author*)

PURPOSE

Paraspinal muscle quality and strength is the main contributor for biomechanical load on thoracic vertebrae. However, the potential impact of paraspinal muscle composition (e.g., myosteatosis and volume) on subsequent bone loss has not been investigated. We evaluated noncontrast chest CT as an opportunistic imaging technique to assess paraspinal muscle composition biomarkers as a potential modifiable risk factor for subsequent vertebral bone loss.

METHODS AND MATERIALS

A secondary analysis of the Multi-Ethnic Study of Atherosclerosis (MESA) included 1316 participants at Exam 5 and follow-up Exam 6 (median follow-up 6.2 years). Deep learning (DL) 3D segmentation of paraspinal musculature at the T1-T10 levels was performed with TotalSegmentator v2. Participants were excluded for incomplete or missing demographic information (n = 62), and/or missing DL segmentation (n = 53). Manual segmentation (n=50 participants) was performed with Dice scores calculated. Paraspinal-derived data (including size and composition metrics) was used to predict bone loss, assigning binary classifications to participants with values =1 st quartile (i.e., "1") and >1 st quartile (i.e., "0"). Additionally, paraspinal size and composition were used to predict incident vertebral fractures at Exam 6.

RESULTS

DL-derived 3D segmentations were correlated with manual segmentations (Dice score: 0.94 [0.91-0.97]). Participants with low paraspinal muscle attenuation (HU: 1.1 [0.0-2.1], =1 st quartile) were older (70.0 yrs. [69.1-71.0] vs. 66.3 yrs. [65.7-66.8]) and more likely to be Caucasian (47% vs. 31%) and female (61% vs. 50%). Bone loss was correlated with low paraspinal muscle attenuation (176 mg/cm 3 [173-180] vs. 204 mg/cm 3 [202-207], P=0.001) and decreased paraspinal muscle volume (181 mg/cm 3 [177-184] vs. 203 mg/cm 3 [200-205], P=0.001). Paraspinal muscle attenuation combined with clinical features (i.e., Fracture Risk Assessment Tool with no BMD (FRAXnb)) better predicted incident vertebral fractures compared with FRAXnb alone (AUC: 0.80 [0.67-0.93] vs. 0.66 [0.51-0.82], P=0.001).

CONCLUSION

DL-derived 3D paraspinal muscle attenuation, rather than volume, demonstrates independent and incremental predictive value for subsequent vertebral bone attenuation loss and incident vertebral fracture.

CLINICAL RELEVANCE/APPLICATION

Routine noncontrast chest CT scans can opportunistically evaluate paraspinal muscle quality. Changes in muscle composition, rather than muscle size, may be targeted as modifiable risk factors for vertebral bone loss with available secondary preventive measures.

S3A-SPMK-6 STRUCTURED PROMPTS, SHARPER DIAGNOSES: OPTIMIZING VISION-LANGUAGE MODELS FOR EXTREMITY FRACTURE DETECTION

Janardhana Ponnatapura, MD (*Presenter*)
Praveen Shastry (*Abstract Co-Author*)
Naveen Kumarasamy (*Abstract Co-Author*)
Eswaramoorthy Sellamuthu, DNB,DMRD,MBBS (*Abstract Co-Author*)
Vishwanath Reddappagari Suryanarayana, MD, MBBS (*Abstract Co-Author*)
Bargava Subramanian (*Abstract Co-Author*)

PURPOSE

To systematically evaluate and optimize prompt engineering strategies for extremity fracture detection using vision-capable large language models (LLMs), thereby enhancing their diagnostic performance and clinical utility in musculoskeletal (MSK) imaging.

METHODS AND MATERIALS

Fifty anonymized knee radiographs (including 42 tibia, 20 femur, 24 fibula, and 12 patella fractures) were analyzed using three leading vision-enabled LLMs: GPT-4V, Claude 3.7 Sonnet, and Grok 2. Various prompting strategies were tested, including tiered prompts (ranging from generic to fully guided clinical prompts), structured versus free-text prompts, iterative refinement techniques, reference image enhancement, and noise testing. AI-generated reports were independently scored by two radiologists on fracture detection accuracy, clarity, appropriate radiological terminology, hallucination frequency, and time efficiency. Inter-rater reliability was assessed using Cohen’s kappa.

RESULTS

Structured, context-rich prompts significantly improved performance across all models. GPT-4V achieved the highest overall mean score (2.0/3.0), outperforming Claude 3.7 Sonnet (1.8/3.0) and Grok (1.5/3.0). Fully guided prompts reduced hallucinations by 42% and improved fracture detection accuracy by 45% compared to generic prompting. Structured prompts outperformed free-text prompts by 45% in detection accuracy and shortened time to acceptable reports by 34%. Reference image enhancement notably increased fracture identification, especially for complex or subtle fractures. Despite optimization, all models demonstrated limitations, particularly in detecting tibial plateau fractures and pediatric growth plate injuries.

CONCLUSION

Optimized, structured prompting moderately enhances the diagnostic performance of vision-capable LLMs in extremity fracture detection but does not yet achieve expert radiologist-level accuracy. Inclusion of clinical context, structured outputs, reference images, and explicit measurement instructions significantly improves outcomes. Nonetheless, human oversight remains essential when integrating LLMs into clinical workflows.

CLINICAL RELEVANCE/APPLICATION

This study provides a practical, evidence-based prompting framework that can enhance the utility of vision-capable LLMs for preliminary extremity fracture detection. While offering potential as assistive tools, vision LLMs currently require optimized prompting and careful validation before clinical deployment in musculoskeletal imaging.

Antonella Capomolla (*Abstract Co-Author*)
Francesco Zappia (*Abstract Co-Author*)
Giovanni Petracca (*Abstract Co-Author*)
Selenia Vallone (*Abstract Co-Author*)
Ilaria Vittoria Trecroci (*Abstract Co-Author*)
Rosario Maccarone (*Abstract Co-Author*)
Francesco Loria (*Abstract Co-Author*)

PURPOSE

To evaluate the diagnostic performance of parametric micro-flow imaging contrast-enhanced ultrasound (PMFI-CEUS) in differentiating melanoma from other skin tumors.

METHODS AND MATERIALS

A total of 130 patients with skin tumors were retrospectively evaluated. All patients underwent high-frequency ultrasound (HFUS) (33 MHz) and PMFI-CEUS (18 MHz). Lesion size, depth, and margins were assessed. Time-intensity curves were generated to analyze vascular patterns and contrast dynamics. All patients underwent surgical excision, and imaging findings were correlated with histopathology.

RESULTS

Histopathology identified 40 basal cell carcinomas (BCCs), 15 squamous cell carcinomas (SCCs), 15 melanomas, and 60 benign lesions. HFUS accurately assessed lesion depth with a 90% correlation to histological measurements. PMFI-CEUS revealed three distinct enhancement patterns: Pattern 1: rapid wash-in (0-18 s) and wash-out (=32 s);Pattern 2 : slower wash-in (>30 s) and wash-out (>50 s);Pattern 3 : delayed wash-in (>30 s) and wash-out (>70 s). At pathological correlation, pattern 1 was correctly identified as melanoma, pattern 2 as BCCs or SCCs and patter 3 as benign lesions. PMFI-CEUS achieved 100% of sensitivity, specificity, positive predictive value and negative predictive value in distinguishing melanomas from other lesions.

CONCLUSION

PMFI-CEUS plays a crucial role in differentiating melanoma from other skin tumors based on their vascular behavior.

CLINICAL RELEVANCE/APPLICATION

Integrating HFUS and PMFI-CEUS into dermatologic workflows allows non-invasive lesion characterization and stadiation, optimizing therapeutic planning.

S3A-SPNMMI-1 FDG PET IN THE ERA OF REVOLUTIONIZED OBESITY MEDICINE

Margit Szabari, MD, PhD (*Presenter*)
Farzana Z. Ali, MD,PhD,MPH (*Abstract Co-Author*)
Mojtaba Olyaie (*Abstract Co-Author*)
Jeremie Calais, MD (*Abstract Co-Author*)
Johannes Czernin, MD (*Abstract Co-Author*)
Ali Salavati, MD, MPH (*Abstract Co-Author*)

PURPOSE

Recent advancements have significantly improved the treatment of type 2 diabetes mellitus and obesity, particularly through the development of glucagon-like peptide-1 receptor agonists (GLP-1RAs), such as semaglutide (Ozempic®, Wegovy®), a long-acting GLP-1RA, and tirzepatide (Mounjaro®), the first approved dual agonist targeting glucose-dependent insulinotropic polypeptide (GIP) and GLP-1 receptors. These medications reduce glucagon release, increase insulin secretion, and slow gastric transit time. Considering the growing use of these medications—and their effects on insulin and blood sugar—understanding their impact on FDG PET imaging is essential. This study aimed to assess the effect of these therapies on FDG PET scan quality.

METHODS AND MATERIALS

We selected 86 patients who underwent FDG PET imaging while taking Ozempic (n = 29), Wegovy (n = 28), or Mounjaro (n = 29). An age-matched group of diabetic patients not on these medications (n = 50) was selected as control. Two nuclear medicine physicians and one radiology resident visually assessed all cases. Limitations in diagnostic evaluation were recorded, and any FDG uptake in muscle was assessed. Logistic regression and subgroup analysis were performed to evaluate treatment effects and compare each drug to the control group. Maximum standardized uptake value (SUVmax) of the liver and blood pool were compared between all the treatment and control groups using independent two-tailed t-tests and in two separate univariate ANOVA models comparing each drug and the control groups.

RESULTS

No significant differences were found between the groups in average blood or liver FDG uptake ($p > 0.05$). The Ozempic group showed no increased muscle uptake, while the Mounjaro group had the highest incidence of muscle uptake (n = 14). The Wegovy group (n = 8) and the control group (n = 6) showed the least muscle uptake. No limitations were noted in the study reports regarding diagnostic accuracy. Only one patient in the control group had gastric contents, compared to 18 in the treatment group. Subgroup analysis revealed that the log odds of having gastric contents increased for Ozempic by 3.44 ($p < 0.01$), for Mounjaro by 3.51 ($p < 0.01$), and for Wegovy by 1.05 ($p > 0.05$).

CONCLUSION

These results suggest that GLP-1RAs and dual GLP-1RA/GIP-RA therapies do not significantly affect FDG biodistribution or image quality.

CLINICAL RELEVANCE/APPLICATION

For patients on these therapies requiring an FDG PET scan, no changes to scan protocol or patient preparation are recommended. However, the relatively small sample size of this single-institution study supports the need for further evaluation in a multi-institutional cohort to confirm the effects of thesemedications on FDG PET image quality.

S3A-SPNMMI-2 VIRTUAL CUTANEOUS AREA SEVERITY INDEX (VCASI): A COMPREHENSIVE METHODOLOGY FOR QUANTITATIVE SKIN DISEASE ASSESSMENT ON POSITRON EMISSION TOMOGRAPHY IMAGES

Mahdie Hosseini, MD (*Presenter*)
Aliasghar Mortazi, MSc (*Abstract Co-Author*)
Jayaram K. Udupa, PhD (*Abstract Co-Author*)
Yubing Tong, PhD (*Abstract Co-Author*)
Drew A. Torigian, MD, MA (*Abstract Co-Author*)

PURPOSE

Quantification of skin diseases such as cutaneous lymphoma or psoriasis is important for pretreatment planning and response assessment. Currently, this quantification relies on clinical assessments, which are cumbersome, error-prone, and subject to inter-reader variability. Fluorodeoxyglucose-positron emission tomography/computed tomography (FDG-PET/CT) is widely used for non-invasive detection and quantification of metabolically active disorders, providing biomarkers of disease extent, severity, and therapeutic response. However, skin disease quantification from PET/CT remains challenging, error-prone, and labor-intensive.

METHODS AND MATERIALS

We proposed a novel comprehensive methodology called virtual Cutaneous Area Severity Index (vCASI) to quantitatively assess the extent and severity of metabolically active skin disease from FDG-PET/CT. Firstly, we used an automated body region localization method, followed by a PET standardization technique to reduce interscan measurement variability. Then, we generated skin shell PET images and developed a standardized Maximum Intensity Projection (MIP) rendering technique to enable reproducible 3D visualization of the skin with disease. Finally, we introduced and validated a new scoring system (vCASI score) to measure the extent and severity of skin disease via these renderings.

RESULTS

Correlations between vCASI scores and ground-truth assessments increased following standardization of PET images, further improved with use of adjusted mean of maximum percentile intensity values as the reference point for MIP rendering, and reached as high as 0.605. Correlations between repeated vCASI score assessments for torso, thorax, abdomen, and pelvis exceeded 0.85, demonstrating high repeatability.

CONCLUSION

The vCASI methodology allows for accurate and reproducible quantitative assessment of the extent and severity of metabolically active skin diseases, such as cutaneous lymphoma and psoriasis, from FDG-PET/CT. It addresses the challenges related to body region localization, non-standardness of PET images, robust visualization, and standardized display of PET images to detect and quantify skin disease. We demonstrated that the vCASI scoring system has high repeatability and good accuracy, and is optimized by the proposed methodology.

CLINICAL RELEVANCE/APPLICATION

The vCASI overcomes the lack of a practical and validated scoring system for quantifying metabolically active skin diseases on PET images.

S3A-SPNPM-2 SUSTAINED IMPROVEMENT IN MAMMOGRAPHY POSITIONING AT MULTIPLE SITES SIMULTANEOUSLY THROUGH SHARED LEARNING

Sarah M. Pittman, MD, FRCPC (*Presenter*)
Kay Zacharias-Andrews (*Abstract Co-Author*)
Kandice Tomkins, RN, MS (*Abstract Co-Author*)
Katherine Hall (*Abstract Co-Author*)
Mythreyi Bhargavan-Chatfield, PhD (*Abstract Co-Author*)
David B. Larson, MD, MBA (*Abstract Co-Author*)

PURPOSE

To establish and sustain excellent performance in mammography positioning at multiple sites simultaneously by utilizing a structured improvement program within a learning network framework that enables participating sites to develop and implement locally successful strategies while collaborating and sharing learnings across cohorts.

METHODS AND MATERIALS

Sites are selected to participate in the ACR Mammography Positioning Improvement Collaborative on the basis of strength of local leadership support, intraorganizational relationships, access to data and analytic support, and experience with quality improvement (QI) initiatives. Cohorts of sites enter the collaborative by first participating in a structured QI program, ImPower. During ImPower, sites organize their teams, develop SMART goals, gather data, evaluate their current state, identify root causes of inconsistent mammography positioning and corresponding key drivers, and develop, test, and refine interventions. Key learnings from each cohort are shared with subsequent cohorts. The impact of interventions implemented at each site is assessed by tracking the percentage of screening mammograms meeting overall passing criteria over time.

RESULTS

All six sites selected to participate in the first cohort of the collaborative completed the QI program in November 2022, and five sites continued to report data. Eight of nine sites in the second cohort completed the program in September 2023 and four sites continued to report data. Both sites in the third cohort completed the program in July 2024. Across cohorts, the most common key driver affecting mammography positioning was developing and maintaining technologist skill, followed by agreement on image quality. From the key drivers, interventions were developed and implemented at each site, and resulted in improvement in the average percentage of screening mammograms meeting overall passing criteria from a cohort mean of 51% at baseline to 86% by the end of the QI program for cohort 1, 36% to 75% for cohort 2, and 51% to 83% for cohort 3. The cohort 1 and 2 sites that continued to report data demonstrate ongoing performance at or near target.

CONCLUSION

Using a structured QI program within a learning network framework, the first three cohorts of the ACR Mammography Positioning Improvement Collaborative collectively demonstrated improvement in mammography positioning performance with sustained improvement beyond completion of the QI program.

CLINICAL RELEVANCE/APPLICATION

Suboptimal mammography positioning can lead to undetected breast cancer. A structured QI program within a learning network framework can facilitate sustained improvement in mammography positioning at multiple sites simultaneously, across multiple cohorts.

S3A-SPNR-1 REGIONAL CEREBROVASCULAR REACTIVITY BIDIRECTIONAL ALTERATIONS IN HEALTHY AGING: MEDIATION BY GRAY MATTER ATROPHY AND ASSOCIATION WITH COGNITIVE PERFORMANCE

Jiajia Zhang (*Presenter*)
Xiuqin Jia (*Abstract Co-Author*)
Qi Yang, MD (*Abstract Co-Author*)

PURPOSE

Cerebrovascular reactivity (CVR) correlates with cognitive performance in neurodegenerative conditions. This study aims to assess age-related alterations in regional CVR and their relationships with gray matter (GM) and cognitive function in healthy aging.

METHODS AND MATERIALS

This cross-sectional study included 301 cognitively unimpaired participants (181 younger: 18-34 years; 120 older: 60-89 years) from Ithaca, New York, and Toronto, Canada. MRI data were acquired at the two sites using high-field 3T scanners (the GE Discovery MR750 and the Siemens TimTrio MRI, respectively) with a 32-channel head coil. All subjects underwent multi-echo resting-state blood oxygen level-dependent (BOLD) fMRI for CVR measurement and T1-weighted MPRAGE for GM quanti&7;cation. Neuropsychological assessments were conducted on 283 participants. Voxel-wise t -tests compared regional CVR between age groups, with significant clusters defined as regions of interest (ROIs). Mediation analyses examined regional GM atrophy as a mediator of the aging-CVR relationships within ROIs. Multivariable linear regression models evaluated the associations between ROI-based CVRs and cognition.

RESULTS

Compared with younger adults, older adults exhibited lower CVR mainly in the temporal, basal ganglia, cingulate, brainstem, and cerebellum regions, whereas higher CVR in the frontal, parietal, occipitotemporal, thalamus, and caudate regions. Regional GM volume loss partially mediated age-related CVR increases in the right frontal pole ($p = 0.004$) and fusiform/lingual gyrus ($p = 0.001$), as well as age-related CVR attenuations in bilateral brainstem/cerebellum vermis 45 ($p < 0.001$). The mediating proportions were 55.9%, 56.6%, and 79.2%, respectively. ROI-based CVR was associated with cognition, with most regions linked to processing speed and episodic memory, followed by executive function and semantic memory.

CONCLUSION

Resting-state CVR performed by BOLD fMRI demonstrated spatially heterogeneous age-related deficits or increases. These CVR alterations were partly attributed to regional GM atrophy and were associated with cognitive performance.

CLINICAL RELEVANCE/APPLICATION

These findings highlight the region-specific cerebrovascular compensation mechanisms and the macrostructural-microvascular interactions in the aging brain, and support CVR as a promising biomarker of preclinical cognitive changes.

S3A-SPNR-2 AI-BASED BEHAVIORAL SEVERITY PROFILING OF AUTISM SPECTRUM DISORDER USING WHITE MATTER CONNECTIVITY FROM DIFFUSION TENSOR IMAGING

Mohamed Khudri, BSc (*Presenter*)
Mostafa Abdelrahim, BSc (*Abstract Co-Author*)
Ahmed Shalaby, PhD (*Abstract Co-Author*)
Yaser Elnakieb (*Abstract Co-Author*)
Andrew E Switala (*Abstract Co-Author*)
Ali Mahmoud (*Abstract Co-Author*)
Asem C. Ali (*Abstract Co-Author*)
Sohail G. Contractor, MD (*Abstract Co-Author*)
Gregory Barnes (*Abstract Co-Author*)
Ayman S. El-Baz SR, PhD (*Abstract Co-Author*)

PURPOSE

To extend our previous work on AI-based ASD diagnosis by developing a novel framework that leverages white matter (WM) connectivity derived from Diffusion Tensor Imaging (DTI) for both diagnostic classification and multidimensional severity profiling. The system quantifies severity across five core behavioral traits: Communication, Cognition, Motivation, Awareness, and Mannerisms.

METHODS AND MATERIALS

DTI data from five ABIDE-II sites (n=226; 126 ASD, 100 TD) underwent standard preprocessing using the FSL tool including brain extraction (BET), eddy current correction (eddy), and susceptibility distortion correction (top-up). WM areas were parcellated using the Johns Hopkins atlas. For each region, DTI metrics (FA, MD, RD, and AD) were extracted and described using three statistical descriptors: mean, standard deviation, and skewness. A two-stage feature selection was applied: (1) Univariate Feature Selection using ANOVA, chi-square, and mutual information, and (2) Recursive Feature Elimination (RFE) with cross-validation. The machine learning pipeline consisted of two phases: Phase I comprised 750 classification experiments covering all combinations of behavioral traits and severity levels using multiple machine learning classifiers. Following these experiments, statistical validation was performed across 10 confidence intervals (90%-99%) to identify the most discriminative WM regions associated with ASD. In Phase II, behavioral probabilities obtained from Phase I were utilized to train the second-stage classifiers for the final classification of ASD versus TD.

RESULTS

Phase I achieved 98% accuracy, 96% sensitivity, and 99% specificity, with awareness as the top-performing trait (98.8% accuracy using LSVM). In Phase II, the SVC achieved the highest overall performance for ASD vs. TD classification (F1 = 0.96, B-Acc = 0.93). Significant WM regions associated with ASD were identified and reported across varying confidence intervals. Case studies showed strong agreement between model predictions and clinical scores.

CONCLUSION

This study presents a validated DTI-based framework for ASD assessment, enabling reliable severity profiling across five behavioral domains through machine learning and robust feature selection. Small sample size present current limitations. Future work will explore multimodal imaging, data augmentation, and genomic correlations.

CLINICAL RELEVANCE/APPLICATION

This non-invasive, AI-based system enables accurate ASD classification and severity profiling across multiple behavioral domains, offering clinically relevant insights for early intervention and personalized care.

S3A-SPNR-3 DELTA HISTOGRAM ANALYSIS OF SYNTHETIC MRI: A METHOD FOR ASSESSING MENINGIOMA GRADE AND CELLULAR PROLIFERATION

Ye Li (*Presenter*)
Xiaofang Zhou (*Abstract Co-Author*)
Yuncong Zhao (*Abstract Co-Author*)
Yizhu Chen (*Abstract Co-Author*)
Yunjing Xue, MD (*Abstract Co-Author*)
Lin Lin (*Abstract Co-Author*)

PURPOSE

Synthetic MRI (SyMRI) can generate quantitative maps simultaneously in a single scan within a shorter time. In addition, changes in radiological features within the image before and after contrast agent injection can be reflected by delta Radiomics or delta histogram. They have shown great potential in the diagnosis, grading, typing, and prognosis assessment of tumors. This study aimed to explore the feasibility of delta histogram analysis of SyMRI in predicting the grade and cellular proliferation of meningioma.

METHODS AND MATERIALS

Consecutive 95 patients with pathologically proven meningiomas were included and divided into low-grade and high-grade group. They underwent conventional MRI and SyMRI before surgery. SyMRI sequences were performed pre- and post-contrast injection to generate quantitative maps (T1, T2, PD, T1C, T2C, PDC) via synthetic reconstruction and post-processing. Histogram parameters (18 first-order radiomics features) and delta histogram parameters (absolute and relative) were calculated from whole tumor volume analysis. Mann-Whitney U test was used to compare histogram parameters. ROC analysis assessed diagnostic efficacy of histogram parameters for differentiating meningioma grades. Spearman’s correlation coefficients analyzed the correlations between histogram parameters and Ki-67 expression.

RESULTS

High-grade meningiomas showed significantly higher T1C (Energy, Total Energy), T2C [Interquartile Range(IR), Mean Absolute Deviation (MAD),Robust Mean Absolute Deviation (rMAD)], PDC Skewness, PD skewness, dPD (IR, MAD, rMAD, Variance) and dPD% (IR, MAD, rMAD, Variance) compared to LGMs (all $P < 0.05$; AUC = 0.645 - 0.785). The 90 Percentile and Median of PD of HGMs was significantly lower than that of LGMs ($P < 0.05$; AUC = 0.658-0.666) . The combination of dPD% (IR, MAD) and PD Skewness in tumors showed the highest AUC of 0.875. Significant correlations were found between the Ki-67 index and histogram parameters of the majority of synthetic MRI (r=-0.223-0.295, all $p<0.05$).

CONCLUSION

Synthetic MRI combined with delta histogram parameters could serve as potential imaging biomarkers for the classification of meningioma grades.

CLINICAL RELEVANCE/APPLICATION

The delta histogram analysis derived from SyMRI sequences has the potential to predict the grade and proliferative activity of meningiomas. This predictive capability may play a role in facilitating personalized treatment strategies and improving prognostic assessment for patients with meningiomas.

S3A-SPNR-4 TOWARDS A NEUROIMAGING CONSENSUS FOR THE WORKUP OF ADULT GENETIC LEUKOENCEPHALOPATHIES ON BEHALF OF THE WHITE MATTER ROUNDS NETWORK: STATE OF PRACTICE

Jenny Feng (*Abstract Co-Author*)
Gabrielle Macaron (*Abstract Co-Author*)
Elka Miller, MD, FRCPC (*Abstract Co-Author*)
Roberta La Piana (*Abstract Co-Author*)

PURPOSE

Adult-onset genetic leukoencephalopathies (AOL) are frequently misdiagnosed due to their overlap with more common acquired white matter diseases. MRI remains a central tool in narrowing the differential diagnosis of white matter diseases; however, a key barrier to optimizing diagnosis is the lack of MRI protocol standardization between institutions. The White Matter (WM) Rounds Network includes radiologists, clinicians, and scientists from more than 30 centers worldwide who meet monthly to discuss undiagnosed white matter diseases. We aimed to 1. assess the state of practice of current MR protocols for investigating suspected genetic leukoencephalopathies and 2. propose a core standard protocol.

METHODS AND MATERIALS

We used a modified Delphi method to facilitate group judgements. We developed a survey and submitted it for feedback to a panel of 40 neuroradiologists, neurologists, and neuroimaging research faculty specializing in white matter disorders from 30 institutions. The final survey was circulated to the entire WM Rounds Network. The

results were analyzed, and specific recommendations were put forward during Delphi rounds, for which the stop criterion was >75% agreement for each recommendation.

RESULTS

The MR protocols in participating institutions had an average magnet time of 40 minutes (range 25-60) and all included the following sequences: sagittal 3D T1 MPRAGE and 3D FLAIR, axial T2 and T2-FLAIR, axial DWI/ADC, axial SWI, and cervical spine imaging (T1 sagittal, T2 sagittal and axial). Thoracic spine imaging was also frequently performed (20/30, 67%). All four recommendations passed the Delphi process and were proposed as follows: 1. Contrast-enhanced T1 sequences should be performed for patients with demonstrable clinical or radiological evidence of adult genetic leukoencephalopathy. 2. Lumbar MR spine imaging has limited utility. 3. Head CT is of little added value and should not be included routinely. 4. MR spectroscopy, diffusion tensor imaging, and other advanced imaging techniques are currently of limited diagnostic utility, but may be helpful in supporting a working diagnosis.

CONCLUSION

Adult onset leukoencephalopathies remain a diagnostic challenge as advancements in imaging and genetics add complexity, requiring extensive collaboration across subspecialties for accurate diagnosis. MRI plays a central role in the initial workup, and timely diagnosis necessitates proper sequence acquisition.

CLINICAL RELEVANCE/APPLICATION

The recommendations of the WM Rounds Network aim to provide a practical guideline to help standardize and improve the diagnostic yield of the initial MRI exam, help improve the time to diagnosis, while also optimizing resource utilization.

S3A-SPNR-5 MRI BIOMARKERS IN DIFFERENTIATING RRMS FROM NMOSD: DIAGNOSTIC VALUE OF CENTRAL VEIN SIGN, PARAMAGNETIC RIM LESIONS, AND CORTICAL LESIONS AND THEIR CLINICAL CORRELATES

Long Ye (*Presenter*)

PURPOSE

The central vein sign (CVS), paramagnetic rim lesions (PRLs), and cortical lesions (CLs) are promising MRI biomarkers for differentiating multiple sclerosis (MS) from neuromyelitis optica spectrum disorder (NMOSD). We evaluated the diagnostic performance of these markers, individually and in combination, and their associations with clinical disability and cognitive function.

METHODS AND MATERIALS

Seventy-two adults with relapsing-remitting multiple sclerosis (RRMS) and 51 patients with NMOSD underwent 3.0 T brain MRI. The CVS and PRLs were assessed on phase images and quantitative susceptibility mapping (QSM), while CLs were assessed on 3D T2-FLAIR. Clinical disability in RRMS patients was evaluated using the Kurtzke Expanded Disability Status Scale (EDSS). Cognitive function was measured using the Mini-Mental State Examination (MMSE), the Symbol Digit Modalities Test (SDMT), and the Montreal Cognitive Assessment (MoCA). In RRMS patients, partial correlations controlling for age and years of education examined relationships between these MRI measures and EDSS and cognitive function.

RESULTS

RRMS patients had a higher burden of CVS-positive lesions (median 10 vs. 0 per patient), PRLs (2.5 vs. 0), and CLs (3 vs. 0) than NMOSD (all $p < 0.001$). Using optimal cutoffs (>20% CVS-positive lesions, >1 CL, >1 PRL), the diagnostic performance for distinguishing RRMS from NMOSD showed sensitivities of 81.6%, 58.3%, and 83.3%, specificities of 84.3%, 94.1%, and 90.2%, and AUCs of 0.887, 0.777, and 0.892, respectively. The combination of all three markers yielded a sensitivity of 79.2%, specificity of 100%, and an AUC of 0.936. In RRMS patients, higher PRL and CL counts were associated with lower cognitive scores (all $p < 0.01$), while a higher CVS proportion and PRL count correlated with higher EDSS scores ($p = 0.001$ and 0.015, respectively).

CONCLUSION

CVS, PRLs, and CLs are more frequently observed in RRMS than NMOSD, and their combined use enhances diagnostic accuracy. PRLs and CLs are strongly associated with cognitive impairment in RRMS, underscoring the clinical value of these imaging markers in diagnosis and disease evaluation.

CLINICAL RELEVANCE/APPLICATION

MRI biomarkers including the central vein sign, paramagnetic rim lesions, and cortical lesions can improve the differentiation between RRMS and NMOSD. Their combined assessment may support more accurate diagnosis, guide treatment decisions, and provide insight into disability and cognitive impairment in RRMS patients.

S3A-SPNR-6 ASSOCIATION OF MRI INDEXES OF THE GLYMPHATIC SYSTEM AND COGNITIVE IMPAIRMENT IN PATIENTS WITH ANTI-LGI1 ENCEPHALITIS

Ziyao Liu (*Presenter*)

PURPOSE

While glymphatic dysfunction is documented in neuroinflammatory disorders like MS and NMOSD, its role in anti-LGI1 encephalitis remains unclear. This study investigated: (1) glymphatic MRI indexes (DTI-ALPS, FW-WM, PVS-VF) across disease stages; (2) their associations with limbic volumes and cognition; and (3) treatment-related changes.

METHODS AND MATERIALS

This single-center prospective study included healthy controls (HCs) and patients with anti-LGI1 encephalitis who underwent MRI and cognitive evaluation between February 2017 to August 2024. We collected basic clinical information, including neuropsychological assessments. Patients were divided into three cognitive subgroups: LGI1-NCI, no cognitive impairment (normal MoCA); LGI1-MCI, mild cognitive impairment (MoCA 18-25); LGI1-SCI, moderate-to-severe cognitive impairment (MoCA <18). For each participant, we obtained the following measures: the diffusion tensor image analysis along the perivascular space (DTI-ALPS) index, hippocampal and amygdala volumes (based on 3D T1-weighted imaging), perivascular space volume fraction (PVS-VF) , and free water in white matter (FW-WM).

RESULTS

A total of 40 patients with anti-LGI1 encephalitis (mean age, 55.9 years ± 12.7[SD]; 25 males) and 42 HCs (mean age, 50.64 years ± 12.57; 24 males) were included. Key imaging biomarkers demonstrated significant alterations in anti-LGI1 encephalitis patients compared to healthy controls (HCs). The DTI-ALPS index was markedly reduced (1.483 vs 1.671, $p<0.001$), while WM free-water fraction (WM-FW) was elevated (0.202 vs 0.165, $p<0.001$). Subgroup analysis revealed progressive DTI-ALPS reduction (LGI1-SCI:1.428 vs HCs:1.671, $p<0.001$) and WM-FW elevation (LGI1-SCI:0.225 vs HCs:0.165, $p<0.001$) correlating with cognitive severity. Bilateral hippocampal atrophy was observed (right:3.27 vs 3.49cm³, $p=0.027$; left:2.94 vs 3.22cm³, $p=0.007$), with left hippocampal volume showing significant positive correlation with DTI-ALPS ($r=0.334$, $p=0.035$) and negative correlation with WM-FW ($r=-0.329$, $p=0.038$). WM-FW additionally correlated with MMSE scores ($r=-0.338$, $p=0.033$). No significant longitudinal changes were detected in the 37.5% (15/40) patients receiving immunotherapy at median 5-month follow-up.

CONCLUSION

This study revealed: (1) impaired glymphatic activity (decreased DTI-ALPS, increased FW-WM) versus HCs; (2) MRI-cognition correlations; (3) left hippocampal volume linked to both imaging markers and cognitive scores.

CLINICAL RELEVANCE/APPLICATION

Reduced DTI-ALPS index and elevated FW-WM may reflect glymphatic dysfunction in anti-LGI1 encephalitis, providing imaging targets for monitoring disease progression and treatment response.

S3A-SPNR-7 CEREBELLAR AND CEREBRAL WHITE MATTER MYELINATION PROCESSES DISTINCTLY DIFFERENT TRAJECTORIES DURING INFANCY

Haiying Lyu, MD, BMedSc (*Presenter*)
Zhengwang Wu (*Abstract Co-Author*)
Weiyan Yin (*Abstract Co-Author*)
Gang Li, PhD (*Abstract Co-Author*)
Yong Lu (*Abstract Co-Author*)
Weili Lin, PhD (*Abstract Co-Author*)

PURPOSE

Myelination of white matter (Wm) is a key process during early human brain development. However, the potential differences of developmental paces between the cerebellum and cerebrum remain largely unknown. The T1w/T2w ratio has been well established as a surrogate marker assessing the extent of WM myelination. To this end, this study aimed to evaluate the distinct myelination development trajectories in infant cerebellum and cerebrum major white matter (WM) tracts using T1w/T2w ratio.

METHODS AND MATERIALS

206 term infants (female: n=103, median chronological age 430 days (q1 200 ; q3 603)) with a total of 816 sessions of structural brain MRI scans were retrospectively included in this study. Data were obtained from the UNC/UMN Baby Connectome Project (BCP), where images were acquired at =3, 6, 9, 12, 18, and 24 months of age using a Siemens Prisma scanner. Data were preprocessed using an infant cerebrum-dedicated pipeline (iBEAT V2.0). After skull-striping, images were resampled to 0.8 × 0.8 × 0.8 mm3, and T2w images were linearly aligned with their corresponding T1w images, and the T1w/T2w ratio were calculated. For image registration, the brain and segmented cerebellum were registered first to an intermediate subject-level template and then to standard space of MNI and SUIT template, respectively. The JHU WM atlas was warped to the individual space using inversed deformation filed to extract the T1w/T2w ratio values at major WM tracts. The trajectories of T1w/T2w ratio were modeled using generalized additive model with REML method in R.

RESULTS

The overall patterns of cerebral and cerebellar WM development were similar, with significant age-related changes in the T1w/T2w ratio in both regions (R2 0.4~0.8, $p<0.001$). The cerebellar WM tracts show higher T1w/T2w values and earlier maturation. The cerebral tracts exhibit a slower growth curve during early infancy, consistent with a protracted developmental process. For cerebellum, the WM tracts in the ventral brain tend to develop faster than the dorsal. For cerebrum, the external capsule exhibits the slowest and lowest level of myelination in comparison to other major WM tracts.

CONCLUSION

The brain myelination development trajectory is tract-specific and the cerebellum myeline matures faster than cerebrum during infancy.

CLINICAL RELEVANCE/APPLICATION

Understanding the development process of brain major WM tracts is important for distinguishing the children with potential brain developmental abnormality. Multiple brain disorders and neurodegenerative diseases might suffer from the involvement of different brain regions due to the distinct trajectories of cerebellum and cerebrum.

S3A-SPNR-8 FROM PHANTOM TO PATIENT: TOTAL MAGNETIC MOMENT ENABLES RELIABLE CEREBRAL MICROBLEED QUANTIFICATION ACROSS MRI FIELD STRENGTHS

Chao Zhang, MD (*Presenter*)
Alexey Dimov, PhD (*Abstract Co-Author*)
Yi Wang, PhD (*Abstract Co-Author*)

PURPOSE

To assess the reproducibility and field strength dependence of total magnetic moment for cerebral microbleed (CMB) quantification using Quantitative Susceptibility Mapping (QSM) in both phantom and in vivo Alzheimer's disease (AD) studies.

METHODS AND MATERIALS

Sixteen AD patients with CMBs and a microbleed phantom underwent QSM imaging on GE and Siemens scanners at 1.5T and 3.0T. QSM was processed using the mSMV method and Morphology Enabled Dipole Inversion (MEDI). CMBs were manually segmented, and total magnetic moment was calculated as susceptibility times field strength. Total magnetic moment and volume ratios were analyzed across echo times. Bland-Altman and linear regression analyses were used to assess intra- and inter-scanner reproducibility.

RESULTS

Phantom experiments at both 1.5T and 3.0T demonstrated strong interscanner agreement in total magnetic moment, confirmed by linear regression ($R^2 = 0.861$; $p < 0.001$) and Bland-Altman analysis. In vivo analysis similarly revealed excellent reproducibility of total magnetic moment across field strengths ($R^2 = 0.832$; $p < 0.001$), with minimal bias on Bland-Altman plots. Moreover, in vivo total magnetic moment remained stable across echo times ($y = -0.001x + 0.962$; $R^2 = 0.035$; $p = 0.655$), in contrast to CMB volume, which showed pronounced TE dependence ($y = 0.085x - 0.199$; $R^2 = 0.994$; $p < 0.001$).

CONCLUSION

Total magnetic moment represents a reproducible, field-strength-independent quantitative biomarker for assessing CMB burden. Its consistency across different echo times, vendors, and field strengths supports its utility in standardized, multi-center imaging protocols and its reliability in microbleed quantification.

CLINICAL RELEVANCE/APPLICATION

This study establishes total magnetic moment as a robust, quantitative imaging biomarker for evaluating CMBs across different MRI platforms. Its stability makes it a valuable tool for longitudinal and multicenter evaluation of imaging abnormalities arising from anti-amyloid therapy in AD.

S3A-SPNR-10 AUTOMATED UNIQUE LESION TRACKING (AULTRA): A FRAMEWORK FOR LONGITUDINAL LESION-WISE MORPHOMETRY ANALYSIS IN MULTIPLE SCLEROSIS

Jinwei Zhang, PhD, MSc (*Presenter*)
Carlos Rivas (*Abstract Co-Author*)
Blake Dewey (*Abstract Co-Author*)
Shuwen Wei (*Abstract Co-Author*)
Samuel Remedios (*Abstract Co-Author*)
Savannah Hays (*Abstract Co-Author*)
Lianrui Zuo (*Abstract Co-Author*)
Scott Newsome (*Abstract Co-Author*)
Peter A. Calabresi, MD (*Abstract Co-Author*)
Jerry L. Prince, PhD (*Abstract Co-Author*)
Aaron Carass (*Abstract Co-Author*)

PURPOSE

To develop an automated tool for tracking individual multiple sclerosis (MS) lesions over time using magnetic resonance imaging (MRI).

METHODS AND MATERIALS

AULTRA Pipeline: Given longitudinal multicontrast MRI data (e.g., T1-weighted, T2-weighted, and FLAIR) for each subject, the AULTRA pipeline performs automatic, unique lesion tracking through the following steps: Longitudinal rigid-body registration with image quality enhancement; MS lesion segmentation using SELF; Lesion filling with BiDDPM; Learning-based longitudinal deformable registration; Forward-backward confluent lesion separation; and Reverse deformable registration to map results back to the original space. For each lesion, AULTRA extracts a range of quantitative metrics that characterize both internal tissue properties and morphological features. These include: 1. Lesion volume , measuring size to monitor growth or shrinkage over time; 2. T1w/T2w ratio , a semi-quantitative measure for myelin integrity derived from co-registered T1w and T2w scans at each timepoint; 3. Sphericity , quantifying how closely a lesion approximates a perfect sphere; and 4. Eccentricity , measuring deviation from circular or spherical shape, with higher values indicating more elongated or irregular structures. These metrics provide a comprehensive lesion-level profile to support individualized and temporally resolved analysis. Dataset: AULTRA was applied to an MS dataset comprising 471 subjects, each with longitudinal MRI scans across at least two timepoints. This resulted in 79,221 lesion-level observations derived from 13,748 unique lesions.

RESULTS

For each lesion, AULTRA successfully extracted quantitative metrics, including volume, T1w/T2w ratio, sphericity, and eccentricity, at each timepoint. The results demonstrated consistent lesion correspondence across time, enabling robust lesionwise temporal profiling. Visual inspection confirmed accurate tracking of lesion trajectories, even in cases of subtle morphological change.

CONCLUSION

Our results demonstrate that AULTRA enables high-resolution, lesion-specific profiling by capturing quantitative metrics of lesion size and shape across timepoints. The method reliably extracts features such as volume, T1w/T2w ratio, sphericity, and elongation from longitudinal scans, supporting detailed characterization of individual lesions in multiple sclerosis.

CLINICAL RELEVANCE/APPLICATION

Automated unique lesion tracking based on morphology and tissue integrity can help monitor MS progression and assess treatment response, providing useful biomarkers for personalized disease management.

S3A-SPNR-11 CONSTRUCTING T1-WEIGHTED CONTRAST-ENHANCED MRI IMAGES FOR GLIOBLASTOMA FROM T1-WEIGHTED IMAGES USING A VISION MODEL: A NOVEL APPROACH FOR AUTOMATIC CE IMAGING IN NEW PATIENTS

Suhrud Panchawagh (*Presenter*)

PURPOSE

Glioblastoma requires precise imaging for diagnosis and treatment. This study develops a deep learning model to synthesize contrast-enhanced T1-weighted Magnetic Resonance Imaging (MRI) from routine non-contrast T1-weighted scans, reducing gadolinium-based contrast agent use.

METHODS AND MATERIALS

Data: Paired T1-weighted and T1-weighted contrast-enhanced scans from 153 glioblastoma patients (3-Tesla MRI) were aligned using Vision Transformer and split into training, validation, and test sets. Model: A hybrid Convolutional Neural Network-Vision Transformer architecture was trained with Mean Squared Error and Structural Similarity Index Measure loss to map T1-weighted inputs to synthetic T1-weighted contrast-enhanced outputs. Evaluation: Quantitative metrics (Structural Similarity Index Measure, Peak Signal-to-Noise Ratio, Root Mean Square Error) and qualitative assessments by three blinded radiologists compared synthetic and ground-truth images.

RESULTS

High-fidelity synthesis: Structural Similarity Index Measure 0.91, Peak Signal-to-Noise Ratio 32.5 decibels, Root Mean Square Error 0.015. 94% of synthetic images were rated diagnostically viable by radiologists. The model outperformed pix2pix and CycleGAN baselines.

CONCLUSION

The model reliably generates T1-weighted contrast-enhanced images, matching diagnostic quality without contrast agents.

CLINICAL RELEVANCE/APPLICATION

Eliminates contrast use, reducing risks of nephrogenic toxicity and gadolinium deposition. Streamlines clinical workflows, particularly beneficial in resource-limited settings.

S3A-SPNR-12 LEVERAGING MRI FEATURES IN MACHINE LEARNING TO PREDICT LIMBIC-PREDOMINANT AGE-RELATED TDP-43 ENCEPHALOPATHY (LATE)

Rasheed Abid, BSc (*Presenter*)
Mahir Tazwar, PhD (*Abstract Co-Author*)
Arnold M. Evia JR, PhD (*Abstract Co-Author*)
Abdur Raquib Ridwan, PhD (*Abstract Co-Author*)
David A. Bennett, MD (*Abstract Co-Author*)
Konstantinos Arfanakis, PhD (*Abstract Co-Author*)

PURPOSE

Limbic-predominant age-related TDP-43 encephalopathy neuropathologic change (LATE-NC) is a common pathologic finding in aged brain, however, definitive diagnosis of this disease is only possible at autopsy. This work aimed to develop a marker of LATE-NC based on in-vivo MRI features from a large group of community-based older adults.

METHODS AND MATERIALS

This study included ex-vivo MRI, in-vivo MRI, and pathology data from four longitudinal clinicopathological cohort studies of aging conducted at the Rush Alzheimer's Disease Center (ROS, Rush MAP, MARS, LATC). LATE-NC was evaluated based on pathologic TDP-43 inclusions in 8 brain regions and categorized into 4 stages. MRI data was processed to obtain fractional anisotropy (FA), deformation-based morphometry (DBM) measurements, and lobar volumes. To develop a marker of LATE-NC, we first trained a classifier to distinguish between advanced (stages 2-3) and early LATE-NC stages (stages 0-1) based on ex-vivo MRI features (N=863). Our classifier used a two-level stacking model for training and cross-validation, where level-1 estimators generated risk scores based on single-modality features, and level-2 estimator (logistic regression) provided the final LATE-NC prediction score based on the combined risk scores. We then translated the classifier to in-vivo and validated it on a separate set of participants (N=60) with in-vivo MRI and pathology data. The entire pipeline was packaged into an automated software container named MARBLE (MARker of Brain LatE).

RESULTS

In the training group, the ex-vivo classifier demonstrated excellent performance, achieving an average AUC of 0.85±0.05 (sensitivity=78%, specificity=76%, balanced accuracy=77%) based on FA, DBM, and lobar volume features. In-vivo validation of MARBLE scores yielded an overall AUC of 0.78 in the test group. Additionally, ordinary least-squares regression revealed higher MARBLE scores with greater LATE-NC stages ($p < 0.001$), controlling for antemortem interval (AMI) and scanners.

CONCLUSION

This study developed MARBLE, a novel, automated, in-vivo marker of LATE-NC based on MRI features. MARBLE was trained on ex-vivo MRI and pathology data from a large number of community-based older adults and showed decent performance in-vivo (AUC=0.78). Future work will explore further validation in external independent cohorts.

CLINICAL RELEVANCE/APPLICATION

Given the prevalence of LATE-NC in older adult brains and the lack of a molecule-specific biomarker, MARBLE has the potential to fill this gap and significantly improve clinical diagnosis, prevention, and treatment of this devastating disease.

S3A-SPNR-13 UNIFIED DEEP LEARNING FOR ACCURATE SEGMENTATION OF 11 CNS TUMOR TYPES BASED ON WHO CLASSIFICATION: A MULTI-SEQUENCE MRI APPROACH WITH ATTENTION AND ADAPTIVE LOSS

Qianqian Zheng (*Presenter*)
Liting Guo (*Abstract Co-Author*)
Yuchi Tian (*Abstract Co-Author*)
Guangliang Ju (*Abstract Co-Author*)
Yujun Zeng (*Abstract Co-Author*)
Anrong Zeng (*Abstract Co-Author*)
Yuting Luo (*Abstract Co-Author*)
Xibiao Yang (*Abstract Co-Author*)
Liping Wang (*Abstract Co-Author*)
Xiaoyun Liang, PhD (*Abstract Co-Author*)
Qiang Yue, MD (*Abstract Co-Author*)

PURPOSE

Develop a unified deep learning model for accurate segmentation of 11 CNS tumor types using standard MRI sequences, addressing the limitations of existing single-tumor models.

METHODS AND MATERIALS

The dataset used in this study consists of 2,881 cases, including 2,049 cases from the BraTS 2023 public dataset and 697 cases from West China Hospital for training, with an additional 115 cases from the hospital reserved for testing. Each case includes four MRI sequences—T1-weighted imaging (T1WI), T2-weighted imaging (T2WI), T2-FLAIR, and contrast-enhanced T1-weighted imaging (CE-T1WI)—along with corresponding brain tumor segmentation masks. The network adopts a U-shaped architecture, incorporating a deep supervision mechanism during training. An attention mechanism is integrated into the network to facilitate the capture of tumor-specific features. Given the wide variety of tumor types and the differing imaging characteristics associated with tumor severity, particularly the issue of distribution imbalance among the whole tumor, necrotic core, and enhancing tumor regions, the Dice loss and Focal loss functions are employed for network training. Furthermore, during training, the loss weights are adaptively adjusted based on the distribution of the whole tumor, necrotic core, and enhancing tumor regions within the dataset.

RESULTS

The proposed model achieved strong overall segmentation performance, with mean Dice scores of 0.8820 for enhancing tumor (ET), 0.8503 for tumor core (TC), and 0.8121 for whole tumor (WT) across all 11 CNS tumor types. Among individual tumor categories, the model demonstrated excellent performance in segmenting glioblastoma (Dice_ET: 0.9029, Dice_TC: 0.8993), brain metastases (Dice_ET: 0.9032, Dice_TC: 0.9073), and choroid plexus tumors (Dice_ET: 0.9729, Dice_TC: 0.9565), indicating high reliability in detecting both aggressive and well-enhanced lesions. Conversely, relatively lower Dice scores were observed in glioneuronal and neuronal tumors (Dice_ET: 0.6173, Dice_TC: 0.4588), which may be attributed to their diverse imaging patterns and limited training samples. Overall, the model maintained robust performance across both adult and pediatric tumor types, showcasing its potential for broad clinical applicability.

CONCLUSION

The unified model achieves accurate segmentation across 11 CNS tumor types by integrating deep supervision, attention mechanisms, and adaptive loss weighting, showing strong generalizability on both public and clinical datasets.

CLINICAL RELEVANCE/APPLICATION

This approach enables efficient, consistent, and scalable tumor segmentation using routine MRI, supporting clinical decision-making and reducing radiologist workload.

S3A-SPNR-14 MACHINE LEARNING-BASED CLASSIFICATION OF CEREBRAL AMYLOID ANGIOPATHY USING QUANTIFIED NON-HEMORRHAGIC MRI BIOMARKERS

Maryam Fotouhi, MD (*Presenter*)
Fardin Samadi Khoshe Mehr (*Abstract Co-Author*)
Nasim Sheikh Bahaei, MD,FRCR (*Abstract Co-Author*)
John Ringman (*Abstract Co-Author*)
Jeiran Choupan (*Abstract Co-Author*)

PURPOSE

To develop and validate a machine learning model using automatically quantified non-hemorrhagic imaging biomarkers from the Boston criteria, including perivascular space (PVS) enlargement and subcortical white matter hyperintensity (WMH) burden, to predict cerebral amyloid angiopathy (CAA).

METHODS AND MATERIALS

A total of 357 imaging sessions from the NACC cohort were included, with ground-truth CAA status determined by neuropathological postmortem confirmation (207 CAA-positive, 150 CAA-negative). Structural T1-weighted MRI scans were preprocessed using the Human Connectome Project (HCP) pipeline. PVS masks were generated using a Frangi filter-based segmentation algorithm, and PVS metrics (count and volume fraction) were extracted across Desikan-Killiany atlas regions, the centrum semiovale (CSO), and major lobar regions. WMH segmentation was performed on T2-FLAIR images using a consensus approach combining SAMSEG and LST-AI, categorizing lesions as subcortical, periventricular, juxtacortical, and infratentorial. Feature selection was performed using LASSO regression. Three classifiers—Random Forest, Support Vector Machine (SVM), and XGBoost—were trained on a balanced dataset generated through SMOTETomek oversampling and evaluated using an 80/20 train-test split. The best model parameters were selected via stratified five-fold cross-validation and subsequently validated on an independent test set.

RESULTS

PVS features, including counts within the basal ganglia, cingulate, temporal, and CSO, along with subcortical WMH count, were identified as the most predictive features through LASSO-based feature selection. Using these features, Random Forest (RF) achieved the highest classification performance on the independent test set, with an accuracy of 81.2%, sensitivity of 83.1%, specificity of 72.4%, and an area under the receiver operating characteristic (ROC) curve (AUC) of 0.80 (95% CI: 0.78 ± 0.04).

CONCLUSION

Non-hemorrhagic MRI features, particularly PVS enlargement and WMH burden, enabled accurate classification of CAA pathology. Adding hemorrhagic imaging markers in future studies may further enhance model performance and facilitate more comprehensive cerebrovascular risk assessment.

CLINICAL RELEVANCE/APPLICATION

Current CAA diagnostic frameworks, including the Boston criteria, rely primarily on hemorrhagic imaging markers assessed visually. This study demonstrates that using machine learning, non-hemorrhagic MRI features, specifically PVS enlargement and WMH burden quantified through automated methods, can supplement the prediction of pathologically confirmed CAA.

S3A-SPNR-15 ASSOCIATIONS BETWEEN ANTIHYPERTENSIVE TREATMENTS AND WHITE MATTER HYPERINTENSITY PROGRESSION IN AGING: INSIGHTS FROM THE ADOPIC CONSORTIUM

Maryam Rahmani, MD (*Presenter*)
Jeremy Strain (*Abstract Co-Author*)
Chia-Ling Phuah (*Abstract Co-Author*)
Donna Dierker (*Abstract Co-Author*)
Jingqin Luo (*Abstract Co-Author*)
Andrei Vlassenko, MD, PhD (*Abstract Co-Author*)

Michael W. Weiner, MD (*Abstract Co-Author*)
Colin Masters (*Abstract Co-Author*)
John C. Morris, MD (*Abstract Co-Author*)
Manu S. Goyal, MD, MSc (*Abstract Co-Author*)

PURPOSE

White matter hyperintensities (WMH) are common in aging brains and are presumed to be of vascular origin. Hypertension is associated with WMH and intensive hypertension treatment has been shown to reduce WMH progression. In this ongoing study we leverage a large dataset of harmonized WMH and clinical data from the ADOPIC consortium to study the longitudinal associations between antihypertensive treatments and WMH progression.

METHODS AND MATERIALS

The ADOPIC dataset merges harmonized amyloid PET, brain MRI, and clinical data from 3 large aging and Alzheimer disease neuroimaging cohorts (ADNI, AIBL, and OASIS-3), enhancing longitudinal statistical power. WMH volumes were quantified using the TrUE-Net algorithm. Antihypertensive medication use and different medication classes were identified through structured queries within each cohort. Linear mixed-effects models assessed associations between antihypertensive treatment and WMH growth, using log normalized global WMH volumes and adjusting for age, sex, AD biomarkers, and cardiovascular risk. Ongoing analyses examine class-specific medication effects upon WMH dynamics.

RESULTS

Drawing from 9,229 imaging and clinical datapoints across 3,589 ADOPIC participants, this analysis included 1,243 individuals (49% female; mean age 71.7) with at least three brain MRIs. At baseline, 52% reported using antihypertensive medications, including ACE inhibitors, calcium channel blockers, and beta-blockers each in over 10% of participants. Though antihypertensive treatment was associated with greater WMH volume at baseline, it was strongly and significantly associated with reduced WMH growth over time. Preliminary findings suggest possible medication class-specific effects, currently under ongoing analysis.

CONCLUSION

In this large, harmonized dataset of aging individuals, antihypertensive treatment was associated with slower progression of WMH over time. Ongoing analyses are evaluating for potential differences across medication classes.

CLINICAL RELEVANCE/APPLICATION

Anti-hypertensive treatment is significantly associated with reduced progression of white matter hyperintensities in aging individuals. Ongoing investigation of medication class-specific effects may inform more targeted approaches to reducing vascular contributions to cognitive decline.

S3A-SPNR-16 EGFR MUTATION SUBTYPES INFLUENCE LEPTOMENINGEAL METASTASIS MRI IMAGING FEATURESAND SURVIVALOUTCOMES IN LUNG ADENOCARCINOMA

Yizhen Jia (*Presenter*)
Mei Yuan (*Abstract Co-Author*)

PURPOSE

Leptomeningeal metastasis (LM) is a severe complication in lung adenocarcinoma (LUAD), particularly in patients with epidermal growth factor receptor (EGFR) mutations. However, the relationship between different EGFR mutation subtypes, their imaging characteristics on magnetic resonance imaging (MRI), and clinical prognosis remains unclear. This study aims to investigate the imaging features and survival outcomes among patients with EGFR L858R (Exon 21), EGFR del19 (Exon 19), and those with non-classic EGFR or other mutations (NCOM).

METHODS AND MATERIALS

A total of 110 LUAD patients with CSF-confirmed LM were retrospectively analyzed and categorized into three groups: EGFR 21 (n=43), EGFR 19 (n=29), and NCOM (n=38). Kaplan-Meier analysis and cox regression analysis was used to evaluate survival outcomes, while chi-square tests were applied to compare imaging characteristics across groups.

RESULTS

Patients with EGFR 21 mutations exhibited significantly longer intracranial progression-free survival (iPFS) and overall survival (OS) compared to the NCOM group, while EGFR 19 patients showed no survival advantage over NCOM. MRI findings revealed distinct imaging patterns among mutation subtypes, with significant differences in the presence of LM, meningeal involvement patterns, and the extent of brain lobe involvement. Notably, EGFR 21 patients had fewer affected brain lobes, while EGFR 19 patients were more likely to present as LM-negative on MRI.

CONCLUSION

Our findings suggest that EGFR mutation subtypes influence both prognosis and imaging characteristics in LUAD patients with LM. The differences in MRI patterns may provide valuable insights for early diagnosis and risk stratification, aiding in personalized treatment strategies.

CLINICAL RELEVANCE/APPLICATION

The high prevalence of MRI-negative LM in EGFR exon 19-mutant patients reveals the limitations of standard imaging. Distinct MRI patterns observed across EGFR mutation subtypes could serve as imaging biomarkers for risk stratification and guide individualized therapy. Prognostically, patients with EGFR exon 21 mutations tend to have more localized and detectable LM, potentially leading to earlier intervention and better treatment response, while EGFR exon 19-mutant LM—being diffuse and MRI-negative—may be associated with delayed diagnosis and poorer outcomes. Thus, mutation-specific differences in CNS involvement not only affect therapeutic

strategies but also have important prognostic implications. Integrating molecular and imaging markers into clinical decision-making could enhance early detection, treatment precision, and ultimately improve survival outcomes for EGFR-mutant LM patients.

S3A-SPNR-17 FREE WATER CORRECTED DIFFUSION MAGNETIC RESONANCE IMAGING REVEALS CORPUS CALLOSUM MICROSTRUCTURAL ALTERATIONS IN PRESCHOOLERS WITH AUTISM SPECTRUM DISORDER

Doudou Cao (*Presenter*)
Shijun Li (*Abstract Co-Author*)

PURPOSE

This study identified preschool children with autism spectrum disorder (ASD) related white matter microstructural changes in the corpus callosum (CC) using free water corrected diffusion magnetic resonance imaging(fwc-dMRI) method that mitigates partial volume effects from extracellular free water, and localized these changes to specific CC subregions.

METHODS AND MATERIALS

Sixty-one children with ASD (6.03±1.08 years) and sixty-two typically developing (TD) children (6.49±1.45 years) were enrolled in this study. Fwc-dMRI technique, a bi-tensor tractography method, was used to investigate the white matter microstructure, which models free water and brain tissues through isotropic and anisotropic tensors to eliminate the partial volume effects caused by extracellular free water. CC was segmented into seven parts automatically according to its alignment to the cortex by a robust machine learning approach based on an anatomically curated white matter atlas (Figure 1), ensuring reproducibility and anatomical accuracy. Fwc-dMRI-derived metrics—fractional anisotropy tissue (FA t), mean diffusivity (MD t), radial diffusivity (RD t), axial diffusivity (AD t), and free water (FW)—were extracted for each CC subregion. Group differences were assessed via independent samples t-test with false discovery rate (FDR) correction for multiple comparisons.

RESULTS

Significant group differences were localized to CC6 (connecting the temporal lobes) and CC1 (projecting to the orbital lobes): compared to TD, FA t value of CC6 in ASD decreased ($t = -3.251$, $P < 0.01$, FDR-corrected), RD t value of CC6 increased ($t = 3.632$, $P < 0.01$, FDR-corrected), and FW value of CC1 decreased ($t = -3.068$, $P < 0.05$, FDR-corrected). No significant differences were observed in MD t , AD t , or other CC subregions. (Table 1).

CONCLUSION

The microstructural disruption in CC6 (reduced FA t , elevated RD t) suggests compromised myelination in temporal lobe connectivity pathways, while reduced FW in CC1 may reflect diminished neuroinflammatory activity in orbital projections. These region-specific CC alterations highlight distinct pathological mechanisms in early ASD.

CLINICAL RELEVANCE/APPLICATION

Fwc-dMRI-derived metrics of CC6 and CC1offer novel imaging biomarkers for early ASD diagnosis and monitoring of targeted interventions.

Hoai H. Le (*Abstract Co-Author*)
Uyen Do (*Abstract Co-Author*)
THANH MINH NGUYEN (*Abstract Co-Author*)
Thach Nguyen (*Abstract Co-Author*)
Nguyen Quoc Khanh Le (*Abstract Co-Author*)

PURPOSE

To develop and evaluate a robust semi-supervised segmentation framework for transvaginal fetal ultrasound that reduces dependence on expert-labeled data while preserving high segmentation accuracy. This framework is designed to address specific challenges in transvaginal ultrasound imaging, including low tissue contrast, acoustic shadowing, speckle noise, and ambiguous anatomical boundaries caused by probe orientation and fetal movement. By leveraging a semi-supervised learning strategy, the proposed method aims to improve generalization to unseen data and enhance the efficiency of automated fetal and cervical structure delineation.

METHODS AND MATERIALS

To address these issues, we propose UltraMatch, a semi-supervised segmentation framework designed to reduce dependence on labeled data while enhancing model robustness under challenging ultrasound conditions. UltraMatch builds upon the GapMatch approach, which applies instance perturbation (input-level augmentation) and model perturbation (e.g., dropout) to enforce prediction consistency. These perturbations work in an iterative, mutually reinforcing way to improve generalization and drive the decision boundary into low-density regions. Furthermore, to better mimic ultrasound-specific noise, UltraMatch incorporates an adversarial augmentation module based on the Iterative Fast Gradient Sign Method (I-FGSM), generating strong perturbations that simulate real ultrasound distortions.

RESULTS

We evaluated UltraMatch on the Fetal Ultrasound Grand Challenge (FUGC) dataset, focusing on segmenting the pubic symphysis and fetal head—two key anatomical structures in labor progression monitoring. Our method achieved average Dice score of 0.9583 and average Hausdorff Distance (HD) of 5.2697 , outperforming both fully-supervised baselines and several state-of-the-art semi-supervised segmentation approaches . The best performance was consistently reached after only 35 training epochs.

CONCLUSION

UltraMatch demonstrates the value of combining dual-perturbation consistency with adversarial augmentation to improve segmentation robustness and accuracy, especially in data-limited, noise-prone ultrasound scenarios.

CLINICAL RELEVANCE/APPLICATION

UltraMatch offers a practical and efficient solution for real-world ultrasound segmentation, enabling accurate localization of fetal structures with reduced annotation cost, supporting better decision-making during pregnancy and labor monitoring.

S3A-SPOB-2 ANALYSIS OF MRI FINDINGS AND FOLLOW-UP OUTCOMES IN EARLY-ONSET VERSUS LATE-ONSET FETAL VENTRICULOMEGALY/TOP NORMAL VENTRICLES

Ali Borhani, MD, MD (*Presenter*)
Behnaz Moradi, MD (*Abstract Co-Author*)
Maryam Movahedi (*Abstract Co-Author*)
Masoumeh Gity, MD (*Abstract Co-Author*)
Sedigheh Hantoushzadeh (*Abstract Co-Author*)
Mahboobeh Shirazi, MD (*Abstract Co-Author*)
Mohammad Ali Kazemi, MD (*Abstract Co-Author*)
Bijan Bijan, MD, MBA (*Abstract Co-Author*)

PURPOSE

To review the prenatal MRI findings and postnatal outcomes of Early-onset versus Late-onset cerebral ventriculomegaly.

METHODS AND MATERIALS

This is a retrospective cohort study of 266 fetuses who were diagnosed with early-onset (before 24 weeks), and late-onset ventriculomegaly/top normal ventricles (at 24 weeks or later)and underwent fetal MRI over the past 8 years. patients were divided into two main groups and six subgroups (top normal, mild and severe ventriculomegaly) based on the severity of it. MRI findings and patient outcomes, including developmental disorders and fetal death, will be analyzed and compared between the groups.

RESULTS

Among the 266 infants evaluated, 197 (74.1%) were classified within the late-onset group, while 69 (25.9%) were categorized as early-onset. The analysis demonstrated that asymmetric ventriculomegaly was more commonly observed in cases of late-onset, mild to moderate ventriculomegaly, whereas bilateral ventriculomegaly was more prevalent among fetuses with early-onset and severe ventriculomegaly ($p < 0.001$). Central nervous system (CNS) and non-CNS anomalies were detected at a higher rate in the early-onset severe group ($p < 0.0001$, $p = 0.338$). Infants with late-onset and top normal ventricles were associated with higher rates of live birth and favorable neurodevelopmental outcomes. Conversely, postnatal mortality and neurodevelopmental impairment were increased in the late-onset severe ventriculomegaly group ($p < 0.0001$).

CONCLUSION

Significant differences in CNS abnormalities, non-CNS abnormalities, live birth rates, and neurodevelopmental outcomes were observed between the early and late groups, with fetuses exhibiting early and severe ventriculomegaly demonstrating the poorest prognosis across the six subgroups.

CLINICAL RELEVANCE/APPLICATION

To improve understanding of the outcomes associated with ventriculomegaly in fetuses

S3A-SPOB-3 STUDY ON THE CORRELATION BETWEEN CEREBRAL OXYGEN METABOLISM IN GRAY MATTER NUCLEI AND COGNITIVE FUNCTION CHANGES IN PREGNANT WOMEN WITH PREECLAMPSIA

Na Wang (*Presenter*)
Linfeng Yang (*Abstract Co-Author*)
Tao Chen (*Abstract Co-Author*)
Xinyue Zhang (*Abstract Co-Author*)
Qingqing Wang (*Abstract Co-Author*)
Qihao Zhang, BS (*Abstract Co-Author*)
Lingfei Guo, MD (*Abstract Co-Author*)
Yi Wang, PhD (*Abstract Co-Author*)

PURPOSE

To investigate the changes of cerebral oxygen metabolism in the deep nucleus during pregnancy in patients with preeclampsia based on region of interest (ROI), and to analyze the relationship between the changes of cerebral oxygen metabolism and cognitive function.

METHODS AND MATERIALS

This study included 112 non-pregnant healthy controls (NPHCs), 43 pregnant healthy controls (PHCs) and 103 patients with preeclampsia aged 20 to 40 years. Quantitative susceptibility mapping plus quantitative blood oxygen level dependent magnitude (QSM+qBOLD, or QQ) were used to obtain OEF maps. Then, the hippocampus, amygdala, striatum, thalamus and nucleus accumbens were automatically segmented using freesurfer and the corresponding OEF values were extracted. Analysis of covariance (ANCOVA) was used to compare the differences in OEF values of each nucleus among the three groups. Regression analysis was used to explore the influencing factors of OEF values in preeclampsia and its correlation with cognitive function in pregnant women.

RESULTS

After Bonferroni correction, the OEF values of amygdala ($F = 5.082$, $P = 0.035$), striatum ($F = 5.681$, $P = 0.020$) and nucleus accumbens ($F = 5.254$, $P = 0.030$) in preeclampsia group were significantly higher than those in NPHCs and PHCs groups. Regression analysis showed that OEF values of amygdala ($t = 2.579$, $P = 0.012$), striatum ($t = 2.033$, $P = 0.046$) and nucleus accumbens ($t = 2.347$, $P = 0.022$) were positively correlated with hemoglobin in preeclampsia patients. Furthermore, the OEF value of striatum was positively correlated with P-tau181 ($t = 3.101$, $P = 0.003$) and negatively correlated with t-tau ($t = -2.274$, $P = 0.026$). The OEF value of amygdala was negatively correlated with fasting blood glucose ($t = -2.117$, $P = 0.038$). Cognitive correlation analysis showed that the time to complete trail making tests (TMT) B was negatively correlated with preeclampsia ($t = -3.363$, $P = 0.001$), positively correlated with the OEF value of amygdala ($t = 2.811$, $P = 0.006$), and negatively correlated with the OEF value of nucleus accumbens ($t = -2.363$, $P = 0.019$).

CONCLUSION

The present study found that OEF values in the amygdala, striatum, and nucleus accumbens were significantly increased in preeclampsia pregnant women, indicating altered regional oxygen metabolism. Although TMT-B performance appeared better in preeclampsia, his may reflect a transient compensatory response to sympathetic activation rather than true cognitive enhancement.

CLINICAL RELEVANCE/APPLICATION

This study highlights altered cerebral oxygen metabolism patterns in preeclampsia and their potential cognitive implications, offering novel insights into the neurovascular pathophysiology of pregnancy-related brain dysfunction.

S3A-SPPD-1 EFFECT OF HEPATIC IRON DEPOSITION ON HEPATOCELLULAR PHASE IMAGES IN GD-EOB-DTPA CONTRAST-ENHANCED MRI ASSESSMENT OF PEDIATRIC ONCOLOGY PATIENTS

Jun Tsukamoto, MD (*Presenter*)
Ayako Imai, MD (*Abstract Co-Author*)
Reiko Okamoto (*Abstract Co-Author*)
Mikiko Miyasaka, MD (*Abstract Co-Author*)
Yoshiyuki Tsutsumi, MD (*Abstract Co-Author*)
Takatoshi Aoki, MD, PhD (*Abstract Co-Author*)
Osamu Miyazaki, MD (*Abstract Co-Author*)

PURPOSE

To assess whether transfusion-induced hepatic iron deposition in pediatric cancer patients results in poor enhancement in the hepatocellular phase of Gd-EOB-DTPA contrast-enhanced MRI.

METHODS AND MATERIALS

This retrospective study included 100 examinations from 46 pediatric cancer patients (with hepatoblastoma, neuroblastoma, etc.), aged 0.08 - 19.08 years (mean, 4.45years), who underwent Gd-EOB-DTPA-enhanced liver MRI between January 2020 and October 2024. The signal intensity of the liver parenchyma was measured at three locations on the in-phase and out-of-phase T1-weighted images, and the median signal intensity ratio (in-phase/out-of-phase: I/O ratio) was calculated. The liver-to-portal vein signal intensity ratio (L/PV ratio) during the hepatocellular phase was also obtained. The relationship between the I/O ratio and the L/PV ratio was statistically analyzed using a linear mixed-effects model, taking into account repeated measurements. The I/O ratio was classified as in being less than 0.88 or not, based on previous literature.

RESULTS

In the linear mixed-effects model, the fixed effect of I/O ratio (less than 0.88 or not) on L/P ratio showed a significant negative association (regression coefficient: -0.10 [95% confidence interval: -1.64- -0.34], p=0.004). The number of red blood cell transfusions was significantly higher in patients with an I/O ratio < 0.88 (mean 29.5) than in those with an I/O ratio = 0.88 (mean 7.5, P < 0.01) .

CONCLUSION

Transfusion-induced hepatic iron overload is associated with reduced enhancement in the hepatocellular phase on Gd-EOB-DTPA-enhanced MRI in pediatric oncology patients. This might affect the diagnostic utility of hepatocellular imaging in this population.

CLINICAL RELEVANCE/APPLICATION

In pediatric patients with suspected transfusion-related hepatic iron deposition, hepatocellular phase images on Gd-EOB-DTPA-enhanced MRI might be suboptimal. Radiologists should consider the possibility of hepatic iron overload when interpreting such images.

S3A-SPPD-2 PEDIATRIC INCLUSION MATTERS: IMPROVING DEEP LEARNING BASED LUNG LOBE SEGMENTATION ACCURACY FOR PEDIATRIC CT WITH MINIMAL PEDIATRIC TRAINING DATA ON PHOTON COUNTING CT

Nolan Dang, BS (*Presenter*)
Nicholas Ekstrom (*Abstract Co-Author*)
Lorna Browne, MD, FRCR (*Abstract Co-Author*)
Anne Taylor (*Abstract Co-Author*)
Donglai Huo, PhD (*Abstract Co-Author*)
Wei Zhou, PhD (*Abstract Co-Author*)

PURPOSE

Lung lobe measurements such as flow perfusion from pediatric CT can provide critical evidence for managing congenital heart disease (CHD) patients. The accuracy of lobe segmentation is fundamental to the quantification accuracy. The morphological variations and positional differences in pediatric patients make the segmentation task challenging for models trained on adult data. This study is to develop and evaluate a deep learning model for accurate lung lobe segmentation for pediatric chest CT scans.

METHODS AND MATERIALS

A nnU-Net-based 3D segmentation model was initially trained on LUNA16 adult chest CT dataset (44 cases, annotated for all 5 lobes). The dataset was randomly divided into training (34), validation (5), and test (5) subsets to develop a model for adult lung lobe segmentation (A-LobeSeg). Subsequently, 6 pediatric chest CTA cases (age: 20 days ~ 8 years) acquired on a photon counting CT (Alpha, Siemens), were manually annotated for lobe segmentation. 4 pediatric cases were randomly selected and added to the adult training set, and the model was fine-tuned using combined dataset to create a comprehensive model (C-LobeSeg). The remaining 2 pediatric cases were used for independent testing. Model performance was assessed using Dice similarity coefficient (DSC), symmetric surface distance (SSD) and Hausdorff distance (HD), comparing the predicted lobe against the ground truth annotations. All processing was performed with a GeForce RTX 4070.

RESULTS

With 4 added pediatric training cases, C-LobeSeg (DSC: 0.843 ± 0.130) performed significantly better than the original A-LobSeg model (DSC: 0.475 ± 0.330) on pediatric test cases, while achieving comparable performance on adult test cases: C-LobeSeg (DSC: 0.956 ± 0.038) vs A-LobeSeg (DSC: 0.954 ± 0.038). The SSD and HD values from both models showed similar trends as DSC. Combining both adult and pediatric data, the C-LobeSeg showed higher overall accuracy (DSC: 0.924 ± 0.091) than A-LobeSeg (DSC: 0.818 ± 0.280).

CONCLUSION

Our results showed improved performance of pediatric lung lobe segmentation when including very limited pediatric data during training phase. This study proves the importance of adding pediatric-specific data when training deep learning-based networks for pediatric imaging applications.

CLINICAL RELEVANCE/APPLICATION

To the best of our knowledge, all existing lobe segmentation tools, whether FDA-approved or used off-label, were developed without incorporating pediatric data and often perform poorly on small patients' data. This study examined the impact of including pediatric cases in deep learning training and proved that inclusion of pediatric data can significantly improve performance and be used to quantify lobe specific blood flow data for CHD patients.

S3A-SPPD-3 ENHANCED DETECTION OF PEDIATRIC SKULL FRACTURE IN EMERGENCY ROOM USING MULTI-LABEL SEGMENTATION

Sungchul On (*Presenter*)
Yoojin Nam, MD (*Abstract Co-Author*)
Gyounghyun Lim (*Abstract Co-Author*)
Junhyeok Ock, MSc (*Abstract Co-Author*)
Dongyeong Kim, MD (*Abstract Co-Author*)
Gil-Sun Hong, MD, PhD (*Abstract Co-Author*)
Namkug Kim, PhD (*Abstract Co-Author*)

PURPOSE

To improve the accuracy of pediatric skull fracture detection by developing a segmentation model that incorporates cranial suture lines and skull labels to differentiate fractures from normal anatomical structures.

METHODS AND MATERIALS

We collected 180 pediatric trauma head CT scans (89 fractures, 91 normal) from a tertiary medical center and 26 scans (13 fractures, 13 normal) from the CQ500 dataset for external validation. The internal dataset was split into training, validation, and test sets (8:1:1), ensuring balanced fracture and normal case distributions. Segmentation masks for suture, fracture, and skull structures were manually generated by a fourth-year radiology resident and verified by a board-certified radiologist. Four models with different label configurations were trained to evaluate the skull fracture segmentation: (1) a fracture-only model, (2) subtracting the output of a suture line model from that of a combined skull line model, (3) a multi-label model of fracture and suture labels, and (4) an extended multi-label model with the broader anatomical context of fractures, sutures, and the skull labels. Models were trained with the 3D nnU-Net framework for 500 epochs with batch size 1 and a combined Dice and focal loss. Metrics included Dice scores, bounding box IoU, and rule-based classification (fracture-positive if any fracture region was detected) with sensitivity, specificity, and accuracy.

RESULTS

The 3rd and 4th models achieved the highest performance, with bounding box IoUs of 63.43% and 70.01% and fracture segmentation Dice scores of 48.67% and 42.61%. Despite the lack of statistical significance between their segmentation performances, both models outperformed the 1st and 2nd models (Label Dice: 40.16%, 37.71%; BBox IoU: 56.01%, 47.29%). For classification, both 3rd and 4th models achieved a sensitivity of 100%. However, the 4th model showed better specificity (72.7% vs. 36.4%), fewer false positives (3 vs. 7), and a higher accuracy (85% vs. 65%) compared to the 3rd model. Although the difference in specificity was not statistically significant ($p = 0.199$), the 4th model identified twice as many true negatives (8 vs. 4), indicating better clinical reliability. External validation further confirmed the robustness of the 4th model with an accuracy of 84%.

CONCLUSION

This model enables automated skull fracture detection in pediatric emergency cases, improving the identification of subtle fractures from normal anatomical structures.

CLINICAL RELEVANCE/APPLICATION

AI-assisted detection of skull fractures in pediatric head CT enhances diagnostic accuracy by highlighting overlooked regions, reducing missed injuries in emergency pediatric head trauma cases.

S3A-SPPH-2 EARLY DETECTION OF CORONARY ARTERY DISEASE USING PHYSICS-INFORMED MULTI-MATERIAL DECOMPOSITION IN PATIENTS WITH ZERO CALCIUM SCORE

Dale Black, BS (*Presenter*)
Christine Nguyen (*Abstract Co-Author*)
Sabee Y. Molloi, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate if Physics-Informed Multi-Material Decomposition (PiMMD) identifies risk for future coronary artery calcium (CAC) progression and Major Adverse Cardiovascular Events (MACE) in patients with zero Agatston score, compared to conventional single energy multi-material decomposition (SE-MMD).

METHODS AND MATERIALS

A previously proposed physics-informed neural network (PiMMD) was used. This network decomposes single-energy CT images into 5 basis materials per voxel (calcium, collagen, water, lipid, air) using a physics-informed loss function. Its architecture, trained with high-fidelity ground truth data, overcomes the two-material per-voxel limitation of conventional SE-MMD. The PiMMD network was applied to baseline scans from the Multi-Ethnic Study of Atherosclerosis (MESA) cohort. Patients from this cohort were grouped into five categories: 1 (high Agatston, MACE+), 2 (moderate Agatston, MACE+), 3 (baseline Agatston=0, follow-up Agatston>0, MACE+), 4 (baseline Agatston=0, follow-up Agatston=0, MACE-), and 5 (high Agatston, MACE-). PiMMD and SE-MMD derived Calcium and Collagen mass were compared between all groups. Primary analysis focused on discriminating these mass measurements between Category 3 (N=10) and Category 4 (N=15), the key groups with identical baseline Agatston=0 but divergent outcomes, via ROC analysis (AUC).

RESULTS

Comparing these zero-baseline groups, PiMMD Calcium mass trended higher in the progression group vs stable controls (Mean±SD: 20.5±43.7 vs 5.5±10.8 mg). PiMMD Collagen mass also trended higher (7.9±24.7 vs 0.1±0.1 mg). SE-MMD showed a similar trend for Calcium mass (19.7±33.4 vs 10.5±11.2 mg) but minimal difference for Collagen mass (5044.3±2336.2 vs 4921.8±1666.9 mg), with high absolute values reflecting noise amplification inherent to the method. For these groups, indistinguishable by their identical zero Agatston scores, ROC analysis showed PiMMD Calcium (AUC=0.613) and Collagen (AUC=0.543) outperformed chance (AUC=0.50) and SE-MMD (Calcium AUC=0.467; Collagen AUC=0.507). Qualitative examples demonstrate PiMMD's superior noise suppression and material specificity, revealing subtle calcifications and associated collagen deposits that remain obscured by noise in SE-MMD.

CONCLUSION

Baseline PiMMD Calcium and Collagen measurements show potential to differentiate progressing from stable zero-Agatston score patients, outperforming SE-MMD. This AUC improvement suggests PiMMD may detect subclinical disease missed by conventional methods, warranting larger studies.

CLINICAL RELEVANCE/APPLICATION

PiMMD analysis of conventional CT scans may improve risk stratification beyond Agatston scoring by identifying subclinical plaque in zero Agatston score patients.

S3A-SPPH-3 LITA: LIVER TUMOR DIAGNOSIS ON MULTI-PHASE CONTRAST-ENHANCED CT WITH THREE CLINICALLY VALUABLE TASKS

Yuan Gao, MSc, PhD (*Presenter*)
ZHANG XIAOMING (*Abstract Co-Author*)
Xiaoli Yin (*Abstract Co-Author*)
Wei Liu, MSc (*Abstract Co-Author*)
Xu Han (*Abstract Co-Author*)
Chunli Li (*Abstract Co-Author*)
Ling Zhang (*Abstract Co-Author*)
Ke Yan (*Abstract Co-Author*)
Yu Shi, MD (*Abstract Co-Author*)

PURPOSE

We present a novel deep learning framework called LITA (LIver Tumor diAgnosis network) for accurate differential diagnosis of liver tumors using multi-phase contrast-enhanced computed tomography (CECT). LITA is used in three diagnostic tasks: cirrhotic liver nodule evaluation, metastatic lesion detection, and early-stage HCC detection.

METHODS AND MATERIALS

LITA employs a dual-headed architecture featuring a segmentation head for lesion delineation and a classification head for patient-level diagnosis. It was trained using a dataset with 2,330 CECT from two centers, with 12,302 meticulously annotated lesions across eight categories (HCC, cholangiocarcinoma, metastasis, hemangioma, cyst, FNH, calcification, and others). We further enhanced the model by incorporating patient clinical history data to improve diagnostic accuracy.

RESULTS

In cirrhotic liver nodule characterization (n=100, 50 benign vs. 50 malignant), LITA achieved good performance (sensitivity: 0.943, specificity: 0.875) compared to both junior radiologists (=10 years' experience; sens: 0.577, spec: 0.921) and senior radiologists (>10 years; sens: 0.652, spec: 0.951). For liver metastasis detection (n=60, 30 positive), LITA's performance is (sens: 0.920, spec: 0.857), while radiologists' performance is junior (sens: 0.563, spec: 0.750) and senior radiologists (sens: 0.737, spec: 0.888). For early-stage HCC (<2cm) detection (n=150, 50 positive), LITA achieved a sens. of 0.930, spec. of 0.860, comparable to senior radiologists reading contrast-enhanced MR. Through score-level fusion of imaging and clinical features, the system achieved further improvements in diagnostic accuracy, with AUCs increasing from 0.945 to 0.964 for HCC and 0.929 to 0.964 for metastasis detection.

CONCLUSION

LITA demonstrates good performance in three clinically valuable diagnostic scenarios, namely cirrhotic liver nodule evaluation, metastatic lesion detection, and early-stage HCC detection, where traditional radiological interpretation is challenging. In all tasks, LITA's sensitivity significantly surpasses junior and senior radiologists. The system's ability to effectively integrate clinical information with imaging features through score-level fusion further enhances its diagnostic capability.

CLINICAL RELEVANCE/APPLICATION

LITA provides radiologists with a diagnostic aid for liver tumor detection and characterization, potentially expediting workflow and improving diagnostic confidence. The system's high sensitivity for malignant cirrhotic liver nodule identification, metastasis detection, and early HCC detection may be particularly valuable for screening high-risk populations, enabling earlier intervention and improved patient outcomes.

S3A-SPPH-4 INCORPORATING CLINICAL KNOWLEDGE INTO AI-DRIVEN PRECISE LIVER FIBROSIS STAGING USING NON-CONTRAST CT

Chunli Li (*Presenter*)
Yuan Gao, MSc, PhD (*Abstract Co-Author*)
ZHANG XIAOMING (*Abstract Co-Author*)
Wei Liu, MSc (*Abstract Co-Author*)
Ke Yan (*Abstract Co-Author*)
Yu Shi, MD (*Abstract Co-Author*)

PURPOSE

We developed and validated a large-scale multi-center non-contrast (NC) CT-based model for liver fibrosis staging, integrating liver segments into the network to capture shape and texture variations among different liver segments.

METHODS AND MATERIALS

Our study used 2,178 patients from center A for development, 572 patients with NC-CT and biopsy-confirmed fibrosis stages for internal validation, and an external cohort of 1,542 patients from 7 centers for generalizability test. We trained a liver segment segmentation model to integrate clinical knowledge into the model as the shape and size of liver segments is correlated with fibrosis. We concatenate the segment mask with NC-CT and then input them into a network combining a Convolutional Neural Network (CNN) and a Vision Transformer (ViT), enhanced with a Mixture of Experts system (MoE), for fibrosis classification. Model performance was gauged using the area under the receiver operating characteristic curve (AUC).

RESULTS

For the classification of F0-F1 vs. =F2 fibrosis grades, the AUCs were 0.843 and 0.865 for internal and external test cohorts, respectively; for F0-F2 vs. =F3, the AUCs were 0.916 and 0.914; and for F0-F3 vs. F4 (cirrhosis), the AUCs reached 0.939 and 0.916. Moreover, the model also showed good diagnostic performance in both chest and abdominal NC-CT subgroups. Notably, our approach demonstrated superior performance compared to Ultrasonic Transient Elastography (UTE) and five serological methods, with the observed differences reaching statistical significance.

CONCLUSION

Integrating clinical knowledge with CNN, ViT, and an MoE system, our proposed model accurately captures liver texture, shape, and size, outperforms UTE and serological methods in multi-cohort fibrosis staging (especially with chest NC-CT), providing a reliable non-invasive diagnostic alternative, and enables early screening across clinical settings.

CLINICAL RELEVANCE/APPLICATION

This study presents a novel, large-scale, multi-center validated model for liver fibrosis staging using NC-CT. By incorporating liver segment information and advanced neural network architectures, the model provides accurate and consistent results across diverse patient cohorts. This non-invasive approach may reduce the need for liver biopsies, avoiding patient discomfort and potential complications. Moreover, its superior performance compared to serological methods suggests that it could serve as a practical and efficient tool in clinical settings, facilitating early detection and management of liver fibrosis, and ultimately improving patient outcomes.

S3A-SPPH-5 WHOLE-LUNG DYNAMIC PERFUSION AREA-DETECTOR CT IN NON-SMALL CELL LUNG CANCER WITH PROGRESSIVE FIBROSING INTERSTITIAL LUNG DISEASE

Yoshiharu Ohno, MD, PhD (*Presenter*)
Daisuke Takenaka, MD (*Abstract Co-Author*)
Yasuko Fujisawa, MS (*Abstract Co-Author*)
Takeshi Yoshikawa, MD (*Abstract Co-Author*)
Kenji Fujii (*Abstract Co-Author*)
Yuya Ito (*Abstract Co-Author*)
Hirona Kimata (*Abstract Co-Author*)
Naruomi Akino (*Abstract Co-Author*)
Takahiro Ueda, MD, PhD (*Abstract Co-Author*)
Masahiko Nomura, MD, PhD (*Abstract Co-Author*)
Yoshiyuki Ozawa, MD, PhD (*Abstract Co-Author*)

PURPOSE

Since 2011, dynamic first-pass CE-perfusion area-detector CT (ADCT) has been in use for CT-based real perfusion matrix evaluation of not only nodules, but also lung cancer management. However, this technique has not been tested for evaluating the dynamic first-pass CE-perfusion matrix based on lung parenchymal changes and disease severity of lung parenchyma diseases. The purpose of this study was to determine the capability of whole-lung dynamic contrast-enhanced (CE-) perfusion area-detector CT (ADCT) for detecting pathological structural changes in stage I non-small cell lung cancer (NSCLC) patients.

METHODS AND MATERIALS

Sixty-three consecutive stage I NSCLC patients with progressive fibrosing interstitial lung disease (PF-ILD) underwent dynamic CE-perfusion ADCT examinations at two or three stations as a single examination, analyzed by dual-input maximum slope (DMS) methods, generated whole-lung total, pulmonary arterial and systemic arterial perfusion (TP DMS , PAP DMS and SAP DMS) maps, surgical treatment and pathological examination. Multicentric ROIs were then placed over sites assessed as normal lung, pulmonary emphysema, GGO or reticular pattern without traction bronchiectasis, reticular pattern with traction bronchiectasis and honeycombing in the resected lung. Next, an analysis of variance (ANOVA) followed by Tukey's honest significant difference (HSD) multiple comparison test was performed for a comparison of each of the perfusion parameters for five groups. Finally, discrimination accuracy for evaluation of lung parenchymal change was compared for all indexes and combined methods.

RESULTS

PAP DMS s of abnormal lungs were significantly lower than that of normal lungs ($p<0.0001$). SAP DMS s of normal or emphysematous lungs were significantly lower than those of others ($p<0.0001$). SAP DMS of GGO or reticular pattern without traction bronchiectasis was significantly lower than that for reticular pattern with traction bronchiectasis and honeycombing ($p<0.0001$). Discrimination accuracy of combined perfusion index was significantly higher than that of each index ($p<0.0001$).

CONCLUSION

Whole-lung dynamic CE-perfusion ADCT is useful for detecting pathological structural changes in stage I NSCLC patients with PF-ILD.

CLINICAL RELEVANCE/APPLICATION

Whole-lung dynamic CE-perfusion ADCT is useful for detecting pathological structural changes in stage I NSCLC patients with PF-ILD.

S3A-SPPH-6 COMPARISON OF CAPABILITY FOR POSTOPERATIVE RECURRENCE PREDICTION WITH MOLECULAR-BASED INFORMATION AMONG SINGLE AND MULTIPARAMETRIC MRIS AND FDG-PET/CT IN STAGE I NON-SMALL CELL LUNG CANCER PATIENTS

Yoshiharu Ohno, MD, PhD (*Presenter*)
Masao Yui (*Abstract Co-Author*)
Kaori Yamamoto (*Abstract Co-Author*)
Natsuka Yazawa (*Abstract Co-Author*)
Masato Ikedo (*Abstract Co-Author*)
Masanori Ozaki (*Abstract Co-Author*)
Takahiro Ueda, MD, PhD (*Abstract Co-Author*)
Masahiko Nomura, MD, PhD (*Abstract Co-Author*)
Takeshi Yoshikawa, MD (*Abstract Co-Author*)
Daisuke Takenaka, MD (*Abstract Co-Author*)
Yoshiyuki Ozawa, MD, PhD (*Abstract Co-Author*)

PURPOSE

To compare the quantitative prediction capability for postoperative recurrence with molecular-based imaging information among single and multiparametric MRIs with chemical exchange saturation transfer (CEST) imaging and diffusion-weighted imaging (DWI) and FDG-PET/CT in stage I non-small cell lung cancer (NSCLC) patients.

METHODS AND MATERIALS

79 pathologically diagnosed and surgically treated NSCLC patients underwent CEST imaging, DWI and FDG-PET/CT as preoperative examinations, follow-up and pathological examinations. According to the follow-up and pathological examination results, all patients were divided as recurrence (n=13) and non-recurrence (n=66) groups. In each lesion, magnetization transfer ratio asymmetry at 3.5ppm (MTR asym), apparent diffusion coefficient (ADC) and SUV max of each nodule were assessed by ROI measurements. To compare all indexes between two groups, Student's t-test was performed. To determine the significant predictors from each index as well as other clinical information, multiple logistic regression analysis was performed among all indexes. Then, ROC analysis was performed to compare distinguishing two groups among all indexes and combined significant predictors. Finally, sensitivity (SE), specificity (SP) and accuracy (AC) were compared among all methods by McNemar's test.

RESULTS

There was significant difference of each index between two groups ($p<0.05$). Multiple logistic regression analyses determined MTR asym (Odds ratio [OR]: 1.31, $p=0.03$) and ADC (OR: 0.002, $p=0.008$) as significant predictors in this setting. When applied each feasible threshold value, SPs and ACs of MTR asym (SP: 81.8%, AC: 82.2%), ADC (SP: 87.9%, AC: 86.1%) and combined predictors (SP: 89.4%, AC: 89.9%) were significantly higher than those of SUV max (SP: 69.7%, $p<0.05$; AC: 72. %, $p<0.05$). Moreover, AC of combined predictors was significantly higher than that of MTR asym ($p=0.03$).

CONCLUSION

Single and multiparametric MRIs with CEST and DWI had better potential for postoperative recurrence prediction than FDG-PET/CT in stage I NSCLC patients. Moreover, DWI can improve prediction capability of CEST imaging in this setting.

CLINICAL RELEVANCE/APPLICATION

Single and multiparametric MRIs with CEST and DWI had better potential for postoperative recurrence prediction than FDG-PET/CT in stage I NSCLC patients. Moreover, DWI can improve prediction capability of CEST imaging in this setting.

S3A-SPPH-7 IMPROVING IMAGE QUALITY OF 40-KEV MONOENERGETIC IMAGES IN LOWER EXTREMITY DUAL-ENERGY CT VENOGRAPHY USING DEEP LEARNING IMAGE RECONSTRUCTION

Yanan Li (*Presenter*)
Jianxin Guo (*Abstract Co-Author*)

PURPOSE

To evaluate the usefulness of deep learning image reconstruction (DLIR) to improve the image quality of 40-keV monoenergetic images in the lower extremity dual-energy CT venography (DECTV).

METHODS AND MATERIALS

32 patients ((14 women and 18 men; mean age, 57.56±14.50 years; range, 28-75 years; mean body mass index, 24.54±2.72 kg/m 2) with suspected lower extremity varix and DVT underwent DECTV were enrolled. Monochromatic images obtained at 40keV were reconstructed using ASIR-V50%, DLIR at medium-, and high-intensity levels (DLIR-M, and DLIR-H) at 1.25mm. CT attenuation and standard deviation (SD) were measured in regions of interest (ROI) in the following locations: inferior vena cava (IVC), right femoral vein (FV), right popliteal vein (PV), and homogeneous subcutaneous fat and adductor muscle at the mid-level of the medial thigh. The signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) were calculated. The overall image quality and diagnostic confidence were scored on a 5-point scale. The repeated measures ANOVA test and Friedman test with the Bonferroni post-hoc test were performed to compare objective and subjective results.

RESULTS

There were no significant differences in CT values of IVC, FV, PV and adductor muscle among all reconstruction algorithms as shown in Table1. DLIR significantly reduced image noise compared to ASIR-V 50%, resulted in significantly higher SNR and CNR values (all $p < 0.001$). For DLIR-H, the CNR values of IVC, FV and PV at 40 keV images were improved by 78.08±9.28%, 78.52±9.51%, and 78.40±9.28%, respectively compared to ASIR-V 50%. The overall image quality and diagnostic confidence of DLIR was rated higher than ASIR-V 50%, with DLIR-H having the highest image quality score.

CONCLUSION

Compared to ASiR-V50% images, DLIR images had higher CNR and diagnostic confidence with lower image noise in 40-keV lower extremity DECTV, and DLIR-H provides the best overall image quality and highest diagnostic confidence.

CLINICAL RELEVANCE/APPLICATION

Deep learning image reconstruction (DLIR) is useful for reducing image noise and improving the CNR of 40keV monochromatic images in lower extremity dual-energy CT venography.

S3A-SPPH-9 OPPORTUNISTIC OSTEOPOROSIS DIAGNOSIS USING TEXTURE-PRESERVING SELF-SUPERVISED PRE-TRAINING AND MULTI-TASK FINE-TUNING WITH MIXTURE OF EXPERTS

Minfeng Xu (*Presenter*)
Jiaxing Huang (*Abstract Co-Author*)
Heng Guo, MS (*Abstract Co-Author*)
Jinrong Yang (*Abstract Co-Author*)
Le Lu (*Abstract Co-Author*)

Fan Yang, MD (*Abstract Co-Author*)
Wei Luo (*Abstract Co-Author*)

PURPOSE

Osteoporosis is a highly prevalent yet underdiagnosed disease, especially where DXA access is limited, it calls for alternative diagnostic strategies. CT-based opportunistic diagnosis offers a promising alternative but faces three key limitations: underutilization of unlabeled CT data (e.g., thoracic vertebrae without DXA reference), heterogeneity of reference DXA devices affecting model compatibility, and inadequate integration of vertebral microstructural features and spatial bone density differences. This study proposes a unified deep learning model to address these challenges.

METHODS AND MATERIALS

We conducted a multi-center retrospective study using data from three tertiary hospitals (Sites A, B, and C) for model development and one independent hospital (Site D) for external testing. After pre-processing, the dataset included 2230 patients (5001 vertebrae) for training, 374 patients (839 vertebrae) for validation, 1100 patients (2498 vertebrae) for internal testing and 193 patients (271 vertebrae) for external testing. An additional 30256 unlabeled thoracic vertebrae were used for pre-training. The framework incorporates three innovations: (1) a texture-preserving self-supervised learning (TP-SSL) captures bone texture features; (2) a device-adaptive Mixture of Experts (MoE) architecture addresses variability across DXA devices by dynamically integrating device-specific features and preventing over-fitting on any single device; (3) a multi-task learning paradigm combines vertebral localization, bone density prediction, and vertebral-level osteoporosis classification, leveraging spatial bone density patterns.

RESULTS

The model demonstrated superior and robust diagnostic performance across diverse clinical settings. Vertebal-level sensitivity/specificity: Site A (82.76%/89.16%), Site B (66.04%/93.85%), Site C (70.15%/95.17%), and external Site D (77.44%/87.68%). Patient-level sensitivity/specificity: Site A (89.93%/86.09%), Site B (79.10%/96.90%), Site C (75.86%/93.51%), and external Site D (77.89%/91.84%).

CONCLUSION

This study proposes a unified deep learning framework that integrates TP-SSL, MoE, and multi-task learning to tackle critical challenges in CT-based osteoporosis diagnosis. Extensively validated across multiple clinical sites and an external hospital, the framework consistently achieves robust, high diagnostic performance.

CLINICAL RELEVANCE/APPLICATION

By leveraging existing CT scans, the model offers a scalable, cost-effective solution for osteoporosis screening without additional radiation exposure or reliance on DXA. It can be deployed within routine CT workflows, facilitating early identification of individuals at risk and timely intervention.

S3A-SPRO-1 CT-BASED QUANTIFICATION OF INTRATUMORAL HETEROGENEITY FOR PREDICTING DISTANT METASTASIS IN RETROPERITONEAL SARCOMA

Jun Xu (*Presenter*)
Ning Lang, MD (*Abstract Co-Author*)

PURPOSE

Retroperitoneal sarcoma (RPS) is highly heterogeneous, leading to different risks of distant metastasis (DM) among patients with the same clinical stage. This study aims to develop a quantitative measure of intratumoral heterogeneity (ITH) on preoperative contrast-enhanced CT (CECT) scans and test its performance for predicting the risk of DM after complete surgical resection in RPS patients.

METHODS AND MATERIALS

We conducted a retrospective analysis of 474 PRS patients who underwent complete surgical resection and were monitored for =36 months at two centers. Conventional radiomics (C-radiomics), ITH radiomics, and deep learning (DL) features were extracted from the preoperative CECT scans and develop single-modality models. Clinical indicators and high-throughput CECT features were integrated to develop a combined model for predicting DM. The performance of the models was evaluated by measuring the receiver operating characteristic curve and Harrell's concordance index (C-index). Distant metastasis-free survival (DMFS) was also predicted to further assess survival benefits.

RESULTS

The ITH model demonstrated satisfactory predictive capability for DM in internal and external validation cohorts (AUC: 0.735, 0.765; C-index: 0.691, 0.729). The combined model that combined clinicoradiological variables, ITH-score and DL-score achieved the best predictive performance in internal and external validation cohorts (AUC: 0.864, 0.801; C-index: 0.770, 0.752), successfully stratified patients into high- and low-risk groups for DM ($p < 0.05$).

CONCLUSION

The combined model demonstrated promising potential for accurately predict the DM risk and stratifying the DMFS risk in RPS patients undergoing complete surgical resection, offering a valuable tool for optimizing treatment selection and follow-up strategies.

CLINICAL RELEVANCE/APPLICATION

The ITH analysis facilitates the identification of high-risk RPS patients prone to DM and poor prognoses, enabling the selection of candidates for more aggressive surgical and post-surgical interventions.

S3A-SPVA-1 EVALUATION OF IMAGE QUALITY, DIAGNOSTIC AGREEMENT, AND CLINICAL UTILITY OF MULTI-PHASE CTA DERIVED FROM DEEP LEARNING-BASED CEREBRAL PERFUSION IMAGING IN ACUTE ISCHEMIC STROKE

Shoushuai Wang (*Presenter*)
Xiaoyan Lei (*Abstract Co-Author*)
Ge Zhang (*Abstract Co-Author*)
Kun Ma (*Abstract Co-Author*)
Weiyuan Huang (*Abstract Co-Author*)
Feng Chen, MD, PhD (*Abstract Co-Author*)

PURPOSE

This study compares multi-phase CT angiography (mCTA) derived from deep learning image reconstruction (DLIR) of cerebral perfusion with conventional spectral mCTA using ASIR-50% for evaluating collateral circulation in acute ischemic stroke (AIS), aiming to explore a low-dose, efficient “one-stop” imaging approach and validate its diagnostic consistency with digital subtraction angiography (DSA).

METHODS AND MATERIALS

In this prospective study, 31 AIS patients (onset 6-12 hours) underwent cerebral perfusion CT (80 kV / 120 mA) and conventional spectral CTA (80-140 kV / 250 mA). Multi-phase CTA images were extracted from perfusion data. Group A images were reconstructed using high-level DLIR (DLIR-H); Group B (spectral CTA) images were reconstructed from 64 keV monochromatic images using ASIR-50%. Both image sets were processed using the FASTStroke workflow and COLORVIZ fusion technology on the GE AW platform to integrate arterial, venous, and late venous phases. Quantitative metrics included CT attenuation, image noise (SD), signal-to-noise ratio (SNR), and contrast-to-noise ratio (CNR) at the ICA siphon, M1 segment, and temporal muscle during the arterial phase. Collateral grading was assessed via COLORVIZ by two radiologists using Cohen’s kappa, with DSA ASITN/SIR scores as reference.

RESULTS

No significant differences were observed in CT attenuation of the ICA siphon or M1 segment between DLIR-H and ASIR-50% CTA ($P > 0.05$). However, DLIR-H showed significantly lower noise and higher SNR in the M1 segment, and lower CT values and noise in the temporalis muscle ($P < 0.05$), indicating enhanced clarity. CNR did not differ significantly between groups. Collateral grading using COLORVIZ revealed similar median scores between DLIR-H and ASIR-50% CTA (Radiologist A: 2 vs. 3, $P = 0.058$; Radiologist B: both 3, $P = 0.655$), with strong interobserver agreement (kappa = 0.794, 0.837). Compared with DSA, DLIR-H mCTA showed higher diagnostic accuracy (79.3% and 89.7% vs. 55.2% and 68.9% for spectral mCTA), confirming superior reliability in collateral assessment.

CONCLUSION

DLIR-H mCTA enables low-dose cerebral imaging with improved noise reduction and preserved vascular detail, showing strong consistency with DSA for collateral evaluation.

CLINICAL RELEVANCE/APPLICATION

This technique offers a noninvasive, efficient alternative to conventional CTA and partial substitute for DSA, especially suitable for patients near treatment windows or unsuitable for invasive procedures.

S3A-SPVA-2 DEVELOPMENT OF A NOVEL SCAN TIMING PROTOCOL BASED ON VENOUS PEAK FOR IMPROVED ENHANCEMENT IN CEREBRAL CTA

Katsuyuki Matsui (*Presenter*)

PURPOSE

In cerebral three-dimensional computed tomography angiography (3D-CTA), achieving preserved contrast enhancement in both arteries and veins remains challenging, especially when using single-phase acquisition method. Conventional scan timing typically relies on estimating the time point of maximum arterial enhancement, however variations in individual arteriovenous transit times (AVTT) can result in inconsistent venous visualization. Such variability can limit the accuracy of post-processing and radiological image interpretation To address this limitation, we developed a novel scan timing strategy using the venous peak as a reference. In this method, by measuring the AVTT via a Test Injection (TI) method and calculating the scan end time as 50% of the AVTT from the arterial peak, stable enhancement in both arterial and venous compartments can be expected; the purpose of the present study was to assess the effectiveness of our method.

METHODS AND MATERIALS

This retrospective study analyzed 60 patients (31 females, 29 males; mean age 61.5) who underwent conventional head 3D-CTA between 2021 and 2023. AVTT was measured using a TI-based Time Enhancement Curve, defined as the interval between arterial (TA) and venous (TV) peaks. Patients were grouped by scan end timing as a percentage of AVTT: A (=39%), B (40-49%), C (50-59%), and D (60-73%). Arterial and venous CT values were compared across groups. Scan start timing was estimated by backward calculation: Scan Delay = Time to Peak - (Scan Duration - AVTT/2). The Tukey-Kramer test was used for statistical analysis.

RESULTS

All groups maintained arterial enhancement above 500 HU. Group C (50-59%) showed the highest mean arterial CT value (597.4 ± 67.2 HU) and sufficient venous enhancement (434.2 ± 97.6 HU). Venous CT values increased with longer scan end times, with Group A (=39%) showing significantly lower venous enhancement. No significant difference was found among Groups B-D. Compared to the conventional method, the proposed method showed similar mean arterial values (591.9 ± 52.2 HU vs. 583.8 ± 66.3 HU) but reduced variability, particularly in venous values (SD: 45.1 vs. 138.6).

CONCLUSION

The proposed scan timing method, using the venous peak to estimate scan end time at 50% of AVTT, provides a stable and individualized method for cerebral CTA. It achieves consistent arterial and venous contrast enhancement while minimizing variability and enhancing reproducibility.

CLINICAL RELEVANCE/APPLICATION

This scan timing method improves venous enhancement stability without compromising arterial visualization, allowing more reliable vascular evaluation. It may reduce post-processing workload and operator dependency, facilitating standardized cerebral CTA in clinical practice.

S3A-SPVA-3 AREA-DETECTOR CT FOR ABDOMINAL AORTIC ANEURYSM FOLLOW-UP: INFLUENCE OF GRAVITY ON IMAGE QUALITY AND DIAMETER MEASUREMENTS IN ROUTINE CLINICAL PRACTICE

Masahiko Nomura, MD, PhD (*Presenter*)
Yui Takagi (*Abstract Co-Author*)
Yunosuke Kumazawa (*Abstract Co-Author*)
Yuya Ito (*Abstract Co-Author*)
Hirona Kimata (*Abstract Co-Author*)
Kenji Fujii (*Abstract Co-Author*)
Takahiro Ueda, MD, PhD (*Abstract Co-Author*)
Takeshi Yoshikawa, MD (*Abstract Co-Author*)
Daisuke Takenaka, MD (*Abstract Co-Author*)
Yoshiyuki Ozawa, MD, PhD (*Abstract Co-Author*)
Yoshiharu Ohno, MD, PhD (*Abstract Co-Author*)

PURPOSE

To determine the influence of gravity on image quality and abdominal aortic aneurysm (AAA) follow-up examination, when compared between upright and supine area-detector CTs (ADCTs) in routine clinical practice.

METHODS AND MATERIALS

This retrospective study included 50 AAA patients who underwent upright and supine ADCT examinations as follow-up CT and assessed as no requirement for surgery without any aneurysm expansion. For assessing quantitative image quality for abdominal structures between two CT systems, CT values and signal-to-noise ratios (SNRs) of abdominal aorta, inferior vena cave, liver, spleen, pancreas, kidney and fat were assessed with region of interest (ROI) measurements. To evaluate qualitative image quality of abdominal structures on each CT system, overall image quality and artifact were evaluated using a 5-point scale in all patients. On AAA evaluation in each patient, maximum long axis diameter (LAD max) and minimum short axis diameter (SAD min) were manually measured on the automatically selected slice which was perpendicular to the automatically drawn centerline of the abdominal aorta, and averaged to final values. To compare quantitative and qualitative image quality indexes, paired t-test and Wilcoxon signed-rank test were performed. To determine the relationship for each diameter measurement between two ADCTs, Spearman correlation was performed. To determine the influence of gravity on AAA diameter measurement, each index was compared between two ADCTs by paired t-test. Finally, each measurement difference between two ADCTs was determined by the Bland-Altman analysis.

RESULTS

Upright ADCT was determined as having significantly higher CT value for kidney and SNRs for liver and kidney than supine ADCT ($p<0.05$). Moreover, upright ADCT demonstrated significantly lower artifact than supine ADCT ($p=0.003$). In addition, upright ADCT demonstrated significantly excellent correlation with supine ADCTs (? =0.97, $p<0.0001$). Furthermore, upright ADCT showed significantly larger diameter than supine ADCT ($p<0.0001$). The limits of agreement between two ADCTs were determined as1.2±3.1 mm at LAD max , and 0.9±2.6mm at SAD min .

CONCLUSION

When AAA patients followed, upright ADCT demonstrates significantly larger diameter than supine ADCT due to gravity, although the difference had little influence on AAA management in routine clinical practice.

CLINICAL RELEVANCE/APPLICATION

When AAA patients followed, upright ADCT demonstrates significantly larger diameter than supine ADCT due to gravity, although the difference had little influence on AAA management in routine clinical practice.

S3B-SPBR-1 ASSOCIATION OF STATIN USE WITH BREAST ARTERIAL CALCIFICATION PROGRESSION

Alyssa T. Watanabe, MD (*Presenter*)

PURPOSE

Breast arterial calcification presence and extent are known risk markers for major adverse cardiovascular events. Statin use is associated with an increase in coronary calcium score. We studied the progression of breast arterial calcifications (BAC) scores in women who were statin users compared to those who were not.

METHODS AND MATERIALS

We retrospectively evaluated 27,780 full-field digital mammograms in 10,348 women (age 26-94 years, mean 56 years at index exam) performed 2006-2016 at a single Southwestern U.S. academic center. Imaging follow-up ranged 6 months-10 years (mean 4.1 years). We used an artificial intelligence model (AI) to generate a BAC score for each exam. BAC-positive scores were age-adjusted to derive percentiles, then binned by quartile (Q): 1st-25th (Q1), 26-50th (Q2), 51-75th (Q3) and 76-100th (Q4). Aalen-Johansen multi-state models estimated probabilities of transitioning to a higher quartile in 5 years. Risk of BAC progression in statin users and non-statin users compared to a reference group of BAC negative non-statin users was calculated as Hazard ratio (HR) which was adjusted for age.

RESULTS

Baseline statin use is associated ($p < 0.05$) with increased risk of five-year BAC progression: BAC-negative statin users had elevated risk of developing BAC with HR=1.44 [1.30-1.60]. Statin users with mild BAC (Q1) had HR= 4.53 [3.49-5.88] versus non-user HR= 3.52 [2.84-4.37]. Statin users with Q3 BAC had HR=2.55 [1.80-3.62] versus non-user HR= 1.59 [1.24-2.05].

CONCLUSION

BAC progression rate on mammography is significantly higher in women on statins. Statin users with mild (Q1) BAC at index had approximately a 29% higher BAC progression risk compared to non-users who also had mild (Q1) BAC. Statin users with higher BAC burden (Q3 BAC) at index had a 60% relative higher BAC progression risk compared to Q3 BAC non- statin users. This could be due to underlying metabolic disease and/or due to the medication itself.

CLINICAL RELEVANCE/APPLICATION

Statin use may be useful to consider as a contributing factor when evaluating progression of breast arterial calcification scores on mammography.

S3B-SPBR-2 COST-EFFECTIVENESS OF MR FINGERPRINTING IN EVALUATING RESPONSE TO NEOADJUVANT CHEMOTHERAPY IN PATIENTS WITH TRIPLE NEGATIVE BREAST CANCER

Zoe Kao, PhD (*Presenter*)
Kinpritma Sangha, PhD, MPH (*Abstract Co-Author*)
Holly N. Marshall, MD (*Abstract Co-Author*)
Bahar Moftakhar (*Abstract Co-Author*)
Mark A. Griswold, PhD (*Abstract Co-Author*)
Chris A. Flask, PhD (*Abstract Co-Author*)
Yong Chen (*Abstract Co-Author*)

PURPOSE

Imaging during neoadjuvant chemotherapy (NACT) for triple negative breast cancer (TNBC) can identify non-responders early, enabling timely treatment adjustments and improving survival outcomes. MR fingerprinting (MRF), a novel quantitative approach that can generate T1 and T2 maps in 5 minutes, can detect response within a week of NACT initiation with higher accuracy than standard imaging. To understand the economic value of MRF, our study evaluates the cost-effectiveness of MRF-guided NACT strategies compared to conventional imaging approaches and no imaging in TNBC patients.

METHODS AND MATERIALS

We developed a Markov model simulating lifetime outcomes for a cohort of TNBC patients undergoing NACT with KEYNOTE-522 regimen (pembrolizumab plus chemotherapy) from a health sector perspective. Five imaging modalities (MRF, MRI, ultrasound [US], PET/CT, mammography) were evaluated when performed during the first two cycles of NACT. Patients were classified as responders or non-responders based on modality-specific sensitivity/specificity (MRF: 81%/95%, MRI: 67%/85%, US: 43%/88%, PET/CT: 75%/97%, mammography: 81%/48%). Responders continued KEYNOTE-522 therapy. For non-responders, we modeled two strategy sets for each modality: (1) imaging-guided NACT adjustment: patients switched to chemotherapy alone prior to surgery; (2) imaging-guided direct-to-surgery: patients immediately underwent surgery. Standard care (SC) without imaging was the comparator. Strategies were compared using lifetime costs, quality-adjusted life years (QALYs), and incremental cost-effectiveness ratios (ICERs) at a willingness-to-pay (WTP) threshold of $100,000/QALY gained. Due to lack of cost data, MRF cost was set at $1,500 in the base-case analysis with a threshold analysis to determine cost-effectiveness cost range.

RESULTS

SC yielded 13.47 QALYs at the highest lifetime cost of $494,061 among all strategies (Table). MRF-guided and PET/CT-guided NACT adjustment strategies both outperformed SC by delivering more QALYs at lower lifetime costs. At the imaging cost of $1,500, MRF-guided NACT adjustment proved most effective (13.61 QALYs) with an ICER of $23,976/QALY gained, below the WTP threshold. Threshold analysis showed that MRF-guided NACT adjustment would remain cost-effectiveness at imaging costs below $8,500.

CONCLUSION

MRF-guided NACT adjustment can improve health outcomes and remain cost-effective across a wide cost range, supporting its use for NACT treatment decision-making in TNBC patients.

CLINICAL RELEVANCE/APPLICATION

Early detection of non-response to NACT through MRF can improve clinical outcomes, reduce unnecessary treatment burden for patients, and increase cost-effectiveness of treatment management in TNBC patients.

S3B-SPBR-3 IMPACT OF TUBE VOLTAGE ON IODINE DETECTABILITY IN CONTRAST-ENHANCED MAMMOGRAPHY

Raj Kumar Panta, PhD (*Presenter*)
Jeffrey Nelson (*Abstract Co-Author*)
Megan K. Russ, PHD (*Abstract Co-Author*)
Ehsan Samei, PHD (*Abstract Co-Author*)

PURPOSE

To assess the impact of tube voltage on iodine detectability in Contrast-Enhanced Mammography (CEM).

METHODS AND MATERIALS

A 1-cm-thick CEM breast phantom of 50/50 glandular-adipose mixture, containing glandular tissue inserts and iodine inserts of four different surface concentrations (0.2 - 2mg/cm²) was imaged using a Hologic 3Dimensions system. ?The phantom included tissue mimicking materials (4-8cm in thickness) across three types of tissue density representing extremely dense (BR-GLAND), heterogeneously dense (BR-MIX, combination of BR-GLAND and BR-50/50), and scattered fibroglandular (BR-50/50) breast tissue. The AEC-indicated tube voltage (kVp) for acquiring the low-energy image was used as the reference kVp for each tissue thickness. Low-energy images were acquired at kVp offsets ranging from -2kVp to +2kVp relative to reference kVp, while the kVp for the high-energy image was unchanged. The Limit of Detection (LOD) was calculated on the recombination images and compared to that at the reference kVp for each tissue density and thickness.

RESULTS

A strong linear relationship ($R^2 > 0.99$) was observed between the mean pixel values of iodine inserts and the exponential of their surface iodine concentrations across all kVp settings. Low-energy acquisitions at lower kVp (-2kVp) enhanced iodine detectability, with LOD decreasing by 53% for BR-Gland (6cm) and BR-MIX (8cm), and by 50% for BR-50/50 (8cm). Conversely, higher kVp settings (+2kVp) degraded iodine detectability, with LOD increasing by 33% for BR-Gland (4cm), and 30% for BR-MIX (4cm) and BR-50/50 (8cm).

CONCLUSION

Tube voltage strongly affects iodine detectability, and it should be optimized by breast thickness and composition.

CLINICAL RELEVANCE/APPLICATION

This study highlights the significance of optimizing tube voltage in CEM protocols to enhance diagnostic performance.

S3B-SPBR-4 LARGE-SCALE DEPLOYMENT OF A MULTISTAGE AI-DRIVEN WORKFLOW INCREASES DETECTION OF DANGEROUS BREAST CANCERS

Leeann Louis, BS, PhD (*Presenter*)
Annie Ng, PhD (*Abstract Co-Author*)
Edgar Wakelin (*Abstract Co-Author*)
Jiye G. Kim, PhD (*Abstract Co-Author*)
Christoph I. Lee, MD,MS (*Abstract Co-Author*)
Diana S. Buist, PhD,MPH (*Abstract Co-Author*)
Bryan Haslam, PhD (*Abstract Co-Author*)

PURPOSE

AI can support increased breast cancer detection, however, there is no large-scale data on the types of additional cancers detected in a United States (US) screening setting. Prospective studies of AI outside the U.S. have shown AI can help detect more clinically relevant invasive cancers, but also ductal carcinoma in situ (DCIS) at a higher rate. The AI workflow employed can also impact the number and types of additional cancers detected. This study assesses the cancer subtypes detected in a large-scale deployment of a multistage AI-driven workflow, compared to the standard of care (SOC) prior to deployment.

METHODS AND MATERIALS

A multi-stage AI-driven workflow was deployed across 109 sites and 4 US states and involved concurrent reading with a CADe/x device, followed by an AI-facilitated safeguard review routing potentially missed findings to breast imaging experts for an additional review. The SOC cohort included screens between Sept 2021 to May 2022. The AI-driven workflow cohort included screens between Aug and Dec 2022. Cancer detection outcomes included cancer detection rate (CDR) and positive predictive value (PPV1). The distribution of cancer subtypes detected by SOC versus the AI-driven workflow was assessed in terms of cancer type, grade, invasivity, hormone receptor status (ER, PR, HER2), triple negative and luminal B proportions and those classified as particularly dangerous i.e. a combination of triple negative, Luminal B, and HER2+. The distributions were compared using an unadjusted chi-square test.

RESULTS

The deployment of the AI-driven workflow (N = 208 891; 1166 cancers) resulted in significantly increased CDR (5.58 vs 4.59, $p < 0.001$) and PPV1 (5.01 vs 4.35, $p < 0.001$) compared to SOC (N = 307 692; 1702 cancers). The majority of cancers detected by the AI-driven workflow were intermediate or high grade (80.6%) and invasive (67.5%) with 9.5% triple negative, 4.8% Luminal B and 7.1% HER2 positive. Dangerous cancers accounted for 16.9%. No differences were found in the distribution of cancer type, grade or invasiveness ($p>0.05$) between cohorts. In particular, the proportion of DCIS cancers (32.5%) did not increase. Accounting for the 21.6% CDR increase, an estimated 20 additional dangerous cancers were found.

CONCLUSION

Employing the multistage AI-driven workflow significantly improved clinical outcomes in terms of CDR and PPV1 in a cohort of over 2400 cancers, with the majority of cancers detected being clinically relevant and no corresponding increase in the proportion of DCIS.

CLINICAL RELEVANCE/APPLICATION

Detecting more clinically relevant cancers without increasing the proportion of DCIS diagnoses shows the AI-driven workflow investigated here increases the benefits of screening mammography without increasing potential harms.

S3B-SPBR-6 ROLE OF IMAGE-GUIDED STEROID INJECTIONS IN MANAGING IDIOPATHIC GRANULOMATOUS MASTITIS

Pooja Sikka, MD (*Presenter*)
Christian J. Ashby, MD (*Abstract Co-Author*)
Zoha Huda, MD,BS (*Abstract Co-Author*)
Jordana Phillips, MD (*Abstract Co-Author*)
Muhammad M. Qureshi, MBBS,MPH (*Abstract Co-Author*)
Dunya M. Imad, MD (*Abstract Co-Author*)
Sona A. Chikarmane, MD (*Abstract Co-Author*)
Priscilla J. Slanetz, MD, MPH (*Abstract Co-Author*)

PURPOSE

To evaluate the role of image-guided steroid injection as a novel treatment for idiopathic granulomatous mastitis (IGM) compared to standard systemic therapy.

METHODS AND MATERIALS

Retrospective review of 50 consecutive patients with biopsy proven IGM from 01/2010-10/2024 was done. Demographics (age, race, ethnicity, BMI, parity), imaging findings and clinical variables including symptom duration prior to treatment were collected. Primary outcome was time from treatment to symptom resolution. Secondary outcome was reported degree of improvement within one month after injection (none, mild, moderate, substantial/near resolution). Outcomes were determined by clinic notes. Systemic therapy included oral prednisone or methotrexate; local therapy included image-guided steroid injection (40mg/mL triamcinolone). Nineteen (38%) had symptomatic resolution without therapy, resulting in 31 in the final cohort, of which 19 received only systemic therapy and 12 received steroid injection in addition to systemic therapy. Association of treatment with time to symptom resolution was analyzed with a negative binomial regression model. Incidence rate ratios (IRR) with 95% CI were computed adjusting for demographics, waiting period and co-treatment with injection and systemic therapy.

RESULTS

Median (range) age was 35 years (20-53), parity 2 (0-6) and BMI 29.8 (24.1-38.1). Those who received steroid injection had shorter median (IQR) time to symptom resolution of 4.3 (5.9) months compared to 6.7 (13.6) months for those who received only systemic therapy (P=0.09). A similar trend was observed in univariable analysis (IRR 0.46; 95% CI 0.25-0.87, P=0.02) and multivariable analysis after adjusting for potential covariates (IRR 0.63; 95% CI 0.36-1.09, P=0.10). In patients who received steroid injection, 100% reported clinical improvement within one month, of which 50% reported substantial improvement.

CONCLUSION

Patients with IGM who received image-guided steroid injection reported clinical improvement within one month and showed a trend towards shorter time to symptom resolution by about 2.4 months as compared to those who received only systemic therapy. We propose routine incorporation of steroid injection into the management of IGM based on this initial promising study. Multi-institutional studies with larger cohorts will help better understand the benefits of this approach.

CLINICAL RELEVANCE/APPLICATION

IGM is a benign, non-cancerous likely immune-mediated breast condition affecting predominantly postpartum women that can take up to two years to resolve even with systemic therapy. Image-guided steroid injection has the potential to provide immediate symptomatic relief and reduce overall symptom duration thereby mitigating morbidity.

S3B-SPBR-7 LONGITUDINAL CHANGE OF MAMMOGRAPHIC AI RISK SCORES OVER REPEATED SCREENING EXAMS

Alec Starzinski (*Presenter*)
Andrew L. Avins, MD,MPH (*Abstract Co-Author*)
Ninah Achacoso (*Abstract Co-Author*)
Laurel Habel (*Abstract Co-Author*)
Tejomay Gadgil (*Abstract Co-Author*)
Vignesh A. Arasu, MD, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate the dynamics of mammographic AI-derived breast cancer risk estimates over repeated screenings and describe how women may be reclassified between hypothetical risk strata across sequential screenings depending on their outcome of future breast cancer.

METHODS AND MATERIALS

We conducted a retrospective cohort study of 5,567 women who underwent two bilateral screening mammograms: the index in 2016 and follow-up between 2017 and 2020. The 2016 mammogram was negative at final imaging assessment based on BI-RADS and benign biopsy assessments. The AI mammography risk model Mirai was used to generate 5-year breast cancer risk scores at both time points. Hypothetical risk groups were defined: High risk (>95th % risk scores), Above Average risk (75th-95th %), Average Risk (25th-75th %), and Below Average risk (<25th %). The thresholds based on the 2016 score distribution were applied to follow-up scores to evaluate risk-group reclassification. Reclassification tables and descriptive summaries were generated and stratified by eventual breast cancer diagnosis status.

RESULTS

Among the 5% of women classified as High risk, 44% of women remained in that group, while 39% shifted to Above Average risk, 16% to Average risk, and <1% to Below Average Risk. Among women initially classified in the Above Average and Average risk groups, 52% and 56% remained in their respective categories, with most reclassifications occurring to adjacent groups. Among women initially in the Below Average group, 51% remained stable, 41% moved upward to Average, and 9% shifted to Above Average or High risk. Women who developed breast cancer (N=469) demonstrated more pronounced upward shifts. Among those initially classified as High risk, 79% remained in that category. In contrast, only 28% of women initially in the Average group and 17% of those Below Average remained stable. Notably, 44% of the Average group moved to High risk and 26% to Above Average, while 83% of the Below Average group moved upward, including 29% to High risk. Among the Above Average group, 60% transitioned to High risk.

CONCLUSION

AI-derived risk estimates exhibit moderate temporal stability, with most women remaining in their baseline or adjacent risk groups. However, women who developed breast cancer more frequently experienced upward risk transitions.

CLINICAL RELEVANCE/APPLICATION

Risk stratification using AI scores appears stable in most women but shows meaningful upward shifts among those who develop cancer. These findings support potential use of AI score trajectories to inform adaptive screening intervals and early intervention strategies. Implementing AI based risk stratification necessitates informing women also of the dynamic nature of this risk factor.

S3B-SPCA-4 PROGNOSTIC VALUE OF CCTA SCORES IN A LARGE REAL WORLD STUDY

Anna Palmisano, MD (*Presenter*)
Francesco Pisu, MS (*Abstract Co-Author*)
Elisa Bruno (*Abstract Co-Author*)
Davide Vignale (*Abstract Co-Author*)
Alberto Colombo (*Abstract Co-Author*)
Antonio Esposito, MD (*Abstract Co-Author*)

PURPOSE

Coronary artery disease (CAD) is a global leading cause of mortality and Coronary computed tomography angiography (CCTA) is able to rule out CAD with very high sensivity and good specificity. Several CCTA semi-quantitative risk scores were developed for staging severity if CAD, variably considering stenosis severity, plaque featurs and segmental distribution. However, their prognostic impact in the real-clinical world is not clearly understood. Aim was to define the prognostic value of semiquantitative CCTA scores in clinical practice.

METHODS AND MATERIALS

In this observational, single-center retrospective study were screened elective CCTA of 2850 patients with low-to-intermediate risk of CAD performed between 2016 and 2020 with at least 4 years of follow-up. Patient with good image quality (Likert score= 4) were considered eligible. Demographics, cardiovascular risk-factors (CVRF), and medical history were collected via phone call and medical records. Calcium score (CACS), CAD-RADS, Leiden risk score, Leaman risk score, SSS, and SIS scores were calculated on a dedicated platform. Composite endpoint was based on the occurrence of MACE (nonfatal myocardial infarction, all-cause mortality, cardiac-related hospitalization, late coronary revascularization).

RESULTS

Among 1878 patients enrolled, 187/1878 (10%) had MACE. Comparing patients with and without MACE, they were similar in terms of sex (men 69%vs65%;p=.035), but older 70 [IQR 61-78]y.o. vs63[IQR 54-71] y.o.;p<.001) and with higher rates of CVRF and higher CCTA scores (all p<.001). At univariate analysis all CCTA scores were predictors of outcome, with the highest HR for CAD-RADS (HR 16.35, 95%CI [7.5-35.61]; p<.001). Predictive models including clinical and a CCTA scores were compared: the model with CAD-RADS outperformed (C-index 0.75 for predicting MACE and 0.78 for predicting death and myocardial infarction). Moreover, adjusting the risk for CACS patients with CAD-RADS 3 that had an HR of 10.35 95%CI [4.67-22.92]) showed in case of CACs=0 an highest risk (HR 15.1 95%CI [3.90-58.26]; p<.001) that was comparable to patients with CAD-RADS 4-5 (HR 16.35 95%CI [7.5-35.61]; p<.001).

CONCLUSION

CAD-RADS emerged as the most effective CCTA-derived score for predicting MACE. It is easy to calculate and apply clinically. Adjustment of CAD-RADS according to CACs allows risk reclassification in patients with moderate stenosis.

CLINICAL RELEVANCE/APPLICATION

CAD-RADS is the simplest CCTA score to be calculated but also the one with huger prognostic impact. Implementation in clinical routine with the integration with calcium score is able to reclassify subcohort of patient with intermediate stenosis but high risk.

S3B-SPCA-7 CORONARY COMPUTED TOMOGRAPHIC ANGIOGRAPHY HIGH-RISK PLAQUE ATTRIBUTES IN NON-CULPRIT VESSELS AND FUTURE CORONARY EVENTS

Qian Chen, MD, PhD (*Presenter*)

PURPOSE

Non-culprit vessel-related major adverse cardiac events (MACE) after percutaneous coronary intervention (PCI) need better characterization.This study aimed to assess the prognostic value of high-risk plaque attributes derived from index coronary computed tomographic angiography (CCTA) in non-culprit vessels in patients with PCI.

METHODS AND MATERIALS

Between June 2013 and June 2023, patients who underwent CCTA and subsequently PCI within 3 months were included. Index CCTA-derived high-risk plaque attributes were evaluated, including significant stenosis, high-risk plaque (HRP), plaque volume (PV), fractional flow reserve (FFR), and coronary inflammation, determined by pericoronary adipose tissue attenuation. The primary endpoint was non-culprit vessel-related MACE, defined as cardiac death, myocardial infarction, or clinically driven revascularization.

RESULTS

A total of 1495 patients with 2014 non-culprit vessels were analyzed with a median follow-up of 3.3 years. The cumulative rate of non-culprit vessel-related MACE was 3.8%. In a multivariate Cox analysis adjusted for high-risk plaque attributes, vessel-specific FFR (adjusted hazard ratio [aHR]: 0.14; 95% CI: 0.03-0.76, P = 0.023) and necrotic core PV (aHR: 1.30; 95% CI: 1.06-1.59, P = 0.010) were independent predictors of the primary endpoint. Vessel-specific FFR and necrotic core PV showed an incremental prognostic value when added to clinical risk factors, including age, sex, clinical presentation, hypertension, diabetes, and previous myocardial infarction (area under the receiver-operating characteristic curve: 0.601 vs. 0.673, P < 0.001). In sub-group analysis, a significant interaction (P interaction = 0.028) was observed between necrotic core PV and the achievement of target blood lipid, defined as LDL-C <1.4 mmol/L at one-year follow-up, in relation to non-culprit vessel-related MACE.

CONCLUSION

High-risk plaque attributes on CCTA have independent and incremental prognostic values for non-culprit vessel-related MACE. Achieving target blood lipid attenuates the impact of necrotic core PV on the risk of MACE in non-culprit vessels.

CLINICAL RELEVANCE/APPLICATION

CT-derived vessel-specific FFR and necrotic core PV exhibited independent and incremental prognostic value beyond traditional cardiovascular risk factors for predicting non-culprit vessel-related MACE. In non-culprit vessels that achieve target blood lipid levels, necrotic core PV did not increase the risk of clinical events compared to vessels without achievement of target blood lipid. Our study confirms the benefits of achievement of target blood lipid in patients following PCI treatment.

S3B-SPCA-10 REFERENCE VALUES OF MYOCARDIAL STRAIN DERIVED FROM MRI FEATURE TRACKING: A STUDY BASED ON A NATIONWIDE CHINESE POPULATION AND DATA FROM THE NATIONAL CENTER FOR CARDIOVASCULAR DISEASES

Jing Xu (*Presenter*)
Wenjing Yang (*Abstract Co-Author*)
Yining Wang, MD (*Abstract Co-Author*)
Leyi Zhu (*Abstract Co-Author*)
Di Zhou (*Abstract Co-Author*)
Minjie Minjie, PhD (*Abstract Co-Author*)

PURPOSE

Population-specific reference values of myocardial strain tailored to the Chinese population remain limited. Our purpose is to establish reference values for myocardial strain across a large, nationally representative sample of the Chinese population and evaluate the impact of the demographic and technical factors on strain measurements.

METHODS AND MATERIALS

A total of 1,033 healthy participants(aged 14-69) from National Center for Cardiovascular Diseases(NCCD) underwent CMR feature tracking(CMR-FT) to measure myocardial strain and strain rate(SR) across all cardiac chambers. Reference ranges were stratified by gender and age, and multiple linear regression assessed the influence of the variables.

RESULTS

The reference ranges for CMR-FT strain and SR were provided. Significant differences in almost all strain and SR parameters were observed between genders and age groups. Female had higher myocardial strain, atrial SR, and early-diastolic ventricular SR (All $P<0.05$ except right ventricular global radial(RVGRS) and circumferential strain(RVGCS)), while male had higher systolic RVGRSR and RVGCSR(both $P<0.05$). Multiple linear regression revealed that gender, age, height, body mass index, field strength, and vendor all had some contribution to strain values.

CONCLUSION

This study provides a comprehensive set of age- and gender-specific reference values for myocardial strain and SR in a healthy Chinese cohort, utilizing a large dataset from the NCCD. The findings highlight the importance of adjusting for demographic and technical factors in clinical interpretations of myocardial strain. The established reference values serve as a foundational resource for future research and clinical applications of CMR-FT in assessing cardiovascular health and disease risk in China.

CLINICAL RELEVANCE/APPLICATION

Establishing population-specific reference values for myocardial strain in the Chinese population holds significant clinical importance. Utilizing a large dataset sourced from the NCCD, this study offers a comprehensive set of age- and gender-specific reference values for myocardial strain and SR in a healthy Chinese cohort. These reference values are anticipated to enhance diagnostic accuracy and prognostic capabilities within cardiovascular medicine, facilitating early detection, monitoring, and treatment of myocardial dysfunction. Furthermore, the study emphasizes that demographic and technical factors should be taken into consideration when conducting clinical diagnoses and research based on CMR-FT. Translating these findings into applicable values for other ethnic groups will necessitate further investigation, but it represents a crucial next step in future cross-ethnic research outcome exchanges.

S3B-SPCA-13 CARDIAC BLOOD POOL T2 SIGNAL IN RELATION TO CARDIOPULMONARY EXERCISE TESTING AND PROGNOSIS IN PATIENTS WITH DILATED CARDIOMYOPATHY

Michinobu Nagao, MD, PhD (*Presenter*)
Atsushi Yamamoto, MD, PhD (*Abstract Co-Author*)

PURPOSE

Blood T2 values can be modulated by hemoglobin oxygenation, as the paramagnetic properties of deoxyhemoglobin shorten T2 relaxation times. This suggests that blood pool signals on T2 map may serves as a surrogate for blood oxygen saturation, offering a potential approach to quantifying intra-chamber oxygen content. Patients with dilated cardiomyopathy (DCM) have a high-energy demand throughout the dilated ventricles due to progressive left ventricular (LV) dysfunction. The total oxygen demand is measured by cardiopulmonary exercise tests (CPX) to determine exercise tolerance and cardiac implantable device therapy (CIDT) or heart transplantation. We examined the correlation between intraventricular T2 values and CPX test in patients with DCM, and the association between these measurements and CIDT or death.

METHODS AND MATERIALS

Data of cardiac MRI and CPX test performed on 64 patients with DCM (mean age, 45 years; mean LVEF, 33%) at the same time was analyzed. Myocardial T2 map was scanned with a 3-tesla scanner and T2prep-based sequence, T2 value was measured throughout the left and right ventricular (LV, RV) cavities. The ratio of T2 values of RV and LV (RV/LV T2) was calculated as a representative value. Anaerobic threshold (AT), peak oxygen uptake (peak VO2), and peak oxygen pulse (peak O2pulse) were extracted from CPX test. The primary endpoint was defined as CIDT or death after cardiac MRI. CIDT consisted of implantable cardioverter defibrillators and cardiac resynchronization therapy.

RESULTS

During a mean follow-up of 22 months, three patients died and CIDT was performed in 12 patients. T2 for RV and LV, and RV/LV T2 were 87.0±112.6msec, 99.2±2.1msec, and 0.88±0.13, respectively. RV/LV T2 showed a moderate positive correlation with peak O2 pulse (Pearson r, 0.413; p=0.0007) and weak positive correlations with peak VO2 and AT (Pearson r, 0.315 and 0.249; p=0.0112 and 0.0475). Simple logistic regression showed a significant association between RV/LV T2 and CIDT or death (Log-likelihood, 6.926; odd ratio, 49.71; p=0.0085), but no association between CPX measurements and those events.

CONCLUSION

RV/LV T2 was significantly correlated with CPX measures, suggesting an association with exercise tolerance in DCM. In addition, a decrease in RV/LV T2 was found to be associated with adverse cardiac accidents.

CLINICAL RELEVANCE/APPLICATION

Cardiac blood pool T2 is a noninvasive analysis that can be calculated simultaneously with myocardial property with a T2 map, and has the potential to estimate patient-burdened CPX test.

S3B-SPCA-14 IMPROVEMENT OF CORONARY ARTERY STENT EVALUATION USING SUPER-RESOLUTION DEEP LEARNING RECONSTRUCTION TECHNIQUE: A MULTICENTER VALIDATION STUDY

Cheng Xu (*Presenter*)
Limiao Zou (*Abstract Co-Author*)
Min Xu, PhD (*Abstract Co-Author*)
Yining Wang, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the impact of a novel super-resolution deep-learning reconstruction (SR-DLR) algorithm on the visible and diagnostic performance of coronary CT angiography (CCTA) in stents evaluation.

METHODS AND MATERIALS

From September 2023 to November 2024, consecutive patients who underwent clinically indicated CCTA and ICA within 2-month interval in 8 hospitals across China were prospectively enrolled. CCTA images were reconstructed with both hybrid iterative reconstruction (HIR) and SR-DLR. The image quality was evaluated using a 5-point scale (1=poor, 5=excellent). The signal-to-noise ratio (SNR), contrast-to-noise ratio (CNR) and stent-lumen attenuation increase ratio (SAIR) were calculated. The maximum visible in-stent lumen diameter were measured. The patency of stent were evaluated and in-stent restenosis was defined as = 50% stenosis. Invasive coronary angiography served as reference standard. The diagnostic confidence was evaluated using a 5-point scale (1= low, 5= high).

RESULTS

A total of 112 stents from 75 patients were included for analysis.The qualitative image quality of coronary stents was superior in SR-DLR compared with HIR, and the average image scores were 4.24±0.71 and 3.30±0.53 ($P<0.001$), respectively. The SNRs of the two images were approximately equal (23.4±14.7 vs. 23.4±15.4, $P=0.53$), while SR-DLR yielded a better CNR (44.0±20.3 vs. 33.6±15.7, $P<0.001$). The SAIR of SR-DLR was lower than that of HIR (0.44±0.36 vs. 0.71±0.55, $P<0.001$). SR-DLR images showed the larger in-stent lumen diameters compared with HIR (2.12±0.60 vs. 1.78±0.48 mm, $P<0.001$). Compared with HIR, the lesion-based diagnostic accuracy of SR-DLR in detecting in-stent restenosis improved from 79.5% to 92.3% ($P<0.001$), with higher diagnostic confidence (4.38±0.56 vs. 3.68±0.63, $P<0.001$).

CONCLUSION

Compared with HIR, SR-DLR improves the visible and diagnostic performance of CCTA in stents evaluation.

CLINICAL RELEVANCE/APPLICATION

SR-DLR algorithm improves the diagnostic accuracy and confidence of coronary stent evaluation.

S3B-SPCH-1 ASSESSMENT OF DELAYS IN DIAGNOSIS OF LUNG CANCER IN INTERSTITIAL LUNG DISEASE

Ali Nowroozi, MD (*Presenter*)
Tician Schnitzler, MD, MSc (*Abstract Co-Author*)
Maya Vella, MD (*Abstract Co-Author*)
Jonathan A. Liu, MD (*Abstract Co-Author*)
Shravan Sridhar, MD, MS (*Abstract Co-Author*)
Jae Ho Sohn, MD, MS (*Abstract Co-Author*)

PURPOSE

To evaluate diagnostic delays in lung cancer among patients with interstitial lung disease (ILD), analyze associated tumor characteristics and patient outcomes, and identify key radiologic factors contributing to missed or delayed detection.

METHODS AND MATERIALS

In this retrospective study, imaging and clinical data of 54 patients diagnosed with ILD and concurrent lung cancer from two tertiary ILD referral centers were reviewed. Four thoracic radiologists independently determined the "earliest callable date," defined as the date when the majority would have first raised concern about a nodule, and compared it to the actual date of clinical suspicion. Tumor characteristics, including size, morphology, staging, volume doubling time (VDT), treatment, and survival outcomes were recorded. Radiologic causes of missed or delayed detection were categorized by consensus for delayed cases.

RESULTS

Diagnostic delays occurred in 50% of the cohort (27/54), with a mean delay of 3.18 years (IQR: 0.94-4.51). Tumors in delayed cases exhibited significantly slower growth (mean VDT: 1.42 years) compared to promptly diagnosed cases (mean VDT: 0.22 years, $p<0.0001$). Key radiologic factors contributing to delayed detection included obscuration by fibrosis, ground-glass opacities, or bronchovascular bundles (63%), misinterpretation as infection or exacerbation (15%), minimal interval growth (11%), and invisibility on prior CT scans (15%). No significant differences in tumor size, morphology, stage, or histologic subtype—predominantly adenocarcinoma (56%)—were noted between delayed and non-delayed cases. Additionally, survival outcomes did not significantly differ between the groups ($?^2=0.4$, $p=0.5$).

CONCLUSION

Diagnostic delays in lung cancer detection among ILD patients occurred frequently, primarily due to radiologic masking and subtle imaging features rather than aggressive tumor biology. Despite prolonged delays, tumor characteristics and patient survival outcomes were comparable to those diagnosed promptly, suggesting a generally less aggressive tumor phenotype.

CLINICAL RELEVANCE/APPLICATION

Recognizing specific radiologic pitfalls leading to diagnostic delays in lung cancer within ILD patients can guide radiologists in early identification, potentially improving timely management and patient counseling despite the generally indolent nature of tumors in delayed detection.

S3B-SPCH-2 INTEGRATING QUANTITATIVE CT MORPHOLOGY, PET METABOLIC PARAMETERS, AND CLINICAL FEATURES TO PREDICT PD-L1 EXPRESSION IN LUNG ADENOCARCINOMA: A MULTIVARIATE LOGISTIC REGRESSION STUDY

Jiaming You (*Presenter*)
Zheng Yuan (*Abstract Co-Author*)

PURPOSE

To establish a non-invasive model that predicts PD-L1 expression in lung adenocarcinoma by combining quantitative CT features, PET metabolic parameters (specifically, the tumor-to-lung SUVmax ratio), and clinical variables, without relying on complex radiomics workflows.

METHODS AND MATERIALS

18F-PET/CT images and clinical data from 431 pathologically confirmed lung-adenocarcinoma patients treated at tertiary hospitals in Shanghai were retrospectively reviewed. Patients were randomly assigned to training and validation cohorts(8:2). Collected variables included sex, smoking history, CT tumor density and morphological features, and PET metabolic parameters, primarily the maximum standardized uptake value of the tumor (SUVmax_tumor) and of reference lung tissue (SUVmax_lung). Continuous variables were compared with the Mann-Whitney U test; categorical variables with $?^2$ or Fisher's exact test. least absolute shrinkage and selection operator (LASSO) regression selected predictors, which were entered into a multivariate logistic model built on the training cohort and displayed as a nomogram. Performance was assessed with ROC and Area Under the Receiver Operating Characteristic Curve (AUC), compared by the DeLong test, and further evaluated with calibration curves, the Hosmer-Lemeshow test, and decision-curve analysis (DCA). Ten-fold cross-validation was used for internal validation. Analyses were performed in R.

RESULTS

LASSO identified four independent predictors—SUVmax_tumor/SUVmax_lung ratio, tumor density, sex, and smoking status—used to construct the model. Discrimination was good in both cohorts (training AUC = 0.762, 95 % CI 0.700-0.824; validation AUC = 0.758, 95 % CI 0.604-0.913), with no significant difference between them (DeLong p = 0.832). Calibration was acceptable (Hosmer-Lemeshow p &gt 0.09). DCA showed consistent net benefit across clinically relevant thresholds. The model achieved high negative predictive values (96.3%-97.6%) and positive predictive values (~28.7 %), mirroring the 21.3 % PD-L1-positive prevalence.

CONCLUSION

A practical logistic model using CT, tumor-to-lung SUVmax ratio, and clinical metrics accurately predicts PD-L1 in LUAD. Its high NPV aids identifying patients unlikely to benefit from immunotherapy, supporting decision-making.

CLINICAL RELEVANCE/APPLICATION

This implementable model, using available clinical and conventional 18F-PET/CT (including tumor-to-lung SUVmax ratio), offers non-invasive pre-operative PD-L1 estimation in LUAD. Its high NPV helps identify patients unlikely for immunotherapy, potentially sparing them ineffective/toxic treatments, optimizing selection and resource allocation without complex radiomics.

S3B-SPCH-3 DETERMINING THE RELATIONSHIP BETWEEN GROWTH RATE CALCULATED BY COMPUTED TOMOGRAPHY AND GRADE AND HISTOLOGICAL TYPE IN LUNG ADENOCARCINOMAS

Hakan Dogan, MD (*Presenter*)
Huseyin Ekin Ergin, MD (*Abstract Co-Author*)
Cetin Atasoy, MD (*Abstract Co-Author*)

PURPOSE

A new histological grading system for lung adenocarcinomas has been proposed by the International Association for the Study of Lung Cancer (IASLC), in addition to classification based on predominant histological subtype. Although studies have shown that the new grading system is successful in determining prognosis, the relationship between nodule growth rate and grade has not yet been investigated. This study aims to examine the relationship between growth rate, grade, and histological predominant subtype and compare their superiority to each other.

METHODS AND MATERIALS

This retrospective study was approved by the institutional review board. Patients diagnosed with invasive nonmucinous adenocarcinoma following surgical resection were included. Volume doubling time (VDT) was calculated by performing nodule segmentation in three planes. The grades and predominant subtypes of the nodules were determined by histopathological evaluation. Due to the limited number of micropapillary predominant subtypes (n=5), they were grouped with the solid predominant subtype for analysis.

RESULTS

Ninety nodules were included in the study. Among the nodules, 49% were solid, 40% were partially solid, and 11% had pure ground-glass opacity. Low, intermediate, and high-grade tumors accounted for 10%, 47%, and 43% of nodules, respectively. Predominant subtype was lepidic in 10%, acinar in 59%, papillary in 10%, and solid or micropapillary in 21% of lesions. VDT was shortest in high-grade tumors ($p < 0.001$), with median VDT values of 1542, 981, and 299 days in low-, intermediate-, and high-grade tumors, respectively. VDT also varied among predominant subtypes ($p < 0.001$), being longest in the lepidic-predominant subtype (1542 days) and shortest in the solid or micropapillary-predominant subtype (210 days), with acinar (774 days) and papillary (437 days) subtypes in between. In multivariate logistic regression analysis, grade was identified as an independent factor associated with VDT, while histological subtypes were not found to be significant.

CONCLUSION

The growth rate of high-grade tumors was found to be higher than that of low and intermediate-grade tumors. The IASLC grading system demonstrated a stronger correlation with growth rate than classification based on predominant histological subtype.

CLINICAL RELEVANCE/APPLICATION

This study provides insights into the correlation between growth rate and tumor grade, which could enhance clinical decision-making. Understanding the relationship between tumor growth rate and histological grade may enable earlier identification of aggressive tumors, facilitating risk-based surveillance strategies and personalized therapeutic approaches.

S3B-SPCH-4 AIR TRAPPING IN NSIP: IS IT A TRAP?

Joao Fonseca, MD (*Presenter*)
Raquel Dias, MD (*Abstract Co-Author*)
Henry Okonkwo (*Abstract Co-Author*)
Jessica Gemmell (*Abstract Co-Author*)
Brianna A. Karim, BS (*Abstract Co-Author*)
Maysa R. de Oliveira, MD (*Abstract Co-Author*)
Pavan Iyengar (*Abstract Co-Author*)
Amanda Acevedo (*Abstract Co-Author*)
Joice C. Prodigios, MD (*Abstract Co-Author*)
Jean Bontemps (*Abstract Co-Author*)
Arman Mahmood (*Abstract Co-Author*)
Udochukwu Amanamba (*Abstract Co-Author*)
Kayla Davis (*Abstract Co-Author*)
Ronak Kundalia, MSc, BS (*Abstract Co-Author*)
C. David Pfaehler (*Abstract Co-Author*)
Bruno Hochhegger, MD, PhD (*Abstract Co-Author*)

PURPOSE

This study aimed to assess the prevalence and prognostic significance of air trapping in patients with interstitial lung diseases (ILDs) exhibiting a non-specific interstitial pneumonia (NSIP) pattern on high-resolution chest computed tomography (hrCT). As air trapping is traditionally considered a hallmark of hypersensitivity pneumonitis (HP), understanding its distribution and implications across diverse ILD subtypes is essential for accurate diagnosis and risk stratification.

METHODS AND MATERIALS

This retrospective, single-center study evaluated 414 hrCT scans acquired over a 10-year period. Patients were categorized into six groups: connective tissue disease-associated ILD (CTD-ILD), HP, idiopathic interstitial pneumonias (IIPs), drug-induced ILDs, smoking-related ILDs, and other etiologies. Air trapping was assessed in exams with adequate expiratory phases, and mortality associations were analyzed using multivariable logistic regression adjusted for age, sex, FVC%, and DLCO%, with results expressed as risk ratios (RR). Analyses were performed in RStudio (version 2024.04.2+764).

RESULTS

Among 313 patients with good-quality expiratory imaging, 59.7% were female with a mean age of 66.2 years. Air trapping was observed in 67.6%, most commonly in drug-induced and smoking-related ILDs (100%), followed by HP (84.8%). Extensive air trapping across all lobes was most frequent in HP (32%). Its prevalence was significantly higher in HP compared to IIP (84.8% vs. 61.3%; $p = 0.0162$). Upper lobe predominance was seen in 12.1%, particularly in smoking-related ILD (33%), though without statistically significant pairwise differences. Among patients with mortality data, 38 deaths (12.1%) were recorded. Air trapping was not significantly associated with mortality (RR = 0.55; 95% CI: 0.24-1.27; $p = 0.16$). DLCO%, however, was independently protective (RR = 0.95; 95% CI: 0.93-0.98; $p < 0.001$).

CONCLUSION

Air trapping is a common feature among ILD patients with NSIP patterns, particularly in HP and smoking-related ILDs. While it aids in differentiating HP from IIP, its presence was not associated with increased mortality in this cohort and appeared linked to relatively preserved pulmonary function.

CLINICAL RELEVANCE/APPLICATION

Air trapping is not exclusive to HP and occurs across various NSIP-pattern ILDs. Its diagnostic utility remains relevant, but its prognostic value may be limited. Further studies using time-to-event analysis are warranted to clarify its relationship with outcomes and pulmonary function trends.

S3B-SPCH-5 STACKING ENSEMBLE MODEL INTEGRATING 18F-PET/CT IMAGING, RADIOMIC, AND CLINICAL FEATURES FOR PRE-OPERATIVE PREDICTION OF HIGH-GRADE PATTERNS IN LUNG ADENOCARCINOMA

Jiaming You (*Presenter*)
Zheng Yuan (*Abstract Co-Author*)

PURPOSE

High-grade histologic patterns (&ge 20 % solid or micropapillary components) portend poorer prognosis in lung adenocarcinoma (LUAD) and can alter surgical and adjuvant-therapy decisions. We developed and validated a non-invasive stacking ensemble model that combines quantitative PET/CT metrics, CT-based radiomic features, and clinical variables to predict the presence of high-grade patterns pre-operatively.

METHODS AND MATERIALS

This retrospective study included 431 pathologically confirmed LUAD patients from tertiary hospitals in Shanghai. Patients were randomly split 8:2 into a training cohort (n = 345) and an independent validation cohort (n = 86). Collected data comprised sex, smoking status, tumor density, SUVmax, SUVmax_tumor/SUVmax_lung ratio, MTV, TLG, and 3380 CT radiomic features (3D Slicer, semi-automatic tumor segmentation). Mann-Whitney U and $?^2$/Fisher tests compared continuous and categorical variables, respectively. LASSO regression selected the most informative features. A two-layer stacking ensemble was built: (i) XGBoost and LASSO-logistic base learners; (ii) a ridge-regression meta-learner fusing their outputs. Ten-fold cross-validation assessed stability in the training set. Discrimination (AUC), calibration (calibration curve, Hosmer-Lemeshow test), and clinical utility (decision-curve analysis, DCA) were evaluated; training vs. validation AUCs were compared with the DeLong test. Analyses were performed in R.

RESULTS

The stacking model yielded a mean cross-validated AUC of 0.888 in the training set. Final performance was excellent in the training cohort (AUC = 0.978) and high in the validation cohort (AUC = 0.950) with significant differences (DeLong p &lt 0.05). Calibration was sub-optimal (Hosmer-Lemeshow p &lt 0.05). DCA showed net benefit versus treat-all/none strategies.

CONCLUSION

A multi-modal stacking ensemble integrating PET/CT quantitative parameters, CT radiomics, and clinical data achieved high discriminatory accuracy for predicting high-grade histologic patterns in LUAD. Significant DeLong and Hosmer-Lemeshow results indicate potential over-fitting and calibration issues that warrant further refinement before clinical deployment, but the model shows promise for guiding personalized surgical and therapeutic planning.

CLINICAL RELEVANCE/APPLICATION

Non-invasively identifying high-grade patterns in LUAD pre-operatively using this stacking ensemble model provides crucial prognostic data. This aids risk stratification and supports clinicians in tailoring personalized treatment strategies (e.g., lobectomy vs. sublobar resection) or deciding on the necessity and type of adjuvant therapy for aggressive tumor biology, aiming to improve patient outcomes.

S3B-SPCH-6 THE SPECTRAL CT QUANTITATIVE PARAMETERS AND PD L1 EXPRESSION PREDICT THE EFFICACY OF IMMUNOTHERAPY FOR ADVANCED NON-SMALL CELL LUNG CANCER PATIENTS

Jingxu Li (*Presenter*)

PURPOSE

This study aimed to investigate the value of spectral CT quantitative parameters combined with programmed cell death-ligand 1 (PD-L1) expression in predicting initial treatment response to immunotherapy in advanced non-small cell lung cancer (NSCLC).

METHODS AND MATERIALS

From July 2021 to July 2024, 106 stage III-IV NSCLC patients with complete clinicopathological data who underwent dual-phase contrast-enhanced chest spectral CT were retrospectively analyzed. Conventional CT morphological features and spectral CT quantitative parameters (arterial and venous phases) were evaluated. Patients received treatment via immune checkpoint inhibitors (ICIs) for 2-3 cycles or until clinical progression, followed by standard CT for initial response assessment. Patients were categorized into response and non-response groups based on RECIST 1.1. Logistic regression identified independent predictors of immunotherapy response. Three models were constructed: clinical-CT features, spectral CT parameters, and a combined model. Predictive performance was assessed using receiver operating characteristic (ROC) curve analysis with area under the curve (AUC).

RESULTS

Among 106 NSCLC patients treated with ICIs, 27 showed response and 79 showed non-response. Univariate analysis revealed PD-L1 expression status, lesion location, spiculation, M-stage, treatment regimen, arterial-phase iodine-water, normalized iodine concentration (NICA), venous-phase effective atomic number (Z-eff), and normalized arterial enhancement fraction (NAEF) were associated with treatment response (all $P<0.05$). Multivariate logistic regression identified arterial-phase iodine-water, NAEF, NICA and venous-phase Z-eff as independent predictors. The combined prediction model demonstrated superior diagnostic performance (AUC=0.947) compared to clinical-CT (AUC=0.880) and spectral CT parameter models (AUC=0.706).

CONCLUSION

Spectral CT quantitative parameters combined with PD-L1 expression provide a novel approach for predicting immunotherapy response in advanced NSCLC, offering valuable insights for clinical decision-making.

CLINICAL RELEVANCE/APPLICATION

Spectral CT during routine scans could optimize immunotherapy selection while avoiding additional procedures.

S3B-SPCH-7 DEVELOPMENT AND VALIDATION OF A PULMONARY VESSEL SEGMENTATION MODEL BASED ON DEEP LEARNING FOR DETECTING CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION AT CT PULMONARY ANGIOGRAPHY

Yue Lin (*Presenter*)
Longfei Zhao (*Abstract Co-Author*)
Sheng Xie (*Abstract Co-Author*)

PURPOSE

To construct a deep learning (DL) model using a multicenter data set for accurate intrapulmonary vascular segmentation and chronic thromboembolic pulmonary hypertension (CTEPH) detection on CT pulmonary angiography (CTPA) images and to compare its performance.

METHODS AND MATERIALS

A multicenter, retrospective analysis of 611 sequential patients with right heart catheterization (RHC)-confirmed CTEPH, CTED, and normal controls was conducted. There are 351 patients for model construction, 152 patients for the internal validation cohort and 108 patients constituted the external validation cohort. The available

CTPAs were identified to examine the differential arterial and venous volumes and tortuosity in all patients. The pulmonary vasculature was reconstructed, and a DL method was used to separate arteries and veins and to compute pulmonary vascular volumes and tortuosity. The significant CT imaging-derived quantification of vascular volumes and tortuosity were included in the stepwise binomial logistic regression to further explore CTEPH. The diagnostic performance was assessed using the receiver operating characteristic curve (AUC). DeLong testing was employed to compare the differences of AUCs. Spearman's correlation analysis was used to analyze the correlation between the hemodynamic parameters obtained by RHC and vascular quantitative variables.

RESULTS

The total vessel volume was greater in the CTEPH cohort compared with the CTED and control cohort (all $P < 0.001$). The CTEPH cohort reflected higher large vessel volume and total arterial volume, and greater median arterial and venous tortuosity compared with the CTED and control group (all $P < 0.05$). Taking RHC results as the gold standard, the vascular segmentation model had perfect diagnostic performance in identifying CTEPH (AUC from 0.95 to 0.97), and the AUC value of the mixed model combined with BNP also increased slightly, but DeLong testing revealed no significant differences among different cohorts (all $P > 0.05$). Decision curve analysis shows that the mixed model provides a slightly greater net benefit than the vessel DL model in the training, internal and external test cohorts.

CONCLUSION

The fully automated vessel segmentation model based on DL that could accurately segment pulmonary vessels and demonstrate promising diagnostic performance in detecting CTEPH at CTPA, with no evidence of a significant difference in diagnostic performance compared with internal and external validation data, while CT quantitative parameters correlating with mPAP and PVR obtained from RHC measurements.

CLINICAL RELEVANCE/APPLICATION

Automated quantification methods using CT imaging can provide a imaging marker for identification of CTEPH and CTED.

S3B-SPCH-8 MOLECULAR CHARACTERIZATION OF CELL DECAY IN INFLAMMATORY STATE AND TOPOLOGICAL ASSIGNMENT OF RELEASED CFDNA FOR INTEGRATIVE OUTCOME PREDICTION

Alexander Hertel, MD (*Presenter*)
Catharina Gerhards (*Abstract Co-Author*)
Michael Neumaier (*Abstract Co-Author*)
Stefan O. Schoenberg, MD, PhD (*Abstract Co-Author*)
Matthias F. Froelich, MD (*Abstract Co-Author*)

PURPOSE

Efficient triage of vulnerable patients in acute, particularly infectious respiratory diseases remains a major clinical challenge. Integrative biomarkers combining molecular and imaging information may significantly enhance early risk stratification. We therefore evaluated the predictive potential of circulating cell-free DNA (cfDNA) characteristics—namely integrity and epigenetics—alongside CT-based Radiomics, to identify high-risk patients and anticipate complications such as ARDS or organ failure.

METHODS AND MATERIALS

The cfDNA Integrity Index was established using automatic gel electrophoresis (TapeStation, Agilent Technologies) in cell culture models of apoptosis and necrosis (HEK293 and Jurkat cells, n = 57), then validated in patients with COVID-19 or other acute diseases (n = 62). cfDNA topological origin and tissue-specific injury were analyzed using the Infinium Methylation 850K assay. Radiomics features were extracted from thoracic CT scans and correlated with clinical endpoints.

RESULTS

Patients with ARDS showed significantly elevated cfDNA concentrations >246 bp ($p = 0.016$), particularly above 100 ng/ml ($p = 0.030$). Larger cfDNA fragments were associated with ICU admission ($p = 0.018$) and mortality ($p = 0.017$), and the cfDNA Integrity Index was higher in non-survivors ($p = 0.018$). cfDNA originated mainly from leukocytes. Hepatocyte-specific epigenetic cfDNA signals correlated strongly with serum GGT ($r = 0.79$), indicating liver involvement. Several radiomics parameters from chest CT correlated with clinical severity. The feature original_glcm_ClusterShade showed a strong negative correlation with ECMO need ($r = -0.84$), suggesting its potential as a non-invasive predictor of respiratory failure. Additionally, RSNA score, reflecting pulmonary infiltrates, moderately correlated with ICU admission ($r = 0.39$) and ARDS ($r = 0.41$), highlighting the prognostic value of imaging biomarkers.

CONCLUSION

This study demonstrates the potential of combining cfDNA-based molecular diagnostics with advanced CT Radiomics for comprehensive patient profiling in acute disease. The integration of laboratory and imaging biomarkers offers a powerful strategy to predict clinical trajectories, guide early intervention, and detect secondary organ complications. Radiomics, in particular, emerged as a valuable, non-invasive predictor of critical illness and therapy escalation such as ECMO.

CLINICAL RELEVANCE/APPLICATION

Integrating cfDNA-based molecular markers with CT radiomics enables early risk stratification, prediction of critical outcomes such as ARDS or ECMO need, and supports precision triage and resource allocation in acute respiratory diseases.

S3B-SPCH-9 REVISITING LLMS AND LUNG CANCER QUESTIONS: HOW AI RESPONDS TO COMMON LUNG CANCER QUESTIONS TWO YEARS LATER

Dan Nguyen (*Presenter*)
Amir A. Rahsepar, MD (*Abstract Co-Author*)
Hamid Chalian, MD (*Abstract Co-Author*)
Cameron Hassani, MD (*Abstract Co-Author*)
Grace Hyun Kim, PhD, MS (*Abstract Co-Author*)
Arash Bedayat, MD (*Abstract Co-Author*)

PURPOSE

Recent advances in artificial intelligence (AI), specifically large language models (LLMs) present themselves as novel tools to enhance healthcare, especially in the context of patient education. Prior research has shown varying levels of accuracy and consistency among these models within disseminating clinical advice for patients, highlighting the need for ongoing evaluation as models evolve. This study aimed to evaluate and compare the accuracy, consistency, and reliability of five state-of-the-art LLMs—ChatGPT-o3, Gemini, DeepSeek R1, Claude, and Perplexity—in answering standardized lung cancer-related questions, building upon prior assessments of earlier models in 2023.

METHODS AND MATERIALS

Forty lung cancer-related questions were developed by experienced radiologists, based on Lung-RADS and Fleischner Society guidelines. On February 16, 2025, each of the five models answered these standardized questions. Responses were independently graded by three radiology experts using a majority-voting system to classify answers as correct, partially correct, incorrect, or no answer (refusal). Statistical analyses included accuracy calculations, logistic regression models to compare response correctness across LLMs, and inter-rater agreement assessments (Cohen's Kappa).

RESULTS

ChatGPT-o3 achieved the highest accuracy (75.83% correct responses), closely followed by Gemini (74.17%). Claude demonstrated the highest rate of partially correct answers (17.5%). Statistical analysis showed ChatGPT-o3 had significantly higher odds of fully correct answers compared to Claude ($p=0.02$). DeepSeek R1 showed the highest agreement, while ChatGPT-o3 had substantial disagreement among raters on Cohen's Kappa. Notably, ChatGPT-o3 identified intentionally incorrect Lung-RADS questions more reliably than DeepSeek or Gemini.

CONCLUSION

ChatGPT-o3 showed the best overall accuracy among the models tested but had notable inter-rater variability. While recent models demonstrated improved accuracy over previous iterations, there continues to be ongoing issues. Nearly two years later, problems such as inconsistent performance, incorrect responses, and refusals emphasize the continued importance of expert oversight. Future research should expand evaluation beyond lung cancer-related content.

CLINICAL RELEVANCE/APPLICATION

LLMs like ChatGPT-o3 show promise in improving patient education by providing accurate lung cancer screening guidance, but clinical oversight remains crucial due to variability and occasional errors in responses.

S3B-SPCH-10 PREDICTING 25-YEAR RISK OF CARDIOVASCULAR DEATH ACCORDING TO BASELINE CORONARY ARTERY CALCIFICATION SCORE AND COMPETING CAUSES OF DEATH

Claudia I. Henschke, PhD, MD (*Presenter*)
Rowena Yip, PhD, MPH (*Abstract Co-Author*)
Matthew D. Cham, MD (*Abstract Co-Author*)
Dorith Shaham, MD (*Abstract Co-Author*)
Joseph Shemesh, MD (*Abstract Co-Author*)
David F. Yankelevitz, MD (*Abstract Co-Author*)

PURPOSE

Coronary artery calcifications (CAC) identified on basesline low-dose CT (LDCT) screening using a ordinal 12 point score has been shown to be a strong predictor of 10-year cardiovascular (CVD) death. We investigated whether this this baseline score could predictor CVD death, given competing causes of death, 25 years later.

METHODS AND MATERIALS

Baseline CAC score of 9047 participants in LDCT screening in New York State between 2000-2008 was determined for the main, left anterior descending, circumflex, and right coronary arteries, each scored separately as 0 (absent), 1, 2, or 3, yielding a possible score of 0-12 for each participant. Total CAC scores were categorized: 0, 1-3, and 4-12. Self-reported smoking history and comorbidities were documented at baseline. Date and cause of death (ICD-10) were obtained from the National Death Index. Adjusted Cox proportional hazards regression models and Fine-Gray subdistribution hazard model analyzed emphysema and mortality outcomes.

RESULTS

Follow-up to December 31 2024 of 9047 participants found that 3738 (42.2%) had died of all causes, 1153 (12.7%) due to CVD (median follow-up 14.5 years IQR: 6.2-22.3), and 295 (3.3%) due to COPD. CVD death increased with increasing Ordinal CAC categories of 0, 1-3, and 4-12 from 8.1%, 13.2%, and 22.0%, respectively (P <.0001). A similar trend was observed for all-cause mortality, 29.5%, 43.6%, 62.7%, respectively (P <.0001). CVD death was significantly higher for Ordinal CAC category of 4-12 compared to CAC 0 (Hazard Ratio=4.2, 95%CI: 3.6-4.9), P <.0001. After adjustment for sex, age, diabetes, and smoking pack-years, the association remained significant: HR=2.1(95%CI:1.8-2.5), P< .0001. Adjusted Fine-Gray subdistribution hazard model, which accounts for competing risks, the association between CAC scores and CVD mortality remained significant but was attenuated (HR3.00; 95%CI,2.57-3.49) (Figure).

CONCLUSION

A single Ordinal CAC score on baseline LDCT consistently predicted CVD and all-cause mortality up to 25 years and provide individualized probabilities based on age, smoking history, years quit. CAC score, and other causes of death which allow for a more meaningful discussion of preventive actions with each individual and further enhances the relevance of combined lung and heart screening.

CLINICAL RELEVANCE/APPLICATION

A single baseline CAC score predicts 25 year CVD death given competing causes of death and provides personalized information given the person's age and smoking history for individualizing smoking cessation counselling.

S3B-SPCH-11 CLINICAL AND RADIOLOGIC CHARACTERISTICS OF SOLITARY PULMONARY CAPILLARY HEMANGIOMA: A COMPARATIVE STUDY WITH LUNG ADENOCARCINOMA

Ye Qing Zhu, MD, PhD (*Presenter*)
Wan Qi, MD,PhD (*Abstract Co-Author*)
Xinchun Li (*Abstract Co-Author*)
Claudia I. Henschke, PhD, MD (*Abstract Co-Author*)
David F. Yankelevitz, MD (*Abstract Co-Author*)

PURPOSE

Solitary pulmonary capillary hemangioma (SPCH) is an underrecognized benign disease that can radiologically mimic lung adenocarcinoma. The purpose of this study was to investigate the clinical and radiologic characteristics of SPCH in a large cohort of histologically confirmed cases and compare these findings with those of lung adenocarcinoma.

METHODS AND MATERIALS

This retrospective study included all histologically confirmed SPCH cases from our institution between July 2015 and December 2024. For comparison, lung adenocarcinomas matched to SPCH by nodule consistency (nonsolid, part□solid, solid) and size within the same period were included. Each nodule's consistency, size, location, shape, presence of spiculation, pleural retraction, air bronchogram and perivascular lucency were evaluated by two chest radiologists independently, blinded to clinical and pathology information. The characteristics between SPCH and lung adenocarcinoma were compared with ?² tests or Fisher exact test for categorical and Mann-Whitney U tests for continuous variables.

RESULTS

The study comprised 44 SPCH patients (28 women, 63.6%; median age, 46 years [IQR, 37-55.2]) and 344 adenocarcinoma patients (194 women, 56.3%; median age, 58 years [IQR,49.8-65.0]). All SPCH were solitary, with the majority located in the lower lobes (33/44,75%). Approximately 79.5% (35/44) of SPCH were located in the peripheral lung zone. For nodule consistency, 54.5% (24/44) of SPCH were solid nodules, 27.3% (12/44) were nonsolid, and 18.2% (8/44) were part-solid nodules. More than half of the SPCH had an average diameter = 10.0 mm (26/44, 59.1%). Comparing with adenocarcinoma, SPCH were more likely to occur in lower lobes (33/44 [75%] vs 112/344 [33%]; P < .001), more often presented with air bronchogram (25/44 [57%] vs 68/344 [20%]; P < .001), and lacked of spiculation (2/44 [5%] vs 192/344 [56%]; P < .001) and pleural retraction (8/44 [18.2%] vs 183/344 [53.2%]; P < .001). Five SPCH cases demonstrated central branching/tubular lucency sign, while 3 cases showed perivascular lucency sign, which were not detected in lung adenocarcinoma.

CONCLUSION

SPCH shares some features with lung adenocarcinoma but typically occurs in the lower lobes, rarely shows spiculation or pleural retraction, and often contains air bronchograms. Central branching/tubular lucency and perivascular lucency may further help radiologists to detect SPCH.

CLINICAL RELEVANCE/APPLICATION

SPCH can manifest as nonsolid, part-solid and solid nodules which can mimic lung adenocarcinoma, but typically occurs in lower lobes, lacks spiculation and pleural retraction, and often shows air bronchograms. Central branching/tubular lucency and perivascular lucency were found in some SPCH.

S3B-SPER-1 IMAGING SPECTRUM OF BLUNT AND PENETRATING CARDIAC TRAUMA: ROLE OF DUAL-ENERGY AND PHOTON-COUNTING CT

Mohammed A. Al Turiqy, MBBS (*Presenter*)
Savvas Nicolaou, MD, FRCPC (*Abstract Co-Author*)

PURPOSE

To define the role of Dual-Energy CT (DECT) in detecting life-threatening cardiac injuries compared to conventional CT, emphasizing protocol optimization and clinical impact.

METHODS AND MATERIALS

This retrospective multicenter study (2018-2023) analyzed 80 cases of blunt/penetrating cardiac trauma imaged with DECT (n=40) and conventional CT (n=40), including: Blunt trauma : myocardial contusion (n=25), hemopericardium (n=20), cardiac rupture (n=10) Penetrating trauma : chamber perforation (n=15), tamponade (n=8), projectile tracking (n=2) Two blinded radiologists evaluated: Injury detection sensitivity Diagnostic confidence (5-point Likert scale) Artifact reduction (iodine maps vs. conventional reconstructions)

RESULTS

Myocardial contusions : DECT iodine maps improved detection (88% sensitivity vs. 65% conventional CT, p=0.01) by highlighting hypoenhancement. Tamponade : Virtual monoenergetic 40-keV images increased pericardial blood conspicuity (mean score: 4.5 vs. 3.1, p<0.001). Artifact reduction : Metal artifact reduction algorithms decreased beam-hardening by 35% (p=0.003). Clinical impact : DECT changed management in 28% of cases (e.g., occult active bleeding on iodine extravasation maps).

CONCLUSION

DECT significantly improves cardiac trauma evaluation through: Functional assessment via iodine mapping (contusions/ischemia) Enhanced lesion conspicuity with monoenergetic reconstructions Superior artifact reduction for penetrating injuries

CLINICAL RELEVANCE/APPLICATION

Use 40-keV monoenergetic series for tamponade assessment Employ iodine maps to distinguish contusion from chronic infarction Activate metal artifact reduction for projectile cases

S3B-SPER-2 AUTOMATED CT DETECTION OF PELVIC FRACTURES WITH YOLO V12 AND SLICE-LEVEL VOTING USING REAL-WORLD FRACTURE PREVALENCE

Taiyu Zhang, PhD (*Presenter*)
Mehrdad Salimitari, PhD, MSc (*Abstract Co-Author*)
David Dreizin, MD (*Abstract Co-Author*)

PURPOSE

To develop and evaluate a deep learning framework for automated detection of pelvic fractures on trauma CT using YOLOv12 and a slice-voting strategy tailored to class-imbalanced data.

METHODS AND MATERIALS

A dataset of 3,420 patients (513 positive, 2,907 negatives; 15% prevalence) was divided into training (2,394), validation (342), and testing (684) sets. Preprocessing included intensity clipping (-500 to 1500 HU), resampling to 0.8×0.8×2 mm, and conversion to 640×640-pixel PNG axial slices. Weakly labeled segmentation masks (25 fracture classes) were merged into a single label. Bounding boxes were generated using connected component analysis with noise suppression. The YOLOv12 large model was trained with focal loss and class-balanced slice sampling. Patient-level classification was performed using a slice-voting threshold (SVT) strategy: a patient was positive if at least n slices exceeded a confidence threshold. Performance metrics were reported for the best thresholds achieving sensitivity of at least 90%.

RESULTS

At respective optimal thresholds (recall > 90%), the model achieved progressively improved patient-level diagnostic performance with increasing SVTs:SVT 1 (Threshold 0.29): Accuracy: 79.6%, Precision: 41.7%, Recall: 90.3%, Specificity: 77.7%, NPV: 95.3%, F1-score: 0.57; SVT 2 (Threshold 0.28): Accuracy: 87.0%, Precision: 54.1%, Recall: 90.3%, Specificity: 86.4%, NPV: 93.2%, F1-score: 0.68; SVT 3 (Threshold 0.27): Accuracy: 92.4%, Precision: 68.6%, Recall: 91.3%, Specificity: 92.6%, NPV: 89.9%, F1-score: 0.78; SVT 4 (Threshold 0.26): Accuracy: 92.4%, Precision: 72.7%, Recall: 90.3%, Specificity: 94.0%, NPV: 86.8%, F1-score: 0.80; SVT 5 (Threshold 0.25): Accuracy: 95.0%, Precision: 78.5%, Recall: 92.2%, Specificity: 95.5%, NPV: 86.1%, F1-score: 0.85These results show that the 5-slice SVT strategy providing the strongest diagnostic performance — combining high sensitivity (90.3%), specificity (94.0%) with a high F1-score (0.80) reflecting a highly favorable trade-off between sensitivity and precision/PPV.

CONCLUSION

This YOLOv12-based framework with an SVT strategy achieved accurate and robust patient-level CT fracture detection in a class-imbalanced trauma dataset reflecting prevalence encountered at major trauma centers, and expected clinical operating conditions, supporting integration into real-time triage and second-reader workflows.

CLINICAL RELEVANCE/APPLICATION

Automated identification of pelvic fractures at the patient level can expedite trauma triage, reduce missed injuries, and improve clinical workflow efficiency in high-volume emergency environments.

S3B-SPER-3 PREDICTING FUTURE VERTEBRAL COMPRESSION FRACTURES: TESTING THE HYPOTHESIS THAT CHEST RADIOGRAPHS ARE BETTER THAN DEXA

Anushree M. Burade, MBBS (*Presenter*)
Parisa Kaviani, MD (*Abstract Co-Author*)
Seyedehelaheh Hosseini, MD (*Abstract Co-Author*)
Javier Contreras Yametti, MD (*Abstract Co-Author*)
Lina Karout, MD (*Abstract Co-Author*)
Minjee Kim (*Abstract Co-Author*)
Jeong Min Song, MD (*Abstract Co-Author*)
Subba R. Digumarthy, MD (*Abstract Co-Author*)
Mannudeep K. Kalra, MD (*Abstract Co-Author*)

PURPOSE

Extremely low rate of DEXA based bone mineral density (BMD) estimation leads to substantial under-diagnosis of osteoporosis/osteopenia, which are key risk factors for predicting vertebral compression fractures (VCFs). We tested the hypothesis that a three-class classification chest radiograph (CXR)-based AI tool can outperform DEXA-based prediction of future VCFs based on 15-site data.

METHODS AND MATERIALS

Our IRB-approved, multi-center, external dataset outcome prediction study included 934 chest radiographs from 934 patients (mean age: 71.9 ± 11.9 years; female: male 745:189) belonging to one of the 15 US sites (primary care, community care, and quaternary care sites). The study inclusion criteria were age> 21 years, posterior-anterior projection CXRs performed within 6 months of DEXA scan, DEXA reports with T and Z scores, and follow-up chest CT or CXRs 3 months to 10 years after the CXR/DEXA exams. We excluded pediatric patients, those with prior spinal surgeries, moderate to severe scoliosis and pacemaker/AICD, traumatic fractures. We used an NLP/CLU-based radiology report data warehouse and search engine to identify consecutive eligible patients. All CXRs were processed with the Promedius AI tool (South Korea), not trained with any US data, to obtain probability scores for normal BMD, osteopenia, and osteoporosis. Next, we classified patients into these three-classes based on T and Z-scores from DEXA reports. Data were analyzed to obtain ROC AUCs and odd ratios (OR) for predicting VCFs on follow-up chest CT and/or CXRs.

RESULTS

Among the 934 patients, 241/934 (25.8%) developed one or more VCFs on follow-up imaging. The OR for predicting VCFs with CXR-AI (OR 3.15; 95% CI: 1.95-5.08 was significantly higher than for DEXA (OR 1.68; 95% CI: 1.13-2.50) ($p<0.001$). Likewise, the ROC AUC for predicting VCFs with CXR-AI (AUC 0.643, 95% CI: 0.603 - 0.682) was also higher than for DEXA ($p<0.01$).

CONCLUSION

Opportunistic screening of BMD with the assessed CXR-based AI model has the potential for predicting future vertebral compression fractures.

CLINICAL RELEVANCE/APPLICATION

Given the underuse of DEXA relative to CXRs, CXR-AI opportunistic screening can represent a viable, initial screening and triaging tool for patients at higher risk of insufficiency fractures.

S3B-SPGI-1 VIRTUAL NON-CONTRAST AND SPECTRAL IMAGING IN PHOTON-COUNTING DETECTOR CT HAVE MODERATE AGREEMENT WITH MRI IN QUANTIFYING LOW-GRADE LIVER FAT

David Klemm, MD (*Presenter*)
Maximilian Russe, MD (*Abstract Co-Author*)
Marco Reisert (*Abstract Co-Author*)
Sebastian Faby, DIPLPHYS (*Abstract Co-Author*)
Lukas Rohloff (*Abstract Co-Author*)
Michael Schultheiss (*Abstract Co-Author*)
Fabian Bamberg, MD, MPH (*Abstract Co-Author*)
Jakob Weiss, MD, PhD (*Abstract Co-Author*)
Stephan Rau, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the agreement of different liver fat quantification methods using photon-counting detector CT via virtual non-contrast (VNC) reconstructions and dedicated spectral post-processing algorithms, with MRI-derived fat fractions (MRI-FF) serving as the reference standard.

METHODS AND MATERIALS

This retrospective study included consecutive patients who underwent clinically indicated abdominal PCD-CT in arterial (art) and portal-venous (pv) phases, and abdominal multiparametric MRI with chemical shift imaging. In PCD-CT, liver fat fraction (FF) was quantified using two methods in all available phases: firstly, via Hounsfield units derived from VNC images using an established formula (HU-FF), and secondly directly by using a spectral post-processing algorithm (SPP-FF). These were compared among themselves and with MRI-FF using Pearson's correlation and mean absolute error (MAE).

RESULTS

A total of 42 patients (mean age 66.9 ± 11.4 years, 50% male) were included. Median MRI-FF was 1.49% (IQR, 0.72%-4.57%). HU-FF and spectral SPP-FF from PCD-CT showed a moderate correlation with MRI-FF in both arterial and portal-venous phases (Pearson’s $r = 0.40$-0.71, $p < 0.05$). A high correlation was observed between HU-FF and SPP-FF regardless of the contrast phase (Pearson’s $r = 0.72$-0.80, $p < 0.05$). Excellent agreement was found between arterial and portal-venous phases within the same FF quantification method (HU-FF: $r = 0.94$; SPP-FF: $r = 0.93$ respectively). The MAE between CT-based liver FF and MRI-FF was smallest for SPP-FF-art (3.30%, 95% CI: 2.20%-4.39%) and largest for HU-FF-pv (4.82%, 95% CI: 3.69%-5.94%), indicating small but systematic differences between methods.

CONCLUSION

PCD-CT offers several methods for liver fat quantification, yet, in a cohort with low liver fat, agreement with MRI serving as reference varied considerably. Due to systematic differences between available approaches, further research is necessary to establish reliable conversion factors and improve generalizability and comparability across approaches and studies.

CLINICAL RELEVANCE/APPLICATION

PCD-CT allows for non-invasive quantification of liver fat using VNC and dedicated spectral post-processing algorithms, although agreement with MRI is moderate. Consistent methodology is essential in research and further validation is needed to improve clinical reliability.

S3B-SPGI-3 FINE-TUNING A RADIOGRAPH FOUNDATION MODEL FOR CROSS-MODALITY PREDICTION OF OSTEOPOROSIS RISK FROM CT-DERIVED SURFACE MESHES

Akash R. Pattnaik (*Presenter*)
Dave Van Veen (*Abstract Co-Author*)
Himanshu Kale (*Abstract Co-Author*)
Muhammad Ahmed Chaudhry (*Abstract Co-Author*)
Sanmi Koyejo, PhD (*Abstract Co-Author*)
Lydia Lagari (*Abstract Co-Author*)
William W. Boonn, MD (*Abstract Co-Author*)
Khan M. Siddiqui, MD (*Abstract Co-Author*)
Ayis T. Pyrros, MD (*Abstract Co-Author*)

PURPOSE

We repurposed a chest radiograph foundation model to extract features from CT-derived 2D surface mesh renderings, enabling cross-modality inference of internal body composition. By doing so, we aim to accelerate opportunistic osteoporosis risk screening using inexpensive surface-based inputs.

METHODS AND MATERIALS

We used 24,588 abdominal CT studies from 19,571 patients and derived internal biomarkers using the OSCAR pipeline. To model skeletal and metabolic risk, we defined three binary classification tasks based on CT-derived body composition markers: (1) L1 bone mineral density (BMD) using a high-sensitivity threshold, (2) L1 BMD using the standard clinical threshold for osteoporosis, and (3) muscle mass at the L3 vertebral level, a surrogate marker for sarcopenia and frailty. CT volumes were converted into 2D mesh renderings simulating surface geometry, then encoded with a chest radiograph foundation model to produce fixed embeddings. A shallow multilayer perceptron (MLP) head was fine-tuned on these embeddings to predict osteoporosis risk, with the foundation model weights frozen. The MLP consisted of three fully connected layers with batch normalization, ReLU, and dropout. Training used a weighted binary cross-entropy loss, Adam optimizer, and early stopping. Performance was evaluated via ROC AUC with optimal threshold selection using Youden’s J statistic and 95% confidence intervals from 1000 bootstraps on a held-out test set.

RESULTS

We evaluated model performance on three binary osteoporosis classification tasks, each based on different CT-derived biomarker thresholds. Using a high-sensitivity BMD cutoff at the L1 vertebra, the model achieved a ROC AUC of 0.718 (95% CI: [0.681, 0.756]). When applying the standard BMD threshold for osteoporosis, performance decreased slightly (ROC AUC: 0.661, 95% CI: [0.591, 0.734]), consistent with the stricter definition. The model performed best when using a composite label based on muscle attenuation—an indirect surrogate of bone health and frailty—achieving a ROC AUC of 0.790 (95% CI: [0.773, 0.808]). These results highlight the model's ability to infer internal skeletal risk factors from surface mesh inputs, with the highest discrimination achieved when leveraging muscle-based biomarkers associated with osteoporosis risk.

CONCLUSION

Radiograph foundation models can be adapted to CT-derived surface meshes for predicting internal biomarkers, enabling low-cost, cross-modality screening using only surface geometry.

CLINICAL RELEVANCE/APPLICATION

Surface-based inference of body composition may unlock scalable, AI-driven screening for osteoporosis and metabolic risk in primary care, home, or global health settings without CT access.

S3B-SPGI-4 AUTOMATED SEGMENTATION AND RADIOMIC ANALYSIS OF ADIPOSE AND MUSCLE TISSUES USING MACHINE LEARNING TO PREDICT OUTCOMES FOLLOWING BARIATRIC SURGERY

Artem Kaliaev, MD (*Presenter*)
Ali Elzieny (*Abstract Co-Author*)
Kevin J. Chang, MD (*Abstract Co-Author*)
Donald Hess (*Abstract Co-Author*)
Perry J. Pickhardt, MD (*Abstract Co-Author*)
John W. Garrett, PhD (*Abstract Co-Author*)
Christina A. LeBedis, MD, MS (*Abstract Co-Author*)

PURPOSE

To identify patterns on CT images before gastric bypass that predict weight regain, using advanced imaging analysis and machine learning algorithms to guide personalized obesity management.

METHODS AND MATERIALS

In this retrospective study, 24 patients (18 female, mean age 40.48 ± 12.77 years) underwent CT imaging before and after a gastric bypass procedure. Patients were classified according to post-procedure BMI course into "Weight Re-Gain" (n=10, weight regain) and "Weight Loss" (n=14, weight loss) groups. Chest, abdomen, and pelvis CT images were segmented using a fully automated algorithm from the Opportunistic Screening Consortium in Abdominal Radiology (OSCAR toolbox version 9.3 / University of Wisconsin) for automated adipose and muscle tissue segmentation and volumetric and radiomic analysis. Adipose and muscle tissue ratios and volumes were calculated with Python algorithm by using Pydicom library and applying DICOM masks. Independent t-tests compared baseline metrics, with $p < 0.05$ indicating significance.

RESULTS

The Weight Re-Gain group had a significantly higher baseline visceral-to-total adipose tissue ratio than the Weight Loss group (0.30 ± 0.12 vs 0.23 ± 0.06, $p = 0.03$). Baseline visceral adipose tissue volume was higher in the Weight Re-Gain versus the Weight Loss (5,739.60 ± 3,737.5 vs 4,435.65 ± 1,474.4 mL, $p = 0.012$). The Weight Loss group achieved greater BMI reduction (-11.60 ± 6.09 vs. -9.46 ± 4.64, $p < 0.001$ and significant visceral fat volume reduction (1,955.84 ± 1,615.92 mL (44.09%), $p < 0.001$ vs 2,063.13 ± 4,928.43 (35.94%) mL, $p = 0.002$) compared to the Weight Re-Gain group.

CONCLUSION

Elevated baseline visceral adipose tissue volume and visceral-to-total adipose tissue ratio on CT predict weight regain post-gastric bypass, highlighting the role of advanced image post-processing and machine learning in identifying at-risk patients for targeted interventions.

CLINICAL RELEVANCE/APPLICATION

Pre-surgical CT imaging with deep learning segmentation can identify patients at risk of weight regain after gastric bypass by assessing fat distribution. Radiologists can incorporate this analysis into routine scans, enabling bariatric teams to target high-risk patients with personalized interventions, including enhanced counseling, specialized diets, or exercise programs, to promote fat loss and improve long-term weight maintenance.

S3B-SPGI-5 AI-ENHANCED MRE FEATURE MAPS IMPROVE CONFIDENCE OF RADIOLOGICAL INTERPRETATION IN STRICTURING CROHN'S DISEASE: A RADIOMICS-READER STUDY

Gargi Vijayan Pillai (*Presenter*)
Prathyush Chirra (*Abstract Co-Author*)
Robert Toth (*Abstract Co-Author*)
Nicholas Fragakis (*Abstract Co-Author*)
Joseph Sleiman (*Abstract Co-Author*)
Ilyssa Gordon (*Abstract Co-Author*)
Florian Rieder (*Abstract Co-Author*)
Amit Gupta, MD, MBBS (*Abstract Co-Author*)
David H. Ballard, MD (*Abstract Co-Author*)
Namita S. Gandhi, MD, MSc (*Abstract Co-Author*)
Satish Viswanath (*Abstract Co-Author*)

PURPOSE

Radiological visual assessment scoring (VAS) of MR enterography (MRE) has gained traction for assessing degree of inflammation and fibrosis in patients with stricturing Crohn's disease, but requires further large-scale evaluation. We conducted an AI-enabled reader study to evaluate whether radiological assessment together with radiomics-based feature overlays improved the accuracy of characterizing inflammation and fibrosis in strictures vs radiological assessment alone.

METHODS AND MATERIALS

Retrospective, multicenter reader study of 25 patients with surgically confirmed stricturing ileal Crohn's disease who underwent MRE within 15 weeks prior to resection. A customized radiological interface with multi-pane display of original MRE sequences and radiomics feature map overlays was developed. Radiomics maps were pixel-wise visualizations of top-ranked features selected via a previously published machine learning model, which had been validated within a separate training cohort for characterizing severe pathologic inflammation and severe pathologic fibrosis on MRE. Three radiologists (R1, R2, R3) independently assessed each case to assign a VAS (0-100) for severe inflammation and severe fibrosis together with Likert confidence ratings (1-5). Two phase evaluation was conducted with a wash-out period in between: (1) VAS assessment via MRE alone, (2) VAS assessment via MRE and phenotype-specific radiomics feature maps. Diagnostic accuracy was evaluated using AUCs against reference standard pathologic severity scores. Weighted kappa was used to assess inter-reader agreement after binning VAS scores.

RESULTS

Utilizing radiomics overlays increased AUCs for identifying severe inflammation in 2 out of 3 readers (R2: 0.63 to 0.66; R3: 0.66 to 0.87); no significant change was observed for severe fibrosis. Radiomic overlays increased confidence scores for all 3 readers; average 21% increase for identifying severe inflammation, average 14% increase for identifying severe fibrosis. Minimal to no change observed in inter-reader agreement between both phases for both phenotypes (? range: -0.048-0.26 for inflammation, -0.044-0.28 for fibrosis).

CONCLUSION

Radiomics-derived overlays enhance radiologist confidence for assessing severe inflammation and severe fibrosis in ileal Crohn's disease via MRE. Specialized training and added interpretability will be critical to translating AI-enabled feature maps as an adjunct for radiological interpretation.

CLINICAL RELEVANCE/APPLICATION

Integrating radiomics visual overlays into MRE interpretation workflows may enable improved reader confidence in detecting inflammatory and fibrotic phenotypes, which could help inform treatment decisions in Crohn's disease management.

S3B-SPGI-6 VALIDATION OF A DEEP LEARNING-BASED AI SOFTWARE FOR THE DETECTION AND CLASSIFICATION OF PANCREATIC CYSTIC LESIONS ON ABDOMINAL CT: A RETROSPECTIVE, SINGLE-CENTER STUDY

Adriana Campmany, MD (*Presenter*)
Ferran Bosch SR, MD (*Abstract Co-Author*)
Francesc Novell Teixido, MD (*Abstract Co-Author*)
Antoni Malet, MD (*Abstract Co-Author*)
Beatriz Consola, MD (*Abstract Co-Author*)
Eva Ballesteros Gomiz, MD (*Abstract Co-Author*)
Marta Sola, MD (*Abstract Co-Author*)
Carlota C. Rodriguez, MD (*Abstract Co-Author*)
Anna Framis Utset, MD (*Abstract Co-Author*)

PURPOSE

To evaluate the performance of a deep learning-based artificial intelligence (AI) software in (1) detecting pancreatic cystic lesions (PCL) and (2) classifying them as mucinous (MUC, potentially malignant) versus non-mucinous (NM, potentially benign), using expert radiologist assessment as the reference standard.

METHODS AND MATERIALS

This retrospective, observational, single-center study included 522 contrast-enhanced abdominal CT scans performed between 2012 and 2021. The scans were obtained from 170 patients, some with a prior diagnosis of pancreatic cystic lesions (PCLs) and others serving as controls. All scans were analyzed using an artificial intelligence (AI) software, with subsequent blinded review by abdominal radiologists. Diagnostic performance metrics, including sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and F1 score, were calculated for PCL detection and lesion classification as mucinous (MUC-positive) or non-mucinous (MUC-negative), with radiological and histopathological reports serving as the reference standard.

RESULTS

For PCL detection, the AI software demonstrated a sensitivity of 89%, specificity of 78%, positive predictive value (PPV) of 66%, negative predictive value (NPV) of 94%, and an F1 score of 76%. For lesion classification as MUC-positive or MUC-negative, the software exhibited a sensitivity of 76%, specificity of 42%, PPV of 83%, NPV of 33%, and an F1 score of 79%. The high NPV for lesion detection suggests a reliable ability to exclude false negatives, which is particularly important in screening contexts. However, the moderate PPV and relatively low specificity highlight the need for further refinement to reduce false positives and enhance classification accuracy.

CONCLUSION

The evaluated AI software demonstrates strong performance in detecting pancreatic cystic lesions, with particularly high sensitivity and NPV, supporting its potential utility as a screening aid. However, its ability to classify lesions as MUC- positive or MUC-negative remains limited, highlighting the importance of continued algorithm development.

CLINICAL RELEVANCE/APPLICATION

AI-based tools may assist radiologists in the early identification and risk stratification of pancreatic cystic lesions. Accurate detection with low false-negative rates can enhance patient management and follow-up protocols. However, clinical integration should consider current limitations in lesion characterization.

S3B-SPGI-7 THREE-DIMENSIONAL MAGNETIC RESONANCE ELASTOGRAPHY FOR PREDICTING HEPATIC DECOMPENSATION RISK IN PATIENTS WITH CACLD: A PILOT STUDY

Jin Wang, MD (*Presenter*)
Xin Jin (*Abstract Co-Author*)
Jie Zhu (*Abstract Co-Author*)
Haimei Chen (*Abstract Co-Author*)
Ying Zeng (*Abstract Co-Author*)
Zhuoya Yi (*Abstract Co-Author*)

PURPOSE

Three-Dimensional magnetic resonance elastography (3D MRE)-derived mechanical properties are well established for staging liver fibrosis, and tissue mechanical heterogeneity assessed by 3D MRE has shown potential as a biomarker of liver disease severity. The value of 3D MRE for predicting hepatic decompensation in compensated advanced chronic liver disease (cACLD) remains unclear. This study aimed to evaluate the prognostic value of mechanical properties derived from 3D MRE.

METHODS AND MATERIALS

This retrospective study included cACLD patients who underwent paired 2D and 3D MRE between January 2015 and December 2018. Mean, standard deviation (SD) and coefficient of variation (CV) of stiffness, storage modulus, loss modulus and damping ratio (DR) of liver (L) and spleen (S) were calculated for each examination. Univariable Fine-Gray analysis and collinearity assessment ($p < 0.05$; VIF < 10) identified significant predictors. Multivariable Fine-Gray models were developed, and its performance was evaluated using Uno's C-index and time-dependent area under the curve (AUC).

RESULTS

Forty-eight cACLD patients (median age, 51 years; 81% male; 75% HBV etiology) were included. Six patients developed decompensation and six developed hepatocellular carcinoma during a median follow-up of 55.0 months (IQR, 20.8-93.2). Stiffness_2D_L_SD (SHR 5.09), and loss_3D_SD_L (SHR 3.77) showed robust associations with hepatic decompensation. Additionally, stiffness_2D_L_mean, stiffness_3D_mean_L, stiffness_3D_mean_S, storage_3D_mean_L, storage_3D_mean_S, storage_3D_SD_S, DR_3D_CV_L, total bilirubin, ALT and gender also showed significant associations in univariable Fine-Gray analysis ($p < 0.05$). Following univariable analysis, variables were further selected for multivariable modeling based on collinearity assessment (VIF <10). Based on this process, four models were developed: Model 1 (stiffness_2D_L_SD), Model 2 (DR_3D_CV1_L, stiffness_3D_mean_L), Model 3 (loss_3D_SD_L, storage_3D_SD_S), and Model4 (ALT and total bilirubin). It showed model 3 achieved the highest discrimination (C-index 0.81), followed by Model 1, 2, and the clinical Model 4. Model2 showed excellent predictive ability for early risk of hepatic decompensation (1- and 2-year AUCs of 0.91), while Model 3 had excellent discrimination for 5-year risk of hepatic decompensation (AUC (0.84).

CONCLUSION

Tissue mechanical heterogeneity assessed at MRE demonstrated potential value for predicting hepatic decompensation in cACLD patients.

CLINICAL RELEVANCE/APPLICATION

MRE-derived tissue mechanical heterogeneity may serve as a useful non-invasive tool for individualized risk stratification in cACLD patients. However, larger prospective studies are warranted.

S3B-SPGI-8 PREOPERATIVE AI-BASED CT ANALYSIS IDENTIFIES HIGH-RISK BODY COMPOSITION PHENOTYPES FOR POSTOPERATIVE COMPLICATIONS IN COLORECTAL CANCER PATIENTS

Chiara Zerbato, MD (*Presenter*)
Bettina Budai (*Abstract Co-Author*)
Joanna Urbaniec-Stompor (*Abstract Co-Author*)
Tobias Nonnenmacher, MD (*Abstract Co-Author*)
Victoria Damerell (*Abstract Co-Author*)
Sheetal Hardikar (*Abstract Co-Author*)
Adetunji Toriola (*Abstract Co-Author*)
Hans-Ulrich Kauczor, MD (*Abstract Co-Author*)
Biljana Gigic (*Abstract Co-Author*)

PURPOSE

Surgery is an integral part of colorectal cancer (CRC) treatment. Body Composition Analysis (BCA) may provide additional value in predicting postoperative complications (POCs). This study aimed to evaluate the association between BCA and POCs in CRC patients.

METHODS AND MATERIALS

In this prospective cohort study, 463 CRC patients who previously underwent elective surgery were included. Preoperative CT scans were analyzed by automated CT-based body composition analysis (BCA) using the "Body and Organ Analysis" (BOA) tool. Five body composition indices including visceral adipose tissue (VAT), subcutaneous adipose tissue (SAT), intermuscular adipose tissue (IMAT), and muscle indeces as well as fat-free mass index (FFMI) were extracted. POCs were collected retrospectively and classified both binary and gradually depending on their severity. Unsupervised K-means clustering identified four phenotypes: cachectic, lean-muscular, fat-muscle-rich, and skinny-fat. Associations with POCs and severity were evaluated using multivariable logistic models.

RESULTS

Among the included patients 213 (46%) developed POCs. Patients who developed complications were older compared to those without complications (63.1 vs 60.4 yo, p=0.018). While individual CT metrics (IMAT, VAT, FFMI) were associated with complications in univariate analyses, these associations diminished in multivariable models. In contrast, phenotype-based classification retained predictive power. The fat-muscle-rich (OR = 2.47, p = 0.0088) and skinny-fat (OR = 2.15, p = 0.0239) phenotypes were independently associated with increased complication severity.

CONCLUSION

Preoperative body composition parameters are correlated with the development and severity of POCs in CRC patients. While traditional multivariable models showed limited predictive value, clustering-based phenotypes significantly stratified complication risk.

CLINICAL RELEVANCE/APPLICATION

A BCA clustering model may support personalized surgical planning and perioperative care, offering a potentially useful tool for clinical decision-making.

S3B-SPGI-9 VOXEL-SCALE IMAGE FUSION AND LABEL TRANSFER BETWEEN PARTIAL WHOLE MOUNT HISTOPATHOLOGY AND RECTAL MRI

Joao Manoel M. Santos, PhD (*Presenter*)
Jon S. Heiselman (*Abstract Co-Author*)
Nil Urganci (*Abstract Co-Author*)
Canan Firat (*Abstract Co-Author*)
Hadi Ghahremannezhad (*Abstract Co-Author*)
Rami Vanguri, PhD (*Abstract Co-Author*)
Jayasree Chakraborty (*Abstract Co-Author*)
Julio Garcia Aguilar (*Abstract Co-Author*)
Marc J. Gollub, MD (*Abstract Co-Author*)
Jinru Shia, MD (*Abstract Co-Author*)
Natally Horvat, MD, PhD (*Abstract Co-Author*)

PURPOSE

To evaluate reproducibility of radiology-pathology image fusion methods for voxel scale mapping between preoperative rectal T2W MRI and whole-mount histology (WMH) in patients with hemisected whole-mount specimens and to evaluate the potential for voxel-based MRI radiomic features to predict pathologic disease state from co-registered WMH.

METHODS AND MATERIALS

This retrospective study compared thirty-eight consecutive patients with rectal adenocarcinoma who underwent total neoadjuvant therapy followed by total mesorectal excision. Complete WMH of the entire rectum was available for 18 patients, whereas hemisected whole-mount specimens were available for 20 patients. Annotations of the rectal wall, 8-15 corresponding landmarks, and 3 corresponding independent validation targets were made by a gastrointestinal pathologist and an abdominal radiologist on WMH and MRI. Ground truth labels of residual viable tumor, tumor bed, and background healthy tissue were also annotated on WMH. Target registration error (TRE) was computed to evaluate co-registration accuracy using rigid point-based registration (PBR) and a deformable linearized iterative boundary reconstruction (LIBR) alignment method. Additionally, 184 MRI radiomic features were extracted for each voxel inside the annotated rectum. The predictive potential for MRI radiomics to separate ground truth tissue pathology labels at voxel scale was assessed using supervised uniform manifold approximation and projection (UMAP).

RESULTS

TRE of the image fusion method for complete WMH specimens was 2.2±0.4 mm using PBR and 1.5±0.3 mm using LIBR ($p<0.001$). For hemisected WMH specimens, TRE was 1.4±0.6 mm using PBR and 1.0±0.3 mm using LIBR ($p<0.001$). TRE for hemisected WMH was lower than TRE for complete WMH using PBR ($p<0.001$) and LIBR ($p<0.001$). UMAP analysis showed clear separation of ground truth tissue pathology that was reproducible across complete and hemisected WMH datasets.

CONCLUSION

Accurate co-registration can be achieved in hemisected whole-mount specimens. Lower TRE was observed, likely due to smaller regions of interest at the expense of smaller territory of ground truth pathology. Hemisected whole-mount specimens are adequate for establishing voxel-to-voxel correspondence between MRI and ground truth histopathology.

CLINICAL RELEVANCE/APPLICATION

The MRI-WMH image fusion workflow establishes a high-quality reference standard that provides voxel-scale correspondences between imaging features and ground truth pathology, enabling greater precision for predictive models to identify residual disease on imaging.

S3B-SPGI-12 AI-BASED LIVER FAT QUANTIFICATION FROM ULTRA-LOW-DOSE CT

Lawrence Carl, MD (*Presenter*)
Arnaldo Mayer, PhD (*Abstract Co-Author*)
Edith M. Marom, MD (*Abstract Co-Author*)
George Biniashvili (*Abstract Co-Author*)
Lilach Arbel (*Abstract Co-Author*)

PURPOSE

To assess a novel AI-based algorithm for the quantification of liver fat fraction (FF) by ultra-low dose (ULD) CT

METHODS AND MATERIALS

We prospectively enrolled 31 consented patients for liver CT and MRI scans performed the same day. Liver MRI: acquired with an Ingenia 3T magnet (Philips, Best, The Netherlands), comprising mDIXON QUANT PDFF scan. Liver CT: non-contrast ULD-CT scan (kVp = 140, fixed current = 10 mA for 0.5 s, and average DLP = 11.49), 256 detectors Revolution CT (GE Healthcare, USA). Following automatic liver segmentation and masking in both CT and MRI, the mDIXON QUANT scan was co-registered to the ULD-CT to provide a ground truth (GT) PD-FF map for each subject's liver. A transformer-based SwinUNETR [1] neural architecture was trained and evaluated in a 7-folds cross-validation scheme to predict the 3D PD-FF maps, with the ULD-CT scans as input and the co-registered mDIXON QUANT PD-FF maps as GT. For comparison, a direct linear regression model (LRM) was also fitted on each training fold, relating ULD-CT HU values at 140 kVp to the MRI-derived PD-FF values, following the approach described in [2] for 120 kVp. Averaging over the folds, leads to: PD-FF [%] = -0.54 · CT [HU] + 33.46. The results for the novel method and the LRM method were presented as a volumetric liver average and on a slice by slice base.

RESULTS

Volumetric analysis using the novel neural method achieved an R 2 of 0.86 and an absolute FF error (L 1) of 1.52% (±1.03%), outperforming the LRM results of R 2 =0.79 and L 1 =1.84% (±1.23%) (P>0.05). Using the per slice method, the novel method performance decreased slightly, with R 2 =0.72, and L1=1.92% (±1.72%). However, for LRM, slice-level performances collapsed entirely at R 2 =-8.80 and L 1 =5.32% (±14.32%) (p<0.01), indicating a stronger spatial localization potential for the proposed neural method in comparison to the LRM. Furthermore, within the PD-FF range corresponding to normal to mild fat content (0-14%), the proposed method maintained a consistent L 1 error of 1.50% (±0.94%) while the LRM error increased to L 1 =1.95% (±1.28%) (P<0.05).

CONCLUSION

The proposed neural model successfully demonstrated the feasibility of predicting liver PD-FF from a ULD-CT scan, outperforming the LRM approach.

CLINICAL RELEVANCE/APPLICATION

These initial results support the potential of ULD-CT as a viable tool for non-invasive NAFLD screening.

S3B-SPGI-13 PROGNOSTIC VALUE OF CT-DERIVED BODY COMPOSITION IN STAGE II RECTAL CANCER MANAGEMENT

Fengli Jiang (*Presenter*)
Dening Ma, MD, PhD (*Abstract Co-Author*)

PURPOSE

This study aims to investigate the ??associations between?? CT-derived body composition parameters ??and?? clinical outcomes, such as overall survival (OS), prolonged length of stay (LOS), and postoperative complications, ??in patients with stage II rectal cancer??, emphasizing their prognostic significance.

METHODS AND MATERIALS

This ??retrospective cohort study enrolled?? patients with stage II rectal cancer ??who underwent curative resection without neoadjuvant therapy from 2010 to 2022??. ??Both univariable and multivariable analyses were performed to assess the ??relationships?? between body composition parameters ??and?? clinical outcomes. ??A nomogram was developed?? using multivariable Cox proportional hazards models to predict overall survival?? in rectal cancer patients. The nomogram's validation involved?? time-dependent receiver operating characteristic (ROC) curve analysis, calibration plots, ?and?? decision curve analysis ??to evaluate its predictive accuracy and clinical utility.

RESULTS

Among 975 patients ??(median age 63 years, IQR 55-70 years; 331 [33.9%] female)??, 183 deaths were recorded during a median follow-up period of 53 months (IQR 33-83 months). ??Low skeletal muscle density (SMD)?? was associated with an ??increased odds?? of severe postoperative complications (Clavien-Dindo =III grade) ?? (OR=0.431; 95% CI 0.204-0.909)??. ??Additionally, a high visceral-to-subcutaneous adipose tissue ratio (VSR)?? ??predicted?? prolonged length of stay (LOS =10 days) ??with an odds ratio of 1.329 (95% CI 1.019-1.734)??. ??Multivariable analysis identified seven independent predictors?? for OS: age, gross tumor type, perineural invasion, lymphovascular invasion, inflammatory burden index, subcutaneous fat area (SFA), ??and?? SMD. ??The nomogram exhibited?? area under the curve (AUC) values of 0.767/0.616, 0.767/0.618, and 0.746/0.665 ??at 1-year, 3-year, and 5-year follow-ups in training/validation cohorts??, respectively. ??This prognostic tool showed?? significantly superior predictive performance compared to single-biomarker models?.

CONCLUSION

Visceral-to-subcutaneous adipose tissue ratio (VSR) emerged as an ??independent predictor of prolonged LOS, ??while low SMD was significantly associated with?? severe postoperative complications (Clavien-Dindo grade III or higher)??. Both low SMD and SFA were identified as high-risk factors for poor prognosis and served as independent predictors of stage II rectal cancer progression.

CLINICAL RELEVANCE/APPLICATION

Our study demonstrates?? that integrating body composition parameters ??significantly enhances?? prognostic stratification ??for stage II rectal cancer?? patients who have not received neoadjuvant therapy??.

S3B-SPGI-14 PORTAL VENOUS PHASE PERITUMORAL HYPOENHANCEMENT ON MRI CAN COMPLEMENT MICROVASCULAR INVASION ON PATHOLOGY FOR PREDICTING HCC RECURRENCE-FREE SURVIVAL

Hanyu Jiang, MD (*Presenter*)
Xinyuan Jia (*Abstract Co-Author*)
Yanshu Wang (*Abstract Co-Author*)
Junhan Pan (*Abstract Co-Author*)
Riccardo Sartoris, MD (*Abstract Co-Author*)
Jules Gregory (*Abstract Co-Author*)
Aurelie Beaufrere (*Abstract Co-Author*)
Danielle E. Kruse, MD (*Abstract Co-Author*)
Ming Kuang, MD, PhD (*Abstract Co-Author*)
Feng Chen, MD (*Abstract Co-Author*)

Bin Song, MD (*Abstract Co-Author*)
Mustafa R. Bashir, MD (*Abstract Co-Author*)
Maxime Ronot, MD, PhD (*Abstract Co-Author*)

PURPOSE

Microvascular invasion (MVI) is associated with increased postoperative recurrence in hepatocellular carcinoma (HCC), but its assessment relies on histopathologic examination which is subject to sampling errors. Therefore, we aimed to propose an MRI-Pathology Criterion (MPC) integrating preoperative peritumoral MRI features with histopathologically-assessed MVI for improving prognostication.

METHODS AND MATERIALS

In this international multi-center cohort study, 1046 patients with single BCLC 0/A HCC who underwent curative-intent resection and preoperative contrast-enhanced MRI at six tertiary hospitals (China, France, USA) were retrospectively included in the training (n =656) or testing (Eastern, n =212; Western, n =178) datasets. Four MRI features were assessed: corona enhancement, portal venous phase (PVP) peritumoral hypoenhancement, T2 peritumoral mild-moderate hyperintensity, and hepatobiliary phase peritumoral hypointensity. Using early recurrence-free survival (RFS=2 years) as the endpoint, the MPC combined histopathologically-assessed MVI with independently prognostic MRI feature(s).

RESULTS

In the training dataset, PVP peritumoral hypoenhancement (HR, 1.83; p <.001) and histopathologically-assessed MVI (HR, 2.59; p <.001) independently predicted early RFS. Based on these two variables, the MPC stratified patients into the high-risk ("MVI and PVP +"; early RFS rate, 32.0%; median RFS, 11.6 months), intermediate-risk ("MVI + PVP -"; 56.1% and 31.0 months; p <.001 vs. high-risk), or low-risk ("MVI -", 78.0% and 60.2 months; p <.001 vs. intermediate-risk) groups. In both testing datasets, early RFS outcomes were consistently distinct among the three risk groups (p values, .023 to .035), and the MPC remained predictive of early RFS after adjusting for 18 other clinico-pathologic-surgical prognostic factors (e.g., a-fetoprotein, tumor size, Edmondson-Steiner grade, resection extent; p values, <.001 to .043).

CONCLUSION

The MPC synergizes MRI (PVP peritumoral hypoenhancement) and histopathologically-assessed MVI to enhance HCC recurrence prediction, which may inform postoperative monitoring and adjuvant therapy decisions.

CLINICAL RELEVANCE/APPLICATION

This study revealed the utility of integrating PVP peritumoral hypoenhancement on MRI with histopathologically-assessed MVI to improve HCC recurrence prediction, mitigating the limitations of sampling variability in histopathologic examination. The developed MPC may serve as a robust tool for stratifying postoperative recurrence risks as well as informing follow-up and adjuvant therapy decisions (e.g., intensified monitoring and prolonged admistrating duration of adjuvant therapy for the MPC-defined high-risk patients).

S3B-SPGI-15 VIRTUAL COLONOSCOPY: CURRENT INDICATIONS AND PATIENT TOLERANCE IN CLINICAL PRACTICE

Patricia M. Carrascosa, MD, PhD (*Presenter*)
Carlos Capunay, MD (*Abstract Co-Author*)
Jimena B. Carpio, MD (*Abstract Co-Author*)

PURPOSE

Virtual colonoscopy (VC), or CT colonography, has emerged as a non-invasive alternative to conventional colonoscopy (CC), offering significant advantages in patient comfort and safety. It is increasingly used in colorectal cancer screening and for the evaluation of various colonic conditions, particularly in patients for whom CC is contraindicated due to medical comorbidities or prior incomplete procedures. One of the key benefits of VC is improved patient experience.The purpuse of this study is to evaluate the current clinical indications for VC at our institution and assess patient-reported experiences regarding the procedure.

METHODS AND MATERIALS

A retrospective review was conducted on 1,217 patients who underwent VC at our institution over the past four years. Examinations were performed using multislice CT scanners (68, 128, and 256 detectors). Technical parameters included 1 mm slice thickness, 0.5 mm reconstruction interval, 80-100 kV, and 200-500 mAs, adjusted for patient size. CO2 insufflation was used to enhance colonic distension and minimize discomfort, as CO2 is rapidly absorbed, allowing for quicker post-procedure recovery. After the procedure, all patients completed a questionnaire evaluating their expectations and level of discomfort, using a Likert scale (1 = no discomfort, 2 = mild, 3 = moderate, 4 = severe).

RESULTS

Among the 1,217 patients, 829 (68.1%) were female and 382 (31.4%) were male. No complications were reported in the patients studied. The most common clinical indication for VC was incomplete colonoscopy (n = 321), followed by abdominal pain (n = 250), constipation or altered bowel habits (n = 210), occult blood in stool (n = 82), diverticulosis (n = 79), rectal bleeding (proctorrhagia) (n = 60), anemia (n = 56), and unexplained weight loss (n = 56). Regarding patient experience, 98% of individuals stated that the procedure met their expectations. When assessing comfort levels, 82% of patients reported no discomfort, 12% experienced mild discomfort, and 6% reported moderate discomfort, while no patient experienced severe pain during the procedure.

CONCLUSION

While conventional colonoscopy remains the gold standard for colorectal cancer screening, virtual colonoscopy provides a valuable non-invasive alternative for patients with specific clinical indications. The high acceptance rate and minimal discomfort reported in our cohort reinforce VC as a patient-friendly diagnostic tool. With ongoing technological advancements, VC continues to play an essential role in colonic evaluation and colorectal cancer screening strategies.

CLINICAL RELEVANCE/APPLICATION

VC continues to play an essential role in colonic evaluation and colorectal cancer screening strategies.

S3B-SPGI-16 THE VALUE OF CT IMAGE FUSION IN PANCREATIC CANCER RESECTABILITY ASSESSMENT A READER STUDY

Mengru Li (*Presenter*)
Wei Wei (*Abstract Co-Author*)

PURPOSE

To evaluate the clinical value of CT arterial-venous phase fused images in assessing the resectability of pancreatic ductal adenocarcinoma through a reader study.

METHODS AND MATERIALS

A retrospective, multireader, multicase reader study was conducted using 30 contrast-enhanced upper abdominal CT images from our hospital between january 2023 and December 2024. Two preliminary reports were generated for pancreatic cancer resectability assessment: one using separate arterial and venous phase images, and the other utilizing arterial-venous phase fused images. Three experienced abdominal radiologists evaluated reading time, report consistency (RADPEER), and compared outcomes between the first session and the second session from February to March 2025. Reading time and report consistency were analyzed using IBM SPSS Statistics 27. Additionally, accuracy, sensitivity, and specificity between the two sessions were compared through Chi-square.

RESULTS

The introduction of arterial-venous phase fused imaging reports significantly reduced average reading times from 316.87 seconds ± 76.14 to 154.03 seconds ±32.05 ($P < .001$). In the analysis of pancreatic cancer resectability assessment, significant improvements in sensitivity were observed across all evaluation categories: resectable (84.3% to 90.8%; $P < .001$), borderline resectable (80.0% to 80.0%; $P < .001$), and locally advanced (30.0% to 100.0%; $P < .001$). Despite overall enhancement in diagnostic performance, inter-reader variability among individual radiologists was still noted.

CONCLUSION

The utilization of arterial-venous phase fused imaging in pancreatic ductal adenocarcinoma enhances both the efficiency and diagnostic quality of resectability assessment reporting.

CLINICAL RELEVANCE/APPLICATION

This study investigates the clinical value of domain-specific CT image fusion technology in pancreatic cancer resectability assessment reports and validates its potential to enhance radiology workflows through a reader study. The findings demonstrate that pancreatic cancer resectability assessment reports generated using fused images reduce radiologists' reading time while improving the consistency, quality, and sensitivity of the reports.

S3B-SPGU-3 TEXTURE ANALYSIS ENHANCES DIAGNOSTIC ACCURACY OF PIRADS 5 LESIONS IN PROSTATE MRI

Chen-Jiang Wu, MD (*Presenter*)

PURPOSE

Prostatitis is frequently observed in false positive lesions scored as PI-RADS 5, necessitating improved diagnostic tools. This study investigated the potential of MRI texture analysis of ADC sequences to enhance the differentiation of prostatitis from prostate cancer (PCa) in PI-RADS 5 lesions.

METHODS AND MATERIALS

This retrospective study enrolled patients undergoing 3T MRI with lesions scored as PI-RADS 5. Lesions were manually delineated on ADC maps, and texture features were extracted using Firevoxel. Clinical data and ADC texture parameters were collected. The diagnostic performance (AUC, sensitivity, specificity, PPV, NPV) of clinical, ADC texture, and a combined model were calculated and compared using the DeLong test.

RESULTS

The final cohort included 185 patients with 185 PI-RADS 5 lesions (160 PCa, 25 prostatitis). The combined model, incorporating clinical indicators (Age, PSAD) and ADC texture parameters (signal coefficient of variation, ADC percentile), demonstrated the best diagnostic performance: sensitivity 98.7%, specificity 60.0%, PPV 97.9%, NPV 71.6%, and AUC 93.1%. Bootstrap resampling confirms the robustness of the model. Decision curve analysis indicated a better net benefit with the combined model for guiding biopsy decisions.

CONCLUSION

ADC imaging texture parameters are valuable for the differential diagnosis of prostatitis from lesions scored as PI-RADS 5. Their combination with clinical indicators significantly improves diagnostic performance, providing valuable information to facilitate surgical decision-making and potentially reduce unnecessary biopsies.

CLINICAL RELEVANCE/APPLICATION

The improved positive predictive value for PI-RADS 5 lesions achieved by the combined model has the potential to significantly reduce the number of unnecessary biopsies performed for highly suspected prostate cancer.

S3B-SPGU-6 A TRANSFORMER-BASED DEEP LEARNING MODEL FOR PREOPERATIVE PREDICTION OF BIOCHEMICAL RECURRENCE FOLLOWING RADICAL PROSTATECTOMY USING MULTIPARAMETRIC MRI

Ye Xiang (*Presenter*)
Fan Li (*Abstract Co-Author*)
Lihua Zhuo (*Abstract Co-Author*)
Ruishan Liu (*Abstract Co-Author*)
Lv Yue (*Abstract Co-Author*)

PURPOSE

To develop and validate a Transformer-based deep learning model using 2.5D multiparametric MRI for the preoperative prediction of biochemical recurrence (BCR) after radical prostatectomy (RP), and to assess whether integrating clinical features enhances prognostic performance.

METHODS AND MATERIALS

This multicenter retrospective study included 1164 patients who underwent RP between August 2013 and September 2021, with follow-up through March 2024. Patients were divided into training (n=498), internal test (n=214), and two external test cohorts (n=378 and n=74). A Transformer-based deep learning model was constructed using 2.5D tumor-centric MRI slices. A combined model was also developed by integrating key clinicopathological predictors. Model performance was evaluated via receiver operating characteristic (ROC) curves, DeLong's test, Hosmer-Lemeshow goodness-of-fit, and decision curve analysis (DCA). Grad-CAM heatmaps provided interpretability, and Kaplan-Meier analysis assessed associations between risk stratification and disease-free survival (DFS).

RESULTS

The Transformer-based model yielded strong predictive performance, with AUCs of 0.92 (95% CI: 0.879-0.974), 0.84 (95% CI: 0.784-0.894), and 0.82 (95% CI: 0.652-0.967) in the internal and two external test sets, respectively. The combined model further improved prediction, achieving AUCs of 0.94 (95% CI: 0.885-0.992), 0.94 (95% CI: 0.900-0.969), and 0.83 (95% CI: 0.693-0.965). Statistical analysis confirmed that the combined model significantly outperformed both the deep learning and clinical-only models ($P < 0.05$). High-risk patients, as identified by the model, demonstrated significantly shorter DFS than low-risk patients ($P < 0.05$).

CONCLUSION

The proposed integrative model combining Transformer-based imaging features with clinical data effectively predicts postoperative BCR and enables robust patient risk stratification.

CLINICAL RELEVANCE/APPLICATION

This model may facilitate personalized surveillance and treatment strategies by identifying patients at high risk of recurrence following prostatectomy.

S3B-SPHN-2 MULTIMODAL DEEP LEARNING MODEL FOR PREDICTING ORIGINS OF METASTATIC CERVICAL LYMPH NODES

Xi Lin (*Presenter*)
Chunyan Li (*Abstract Co-Author*)
Jinjing Ou (*Abstract Co-Author*)
Cuiju Yan (*Abstract Co-Author*)

PURPOSE

To develop an artificial intelligence (AI) model for predicting the potential primary tumor of metastatic cervical lymph nodes, thereby providing clinical decision support for origin identification.

METHODS AND MATERIALS

The retrospective study analyzed 7880 metastatic cervical lymph nodes from 7810 patients across two centers. At center 1, a total of 7633 nodes from 7570 patients were divided into a training set (6106 nodes) and an internal test set (1527 nodes) at an 8:2 ratio. An independent external test set consisted of 247 metastatic cervical lymph nodes from 240 patients at center 2. An AI model based on the InceptionResNetV2 architecture was developed to combine ultrasound with clinicopathological metadata (sex, age, nodal level, pathological subtype). Predictive performance for metastases from head-neck, thyroid, respiratory, female reproductive, and digestive systems cancers was evaluated in the internal and external test sets. The performance for the five-class prediction was evaluated using macro-AUC and top-k accuracy, while for individual classes was assessed via AUC.

RESULTS

The AI model exhibited a macro-AUC of 0.851 (95% CI: 0.838-0.864) and 0.800 (0.768-0.828) in the internal and external test sets, respectively. The model's top-2 and top-3 accuracy were 0.887 (0.879-0.894) and 0.907 (0.901-0.914) in the internal test set, and 0.871 (0.851-0.891) and 0.893 (0.876-0.909) in the external test set. AUCs were 0.949 for the thyroid, 0.942 for the head and neck, 0.820 for the respiratory system, 0.793 for the female genital system, and 0.747 for the digestive system in the internal test set. Corresponding external evaluation results were 0.903 for thyroid, 0.876 for the head and neck, 0.759 for the respiratory system, 0.758 for the female genital system, and 0.690 for the digestive system.

CONCLUSION

Our model exhibited good predictive performance for identifying the primary tumor of metastatic cervical lymph nodes from routine ultrasound images and clinicopathological metadata.

CLINICAL RELEVANCE/APPLICATION

To search for the primary tumor of nodal metastasis, whole body radiological imaging and multitudinous immunohistochemical markers are required. Considering that ultrasound is the first examination method for superficial lymph nodes, AI based on ultrasound and clinicopathological metadata may reduce unnecessary following imaging examination sites, and guide the targeted selection of markers.

S3B-SPHN-5 EVALUATION OF BAYES'RULE BETWEEN NASOPHARYNGEAL LYMPHOID HYPERPLASIA AND NASOPHARYNGEAL CARCINOMA BASED ON MR SIGNAL INTENSITY RATIO

Jiuping Liang (*Presenter*)
Xueling Qin (*Abstract Co-Author*)
Yiyong Liu (*Abstract Co-Author*)

PURPOSE

To evaluate the efficiency of Bayes'rule, a method based on MR signal intensity ratio (SIR),to distinguish nasopharyngeal lymphoid hyperplasia (NPLH) from nasopharyngeal carcinoma (NPC).

METHODS AND MATERIALS

One hundred and twenty- six patients with pathologically proved nasopharyngeal lesions (27 cases of NPLH and 99 cases of NPC) from July 2017 to July 2023 were retrospectively analyzed. Max-signal intensity (Max-SI), Min-signal intensity (Min-SI) and Mean-signal intensity (Mean-SI) of nasopharyngeal lesions were obtained on axial T2WI and T1WI+C, and the ratios with Mean-SI of longuscapitis were calculated to construct the Bayes'rule of NPLH and NPC.

RESULTS

(1) The Max-SIR (6.70±0.99 vs 4.59±0.76), Min-SIR (4.40±0.65 vs 3.04±0.73), Mean-SIR (5.49±0.71 vs 3.83±0.69) on T2WI and Min-SIR (1.55±0.30 vs 1.73±0.29) on T1WI+C were significantly different between NPLH and NPC($P < 0.05$). (2) Using the stepwise method, Max-SIR on T2WI and Min-SIR on T1WI+C demonstrated statistical significance in distinguishing NPLH from NPC. Two sets of classification functions were derived as follows: Y1=-29.64+6.09×T2WI-Max-SIR+17.34×T1WI+C-Min-SIR and Y2=-43.36+9.47×T2WI-Max-SIR+14.06×T1WI+C-Min-SIR. The Original results indicate an overall discriminant coincidence rate of 95.2%, while the cross-validated results demonstrate a slightly lower overall discriminant coincidence rate of 93.7%.

CONCLUSION

The MR-SIR-based Bayes'rule is a non-invasive and ease of use method in identifying NPLH from NPC with a high accuracy.

CLINICAL RELEVANCE/APPLICATION

The MR-SIR-based Bayes'rule is a practical method without additional scanning techniques in differentiating NPLH from NPC with a high accuracy.

S3B-SPHN-6 DEVELOPMENT AND VALIDATION OF A MULTIMODAL DEEP LEARNING MODEL FOR PREOPERATIVE DIAGNOSIS OF GLAND TUMORS: A DUAL-CENTER STUDY BASED ON ULTRASOUND AND CLINICAL DATA

Shaozheng He (*Abstract Co-Author*)

PURPOSE

To develop and evaluate a deep learning-based multimodal fusion model integrating grayscale ultrasound (US), color Doppler ultrasound (Color US), and clinical data for the preoperative classification of Parotidular tumors, and to compare its diagnostic performance with single-modality models

METHODS AND MATERIALS

A total of 306 cases from two centers were divided into a training set (n=214) and validation set (n=92). The multimodal model achieved the best performance (AUC = 0.9118, accuracy = 0.8804). A multimodal framework was proposed to classify benign and malignant parotid Parotid tumors by fusing grayscale US, Color US, and clinical data. Grayscale and Color US images were processed via separate ResNet-18 CNNs, followed by Transformer Encoders to extract modality-specific contextual features. Clinical data were embedded using an MLP and refined with a Transformer Encoder to model feature dependencies. The imaging features and clinical embedded features were integrated via a Cross-Transformer Encoder, where clinical features served as Query, and the concatenated image features as Key and Value. The fused representation was passed through fully connected layers with sigmoid activation for classification.

RESULTS

The multimodal model achieved the best performance (AUC = 0.9118), surpassing single-modality models: Gray US (AUC = 0.8361), Color US (AUC = 0.8118), and Clinical (AUC = 0.8500). The multimodal model consistently demonstrated better discriminative ability in ROC and PR curves, a more favorable clinical net benefit in DCA, and better calibration with the lowest Brier score. Additionally, the radar plot highlights its balanced and superior performance across all key metrics. The kernel density estimate (KDE) plots of predicted probabilities further illustrate the clearer separation of positive and negative cases achieved by the multimodal fusion model compared to the single-modality models.

CONCLUSION

The multimodal fusion model combining Gray US, Color US, and clinical features outperformed single-modality approaches, offering a more accurate and reliable diagnostic solution for Parotidular tumors.

CLINICAL RELEVANCE/APPLICATION

By significantly improving the diagnostic accuracy of Parotidular tumors, the multimodal fusion model enhances clinical decision-making and helps reduce diagnostic uncertainty. Its implementation may lead to earlier and more precise treatment strategies, minimize unnecessary biopsies or surgeries, and ultimately improve patient outcomes.

S3B-SPHN-7 BEYOND THE T: QUANTITATIVE VOLUMETRIC 3D MRI ANALYSIS FOR LYMPHATIC SPREAD IN HNSCC IN COMPARISON WITH TNM

Christian Booz, MD (*Presenter*)
Andreea-Ioana Nica (*Abstract Co-Author*)
Thomas J. Vogl, MD, PhD (*Abstract Co-Author*)
Maximilian Fleischmann (*Abstract Co-Author*)
Robert Sader, MD, PhD (*Abstract Co-Author*)
Ibrahim Yel, MD (*Abstract Co-Author*)
Philipp Thoenissen (*Abstract Co-Author*)

PURPOSE

To investigate the relationship between primary tumor volume, the spatial distribution of cervical lymph node metastases, and TNM staging in patients with oral and pharyngeal squamous cell carcinoma using high-resolution MRI-based volumetric and distance measurements.

METHODS AND MATERIALS

In this retrospective analysis, 116 predominantly male (62.9%) patients with a mean age of 67.7 ± 11.5 years with histologically confirmed oral and pharyngeal squamous cell carcinoma who underwent either primary surgical resection with neck dissection or definitive chemoradiation were evaluated. MRI-based volumetric analysis and center-to-center distance measurements between the primary tumor and cervical lymph node metastases were performed using dedicated 3D postprocessing software. Spearman correlation coefficients were calculated to assess relationships between tumor volume, lymph node distance, and TNM staging parameters.

RESULTS

Tumor-to-lymph node distances on MRI ranged from 11.7 to 117.3 mm (mean: 47.6 ± 19.4 mm). Tumor volume varied from 0.5 to 87.2 cm^3 (median: 13.3 ± 13.2 cm^3), and was higher in male patients. A significant correlation was observed between tumor volume and both lymph node distance and pT stage ($p < 0.0001$). No correlation was found between lymph node volume and metastasis distance ($p = 0.3436$). The correlation between tumor volume and the distance to metastatic lymph nodes was stronger (Spearman's $r = 0.4541$, $p < 0.0001$) than the correlation between the T-stage (TNM classification) and nodal distance (Spearman's $r = 0.2682$, $p = 0.0036$). Bilateral nodal metastases were associated with larger tumors (16.3 cm^3 vs 12.3 cm^3, $p < 0.0001$) and greater spread distances (52 mm vs 46 mm, $p < 0.0001$).

CONCLUSION

Tumor volume is a stronger predictor of the spatial extent of lymph node metastases than T-stage alone. Larger tumors were associated with greater distances to metastatic lymph nodes, particularly in cases with bilateral involvement. Lymph node volume did not correlate with spread distance, suggesting that even small nodes may be located at significant distances. Findings highlight the added value of quantitative 3D MRI-based volume and distance analyses in predicting metastatic spread patterns in head and neck cancer, ptotenially improving surgical and radiotherapeutic planning compared with traditional level-based anatomical classification systems.

CLINICAL RELEVANCE/APPLICATION

MRI-based 3D volumetric and spatial analysis may offer a more precise prediction of metastatic spread in oral and pharyngeal squamous cell carcinoma than conventional TNM staging, supporting improved surgical and radiotherapy planning.

S3B-SPIN-1 ENHANCING HEMORRHAGE SEGMENTATION PERFORMANCE IN PEDIATRIC HEAD CT USING PRE-TRAINED ADULT HEMORRHAGE SEGMENTATION MODEL

Jihwan Kim, BSc, MSc (*Presenter*)
Joonseo Oh (*Abstract Co-Author*)
Jongjun Won, BS (*Abstract Co-Author*)
Hyungbin Park (*Abstract Co-Author*)
Joon Park, MD (*Abstract Co-Author*)
Gil-Sun Hong, MD, PhD (*Abstract Co-Author*)
Namkug Kim, PhD (*Abstract Co-Author*)

PURPOSE

Although numerous artificial-intelligence models have been developed to segment intracranial hemorrhage (ICH) in adults, their performance in pediatric patients remains uncertain. To bridge this gap, we investigated targeted strategies to enhance segmentation accuracy for pediatric ICH.

METHODS AND MATERIALS

The adult cohort comprised 965 training scans (643 hemorrhage, 322 normal; mean age ± SD 52.1 ± 17.6 years; 61 % male) and 889 test scans (169 hemorrhage, 720 normal; mean age 48.9 ± 16.4 years; 51 % male). The pediatric cohort, collected at a tertiary medical centre, contained 1,060 training scans (133 hemorrhage, 927 normal; median age 7.8 years, inter-quartile range 4.0-11.0; 58 % male) and 291 test scans (33 hemorrhage, 258 normal; median age 8.1 years, IQR 4.0-12.0; 58 % male). We employed STUNet—an nnUNet variant—for segmentation and compared four training strategies: (1) adult-only, (2) pediatric-only, (3) combined adult + pediatric, and (4) fine-tuning a model pre-trained on adults with pediatric data. Model performance on the pediatric hemorrhage test set was evaluated using the Dice similarity coefficient (DSC), sensitivity, and specificity.

RESULTS

The adult-only model performed well on adult data (DSC = 0.675; sensitivity = 0.982; specificity = 0.831) but its specificity collapsed when applied to pediatric cases (DSC = 0.555; sensitivity = 0.939; specificity = 0.109). The pediatric-only model also showed poor specificity on the pediatric test set (DSC = 0.508; sensitivity = 0.970; specificity = 0.202). Training on the combined adult + pediatric dataset improved the Dice score but still yielded low specificity (DSC = 0.596; sensitivity = 0.970; specificity = 0.248). By contrast, the fine-tuned model—pre-trained on adults and then fine-tuned with pediatric data—achieved a dramatic gain in specificity with only a modest drop in sensitivity (DSC = 0.541; sensitivity = 0.879; specificity = 0.818). Importantly, this fine-tuned model retained solid performance on the adult test set as well (DSC = 0.546; sensitivity = 0.923; specificity = 0.918).

CONCLUSION

The adult-only segmentation model—despite never encountering pediatric ICH—exhibited respectable generalization, particularly in sensitivity. Fine-tuning this model with pediatric data, however, dramatically increased specificity with only a minor reduction in sensitivity.

CLINICAL RELEVANCE/APPLICATION

These findings suggest that while adult-trained models can serve as strong initialization points, domain adaptation is essential for achieving clinically reliable performance in relatively limited pediatric populations.

S3B-SPIN-2 A DEEP LEARNING METHOD FOR THE AUTOMATIC CHARACTERIZATION OF LESIONS IN TAP CT SCANS FROM CANCER PATIENTS

Marc-Michel Rohe (*Presenter*)
Sophie Loizillon (*Abstract Co-Author*)
Arnaud Marcoux (*Abstract Co-Author*)
Alexandre Bone (*Abstract Co-Author*)

PURPOSE

TAP-CT imaging plays a pivotal role in the clinical management of cancer patients, but their analysis can be of burden for overstretched radiology services. Computer-assisted detection has the potential to streamline TAP-CT workflows but must avoid the pitfall of over-detection. This is why, in this study, we present a deep learning method for the automatic characterization of lesions in cancer patients, which could allow to filter out irrelevant detections such as cysts.

METHODS AND MATERIALS

In this retrospective study, we use a multicentric database containing 4176 cancer patients with 4765 CT scans from multiple international institutions. These images were acquired on a large variety of scanners with heterogeneous acquisition protocols, which reflect routine clinical setting. Expert radiologists manually contoured in 3D all visible lesions with access to the original radiology reports include medical background, and characterized, when possible, in one of the following classes: solid, cystic, lymphadenopathy, ground-glass opacity, lytic and sclerotic. The dataset was split between 3980 scans (35136 lesions) used for training and an independent test set of 724 randomly selected scans (5207 lesions). We train a deep learning model based on a ResNet architecture to automatically characterize lesions. The model input consisted of a 2D patch centered on the lesion, with the segmented lesion serving as an additional layer to the original patch. Evaluation was performed on the test set using ROC analysis. and comparison of model performance was assessed using DeLong's test.

RESULTS

Our deep learning model achieved an accuracy of 0.91 on our test set for the semiology classification of lesions in the 6 classes of interest. In particular, characterization of soft tissue lesions allowed cysts to be distinguished from solid lesions with an AUC of 0.94, significantly outperforming a baseline approach based on median HU

thresholding (AUC: 0.62; p-value: 2e-16). With regard to bone lesions, the AI model achieved an excellent AUC of 0.97 for the differentiation of lytic from sclerotic lesions. A very good sensitivity (0.90) was also found for the detection of lymphadenopathy.

CONCLUSION

The proposed AI solution for the automatic lesion characterization on TAP CT scans in oncology imaging showed promising performance on a large multi-center real-world dataset with different scanners, manufacturers and imaging protocols.

CLINICAL RELEVANCE/APPLICATION

This AI system may help radiologists to reduce the time needed to analyze TAP CT scans in oncology imaging.

S3B-SPIN-3 RADFORMER: A SELF-SUPERVISED FOUNDATION MODEL TO ADDRESS INCOMPLETENESS IN RADIOMICS FEATURES

Khashayar Namdar, PhD, MSc (*Presenter*)
Saeidehsadat Mirjalili (*Abstract Co-Author*)
Pascal N. Tyrrell, PhD (*Abstract Co-Author*)
Leo Anthony Celi (*Abstract Co-Author*)

PURPOSE

Radiomics-based AI has shown competitive performance compared with deep learning across various medical imaging tasks. However, radiomics pipelines suffer from poor reproducibility due to sensitivity to feature extraction settings and missing feature subsets. We propose RadFormer, a self-supervised transformer-based radiomics foundation model designed to improve robustness and reproducibility in downstream tasks, even when incomplete feature sets are available.

METHODS AND MATERIALS

Using the OpenRadiomics dataset, we collected 476,424 radiomics feature vectors via PyRadiomics across multiple imaging modalities and institutions. We trained a transformer-based autoencoder with 768-dimensional embeddings using self-supervised learning, combining reconstruction, contrastive, and feature decorrelation losses. Random masking of features and feature families simulated feature dropout during training. For evaluation, we used the 2021 PI-CAI prostate cancer dataset from RadMLBench, which includes 3,045 radiomics features extracted from T2-weighted, apparent diffusion coefficient (ADC) maps, and diffusion-weighted imaging (DWI) MRI for 969 patients. The clinical task was binary classification of csPCa (Gleason score >3+3, n=637) versus non-csPCa (n=332). We applied 20-fold cross-validation with LightGBM, using a 75/25 train/validation split to guide grid search based on validation area under the receiver operating characteristic curve (AUC). We compared three pipelines on the same splits: (1) Benchmark (all features), (2) Baseline (shape + first-order only), and (3) RadFormer-Augmented (RadFormer embeddings from incomplete features).

RESULTS

The benchmark model, trained on the full radiomic feature set, achieved a mean AUC of 0.733 [95% CI: 0.684-0.781]. In contrast, the model trained solely on shape and first-order features showed reduced discriminatory performance, with an AUC of 0.693 [95% CI: 0.648-0.738], indicating a substantial loss of predictive information. Using RadFormer-augmented features in place of the omitted higher-order radiomic features, achieved an AUC of 0.729 [95% CI: 0.680-0.779], outperforming the reduced feature model ($p = 0.0471$). Although this performance did not significantly exceed the benchmark, there was no significant difference.

CONCLUSION

RadFormer recovered much of the lost performance due to feature incompleteness, reinforcing its utility as a substitute for handcrafted higher-order features in radiomic modeling.

CLINICAL RELEVANCE/APPLICATION

RadFormer is, to our knowledge, the first radiomics foundation model. It addresses a major barrier in radiomics reproducibility by learning generalizable embeddings from large-scale feature distributions.

S3B-SPIN-4 FROM DICTATION TO DIAGNOSIS: ENHANCING RADIOLOGY REPORTING WITH INTEGRATED SPEECH RECOGNITION IN MULTIMODAL LARGE LANGUAGE MODELS

Roman J. Gertz, MD (*Presenter*)
Nedim Beste, MD (*Abstract Co-Author*)
Thomas M. Dratsch, MD, PhD (*Abstract Co-Author*)
Simon Lennartz, MD (*Abstract Co-Author*)
Johannes Bremm (*Abstract Co-Author*)
Andra-Iza Iuga (*Abstract Co-Author*)
Alexander C. Bunck (*Abstract Co-Author*)
Kai Roman Laukamp, MD (*Abstract Co-Author*)
Jonathan M. Kottlors, MD (*Abstract Co-Author*)

PURPOSE

This study evaluates the efficiency and quality of radiology reporting using multimodal large language models (LLMs) compared to conventional reporting with speech recognition software. We hypothesized that by providing patient history, clinical questions, and pathological findings as minimal audio input, LLMs could generate complete radiological reports, including impressions tailored to the clinical question.

METHODS AND MATERIALS

A total of 480 reports from 80 imaging studies (radiographs, ultrasound, CT, MRI) were generated by two board-certified radiologists using three workflows: one using speech recognition software (conventional workflow), and two reports using the audio input capabilities of GPT-4o and Claude Sonnet 3.5, respectively within an LLM-based workflow. Reporting time, number of corrections, and cost per report were recorded. Using a 5-point Likert scale two independent radiologists assessed formal structure and report quality.

RESULTS

LLM-WF significantly reduced reporting time (GPT-4o/Sonnet 3.5: 38.9 ± 22.7 s vs. (C-WF): 88.0 ± 60.9 s, $P < 0.01$), required fewer corrections (GPT-4o: 1.0 ± 1.1, Sonnet 3.5: 0.9 ± 1.0 vs. C-WF: 2.4 ± 2.5, $P < 0.01$), and lowered costs (GPT-4o: $2.3 ± 1.4, Sonnet 3.5: $2.4 ± 1.4 vs. C-WF: $3.0 ± 2.1, $P < 0.01$). Reports generated with Sonnet 3.5 were rated highest in quality, while GPT-4o and conventional reports showed no difference.

CONCLUSION

Multimodal LLMs can generate high-quality radiology reports based solely on minimal audio input, with greater speed, fewer corrections, and reduced costs compared to conventional speech-based workflows. Their integration into clinical systems could address key efficiency gaps and should be further evaluated in prospective real-world settings.

CLINICAL RELEVANCE/APPLICATION

LLM-based reporting from minimal audio input has the potential to improve efficiency and report quality, supporting more streamlined workflows in clinical radiology.

S3B-SPIN-5 HARNESSING SPECTRAL RADIOMICS FROM PHOTON-COUNTING CT FOR NEXT-GEN LIVER METASTASIS CLASSIFICATION

Simon Hellbruck, BSc, MSc (*Presenter*)
Thilo Brandmayr (*Abstract Co-Author*)
Humberto Abraham Cortes Magdaleno, MD (*Abstract Co-Author*)
Thomas Wendler (*Abstract Co-Author*)
Thomas J. Kroencke, MD (*Abstract Co-Author*)
Josua A. Decker, MD (*Abstract Co-Author*)

PURPOSE

Photon-counting computed tomography (PCCT) introduces the capability to extract spectral radiomics features by leveraging multi-energy level data. This study explores the use of spectral radiomics to distinguish healthy from metastases-loaded livers using PCCT (NAETOM Alpha, Siemens Healthineers, Erlangen, DE).

METHODS AND MATERIALS

A retrospective analysis was conducted on 247 PCCT datasets: 148 healthy liver cases (mean age: 69 years; 95% CI: 67-71; 56 females, 92 males) and 99 with liver metastases (mean age: 71 years; 95% CI: 69-73; 50 females, 49 males). All datasets were reconstructed using a Qr40 kernel to generate monoenergetic images from 40 to 80 keV in 10 keV steps, as well as virtual non-contrast (VNC) images. Liver segmentation was performed on both healthy livers and livers with metastases using TotalSegmentator, applied to 70 keV and VNC images. All segmentations were reviewed and manually refined by a radiologist. Radiomic features were extracted from the segmented volumes using PyRadiomics. Feature selection was conducted using the Boruta algorithm, capped at 22 features. A random forest classifier with five-fold cross-validation was used for model training and evaluation.

RESULTS

Using radiomics features from only the 70 keV image yielded an average AUC of 0.81 for differentiating healthy and metastatic tissue. Including features from additional monoenergetic levels improved performance to an average AUC of 0.84. The inclusion of inter-energy-level features, such as intensity differentials and feature ratios, further enhanced performance, achieving an AUC of 0.89. The calculated contrast ratio of VNC vs. Mono 40 keV emerged as one of the most important features.

CONCLUSION

Overall, these findings provide initial evidence for the added value of spectral radiomics into PCCT-based imaging workflows. In this preliminary evaluation, the use of such information offers a more nuanced and stronger tool for the classification of liver CT texture, opening new avenues for opportunistic approaches and spectral radiomics research.

CLINICAL RELEVANCE/APPLICATION

This study demonstrates the clinical potential of integrating spectral radiomics into routine PCCT analysis pipelines. The improved discrimination between healthy and metastatic liver tissue may aid radiologists in earlier and more accurate diagnosis, treatment planning, and monitoring of oncologic patients. By surpassing traditional single-energy approaches, spectral radiomics can contribute to more personalized and precise patient care in liver oncology and beyond.

S3B-SPIN-6 PARROT, AN OPEN MULTILINGUAL RADIOLOGY REPORTS DATASET

Bastien Le Guellec, MD (*Presenter*)
Keno K. Bressem, MD (*Abstract Co-Author*)

PURPOSE

To develop and validate PARROT (Polyglottal Annotated Radiology Reports for Open Testing), a large, multicentric, open-access dataset of fictional radiology reports spanning multiple languages for testing natural language processing applications in radiology.

METHODS AND MATERIALS

From May to September 2024, radiologists were invited to contribute fictional radiology reports following their standard reporting practices. Contributors provided at least 20 reports with associated metadata including anatomical region, imaging modality, clinical context, and for non-English reports, English translations. All reports were assigned ICD-10 codes. A human vs. AI report differentiation study was conducted with 154 participants (radiologists, healthcare professionals, and non-healthcare professionals) assessing whether reports were human-authored or AI-generated.

RESULTS

The dataset comprises 2,658 radiology reports from 76 authors across 21 countries and 14 languages. Reports cover multiple imaging modalities (CT: 36.1%, MRI: 22.8%, radiography: 19.0%, ultrasound: 16.8%) and anatomical regions, with chest (19.9%), abdomen (18.6%), head (17.3%), and pelvis (14.1%) being most prevalent. In the differentiation study, participants achieved 53.9% accuracy (95% CI: 50.7%-57.1%) in distinguishing between human and AI-generated reports, with radiologists performing significantly better (56.9%, 95% CI: 53.3%-60.6%, $p<0.05$) than other groups.

CONCLUSION

PARROT represents the largest open multilingual radiology report dataset, enabling development and validation of natural language processing applications across linguistic, geographic, and clinical boundaries without privacy constraints.

CLINICAL RELEVANCE/APPLICATION

PARROT, a novel open-access dataset of 2,658 fictional radiology reports spanning 14 languages, enables cross-linguistic natural language processing research while circumventing privacy constraints.

S3B-SPIN-7 CREATION OF A LARGE LANGUAGE MODEL-BASED REVIEW TOOL FOR FOLLOW-UP OF CHEST X-RAYS

Shu Wen Goh, FRCR (*Presenter*)
Qi Wei Fong, MBBS (*Abstract Co-Author*)
Alvin Y. Soon, MBBS, FRCR (*Abstract Co-Author*)
Yao An Kendrick Chia (*Abstract Co-Author*)
Wilson Wen Bin Goh (*Abstract Co-Author*)
Cher Heng Tan, MBBS, FRCR (*Abstract Co-Author*)

PURPOSE

Traditionally, radiology reports are classified manually by radiologists into categories such as normal, abnormal, and critical, guiding clinical management. Errors can lead to delayed management of emergent conditions. We aim to investigate how Large Language Models (LLMs) can be used in the classification of chest X-ray (CXR) reports for quality assurance. A key strength of our approach is the preservation of human oversight at critical points, ensuring that automation does not compromise safety where failure may have serious consequences.

METHODS AND MATERIALS

This tool was developed based on 200 anonymized CXR reports, 100 from a tertiary care hospital and 100 from a primary care clinic. The ground truth was obtained by expert annotation. Reports were graded on a scale of 1 to 5: 1 is normal, 2 is a normal variant, 3 is abnormal but not requiring immediate follow-up, 4 is a potentially important finding and 5 is a critical result. OpenAI o4-mini and Llama3.1-8B were employed. 3 approaches were tested - in the LLM Approach, the LLM was prompted to grade the report directly, in the Semialgo Approach, findings were extracted and then graded according to predefined categories (Semialgo approach), and in the Judge Approach, a “reasoning” LLM was asked to judge which is a better result. The Cohen Kappa, a measurement of the agreement between the manual classification and the model’s results, was used as a primary performance metric.

RESULTS

All 3 approaches are promising, with a Cohen Kappa of 0.406, 0.221 and 0.466 for the LLM, Semialgo and Judge approaches respectively, and a within-1 agreement of 91.5, 90.0 and 98.0% for the three approaches respectively. Grouping the gradings into three categories,1/2 (within normal limits), 3 (abnormal) and 4/5 (urgent, actionable), yields an improved Cohen Kappa of 0.524. The critical undergrading rate, where a rating of less than 4 was assigned when it should be 4/5, was the lowest for the Semialgo approach at 5 out of 46 cases.

CONCLUSION

This study demonstrates that LLM-based tool accurately categorizes CXR reports with strong agreement to human raters, with some approaches also demonstrating low critical undergrading rates, essential for prompt clinical decision-making and ensuring patient safety.

CLINICAL RELEVANCE/APPLICATION

Through the automation of the final classification step in reporting, our proposed tool is a productive and meaningful application of LLMs in radiology. Seamless integration before reports are finalized can alleviate radiologists' cognitive load, allowing them to focus on image interpretation and complex cases.

S3B-SPIN-8 COMBINED RADIOMICS, DEEP LEARNING, AND CLINICAL DATA FROM CT PREDICTS SURVIVAL ACROSS TREATMENT MODALITIES IN ESOPHAGEAL SQUAMOUS CELL CARCINOMA: A MULTICENTER STUDY

Zhaoqi Wang (*Presenter*)
Jin Rong Qu, MD (*Abstract Co-Author*)
Binbin Han (*Abstract Co-Author*)
funing Chu (*Abstract Co-Author*)
Bingmei Bai (*Abstract Co-Author*)

PURPOSE

To develop and validate a predictive model integrating clinical data with contrast-enhanced CT-derived radiomics and deep learning features for overall survival (OS) prediction in a large cohort of esophageal squamous cell carcinoma (ESCC) patients undergoing diverse definitive treatment strategies.

METHODS AND MATERIALS

This retrospective study, approved by the IRB with waived consent, included 488 ESCC patients (training n=342, validation n=146) from our hospitals (Jan 2015 - Dec 2020). Patients had pretreatment contrast-enhanced CT and received one of four treatments: untreated (n=62), surgery alone (n=148), definitive chemoradiotherapy (dCRT, n=172), or neoadjuvant CRT plus surgery (n=130). Primary tumors were manually segmented on CT. A total of 1,216 radiomics features and 1,024 deep learning features were extracted from tumor ROIs after image preprocessing. Features were fused, normalized, and selected using univariate Cox regression ($p<0.10$) followed by LASSO-Cox regression. Three Cox proportional hazards models were developed to predict OS: 1) Clinical, 2) Imaging (radiomics+DL), and 3) Combined (Clinical+Imaging). Treatment group was included as a stratified covariate. Model performance was evaluated using time-dependent concordance index (C-index), 1-, 2-, and 3-year AUC, calibration curves, and decision curve analysis (DCA).

RESULTS

LASSO regression selected 8 radiomics features and 6 deep learning features for the Imaging model. In the independent validation cohort (n=146), the Combined model achieved significantly higher prognostic performance (C-index = 0.79; 95% CI: 0.74-0.84) compared to the Imaging model (C-index = 0.73; 95% CI: 0.67-0.79; $p=0.008$) and the Clinical model (C-index = 0.66; 95% CI: 0.60-0.72; $p<0.001$). The 3-year OS AUC for the Combined model was 0.82, superior to the Imaging (AUC=0.76) and Clinical (AUC=0.70) models. Calibration curves confirmed good agreement between predicted and observed survival probabilities for the Combined model. DCA demonstrated the highest net benefit for the Combined model.

CONCLUSION

A model integrating baseline clinical data with CT-derived radiomics and deep learning features significantly improves overall survival prediction accuracy in ESCC patients, irrespective of the specific treatment modality employed, outperforming models based on clinical or imaging information alone.

CLINICAL RELEVANCE/APPLICATION

This validated, integrated prognostic model utilizing readily available pretreatment CT scans provides enhanced risk stratification for ESCC patients across different therapeutic pathways, potentially informing personalized treatment discussions, follow-up intensity, and clinical trial eligibility.

S3B-SPIN-10 GAN-BASED SYNTHESIS OF VIRTUAL CONTRAST-ENHANCED ABDOMINOPELVIC CT FOR IMPROVED VISUALIZATION OF TUMORS AND LYMPH NODES

Yuma Fuzawa, MD (*Presenter*)
Motohiko Yamazaki, MD, PhD (*Abstract Co-Author*)

PURPOSE

The purpose of this study was to develop a Generative adversarial network (GAN)-based model capable of generating contrast-enhanced abdominopelvic CT images from non-contrast CT images, and to evaluate its efficacy in improving the visualization of lymph nodes and malignant tumors.

METHODS AND MATERIALS

A total of 255 abdominopelvic CT examinations were utilized as training data. The test dataset comprised 70 CT examinations, including 35 cases obtained from an external institution. Virtual non-contrast and contrast-enhanced CT images acquired via dual-energy CT were input into Pix2Pix, a GAN-based architecture. The input image size was 512 × 512 × 8, the batch size was set to 1, and training was conducted over 20 epochs. The similarity between the virtual and true contrast-enhanced CT images was assessed using the structural similarity index (SSIM). Quantitative evaluation of image quality for lymph nodes was performed by comparing signal-to-noise ratio (SNR_Ln) and contrast-to-noise ratios (CNR_LnFat and CNR_LnA) between non-contrast and virtual contrast-enhanced images. In addition, tumor SNR (SNR_Tumor) and tumor CNR (CNR_Tumor) relative to surrounding tissues were assessed. Furthermore, two radiologists, blinded to the image type, independently and subjectively evaluated lesion visibility across non-contrast, virtual contrast-enhanced, and true contrast-enhanced CT images.

RESULTS

In the test dataset, SSIM values were high at both our institution and the external institution (ours: 0.88 ± 0.02; external: 0.87 ± 0.03). SNR and CNR values were significantly higher in generated contrast-enhanced CT images compared with non-contrast CT images (SNR_Ln: 8.00 ± 2.48 vs. 3.26 ± 1.01; CNR_LnFat: 17.37 ± 7.65 vs. 8.85 ± 2.91; CNR_LnA: 4.51 ± 1.84 vs. 0.85 ± 0.62; SNR_Tumor: 6.18 ± 2.46 vs. 3.13 ± 0.91; CNR_Tumor: 10.37 ± 5.18 vs. 6.21 ± 2.95) (all $P < 0.001$). The virtual contrast-enhanced CT images were judged to exhibit superior lesion visibility compared with non-contrast CT images in 77.1% (37/48) of cases by Reader 1 and 95.8% (46/48) by Reader 2, and were considered equal to or superior to true contrast-enhanced CT images in 62.5% (30/48) and 60.4% (29/48) of cases, respectively.

CONCLUSION

The GAN-based model developed in this study significantly improved the CNR and SNR of lymph nodes and tumors while also enhancing their visualization in qualitative assessment.

CLINICAL RELEVANCE/APPLICATION

The generation of virtual contrast-enhanced CT images using the proposed GAN-based model holds promise for improving image quality and facilitating lesion detection, particularly in patients for whom the administration of contrast agents is contraindicated.

S3B-SPIN-11 CLASSIFICATION OF NINE ANATOMICAL VIEWS IN SHOULDER ULTRASOUND IMAGING USING RESIDUAL KOLMOGOROV-ARNOLD NETWORKS FOR ROTATOR CUFF TEAR ASSESSMENT

Chang Yong Choi, MS (*Presenter*)
Jinyoung Seo (*Abstract Co-Author*)
Sangah Park (*Abstract Co-Author*)
Seung Min Ryu, MD (*Abstract Co-Author*)
Namkug Kim, PhD (*Abstract Co-Author*)

PURPOSE

To develop an automated classification model using Residual Kolmogorov-Arnold Networks (ResKAN) for nine anatomical views in shoulder ultrasound to support standardized rotator cuff tear assessment.

METHODS AND MATERIALS

A total of 1,177 shoulder ultrasound images were labeled by a board-certified orthopedic specialist according to nine anatomical views commonly used in rotator cuff tear evaluation: short/long-axis views of the long head of the biceps tendon, subscapularis tendon, supraspinatus-infraspinatus tendons, infraspinatus-teres minor tendons, and the acromioclavicular joint. The dataset was split into training, validation, and internal test sets (7:1:2). An external test set of 449 images from another institution was used to assess generalizability. We compared three models: (1) ResKAN50, which integrates Kolmogorov-Arnold Networks into a ResNet50 backbone; (2) ResNet50; and (3) ImageNet-pretrained ResNet50. All models were trained for nine-class classification and evaluated using accuracy, precision, recall, specificity, and F1-score.

RESULTS

On the internal test set, ResKAN50 achieved the highest performance with an average accuracy, precision, recall, specificity, and F1-score of 0.963 (±0.016), 0.892 (±0.095), 0.873 (±0.157), 0.978 (±0.029), and 0.840 (±0.100), respectively. On the external test set, it maintained top performance with 0.901 (±0.049), 0.589 (±0.183), 0.543 (±0.219), 0.947 (±0.065), and 0.532 (±0.163), respectively. ResKAN50 also achieved the highest average AUROC (0.98 internal, 0.83 external), outperforming ResNet50 (0.97/0.77) and ImageNet-pretrained ResNet50 (0.95/0.78). To assess human-level performance, three observers (R1, R2, and R3) independently classified the internal test set. R1, a musculoskeletal specialist, achieved 79.15% accuracy, while R2 and R3 achieved 49.79% and 50.64%. Class-wise accuracy varied, with lower performance in difficult views such as IST-TM short (R1: 50.00%, R2: 31.25%, R3: 25.00%).

CONCLUSION

The proposed ResKAN model showed superior performance in classifying anatomical views in shoulder ultrasound, exceeding human observer accuracy and generalizing well to external data.

CLINICAL RELEVANCE/APPLICATION

Shoulder ultrasound interpretation is highly operator-dependent and often unclear to other clinicians reviewing stored images. The proposed model provides real-time guidance to non-expert users and standardizes image acquisition, enabling consistent interpretation across institutions and improving diagnostic confidence in rotator cuff tear assessment.

S3B-SPIN-12 VISION-LANGUAGE AGENTS FOR STRUCTURED REPORT GENERATION AND PROGNOSIS IN PULMONARY EMBOLISM CT ANGIOGRAPHY

Zhusi Zhong, PhD (*Presenter*)
Lulu Bi (*Abstract Co-Author*)
Yuli Wang (*Abstract Co-Author*)
Vineethsubbu Somasundaram, BS (*Abstract Co-Author*)
Shreyas Kulkarni, BS (*Abstract Co-Author*)
Sun Ho Ahn, MD (*Abstract Co-Author*)
Cheng Ting Lin, MD (*Abstract Co-Author*)
Grayson L. Baird, PhD, MS (*Abstract Co-Author*)
Ihab R. Kamel, MD, PhD (*Abstract Co-Author*)
Michael K. Atalay, MD, PhD (*Abstract Co-Author*)
Harrison X. Bai, MD (*Abstract Co-Author*)
Zhicheng Jiao, PhD, BS (*Abstract Co-Author*)

PURPOSE

Timely and accurate interpretation of CT Pulmonary Angiography (CTPA) is critical in diagnosing and managing pulmonary embolism (PE), a life-threatening condition. However, traditional AI tools often lack specificity and clinical interpretability. We propose a vision-language agent framework that integrates 3D imaging features, clinical variables, and structured diagnostic reasoning to improve PE abnormality detection, radiology report generation, and outcome prediction.

METHODS AND MATERIALS

Our framework comprises two core modules: a multi-label abnormality classifier based on an inflated 3D ResNet-152, and a report-generation pipeline guided by vision-language models (VLMs) and large language models (LLMs). The classifier detects 32 clinically relevant CTPA abnormalities across 7 anatomical regions. Identified findings are used to prompt medical VLMs, the CT-CHAT model for region-wise report generation. These structured outputs are then synthesized by a LLaMA3-based LLM into full radiology reports. A multimodal survival prediction module integrates imaging, abnormality labels, generated reports, and PESI clinical scores using a Cox regression model. Evaluation was conducted on over 69,000 image-report pairs from three datasets: INSTITUTION 1, INSTITUTION 2, and the public CTPA dataset.

RESULTS

The proposed classifier achieved AUROCs of 0.788 (INSTITUTION 1), 0.710 (INSTITUTION 2), and 0.754 (PUBLIC) across the 32 abnormalities. Abnormality-guided image-level report generation outperformed organ-based and holistic captioning methods across all evaluation metrics, while study-level report synthesis yielded superior BERT-F1 scores for both the Findings (up to 0.891) and Impression (up to 0.879) sections, demonstrating improved semantic precision and diagnostic relevance. Multimodal survival prediction achieved a C-index of 0.863 (INSTITUTION 1) and 0.731 (INSTITUTION 2), surpassing PESI scores and unimodal baselines. Decision curve and Kaplan-Meier analysis confirmed the model's clinical utility for risk stratification.

CONCLUSION

This framework offers a comprehensive and interpretable solution for CTPA analysis in pulmonary embolism. By integrating 3D imaging, structured abnormality detection, report generation, and multimodal outcome prediction, it mirrors core elements of the radiologist's workflow. The system produces accurate diagnostic reports and meaningful survival risk estimates, demonstrating scalability and clinical validity across diverse institutions.

CLINICAL RELEVANCE/APPLICATION

This system automates CTPA interpretation for PE, enhancing diagnostic consistency, enabling risk stratification, and supporting quality improvement across clinical settings.

S3B-SPIR-1 AI-POWERED MODEL FOR CARDIAC RISK PREDICTION IN HEMODIALYSIS PATIENTS UNDERGOING INTERVENTIONAL RADIOLOGY PROCEDURES

Krishna Parvataneni (*Presenter*)
David Schramm (*Abstract Co-Author*)
Jie Cui (*Abstract Co-Author*)
Christopher Bridge, DPhil (*Abstract Co-Author*)
Dania Daye, MD,PhD (*Abstract Co-Author*)

PURPOSE

Interventional radiology procedures for dialysis access carry poorly defined peri-procedural cardiac risks in hemodialysis patients. This study developed and validated AI models to predict early post-procedure cardiac arrest, myocardial infarction (MI), and 30-day mortality in this population.

METHODS AND MATERIALS

This project uses the American College of Surgeons National Surgical Quality Improvement program (ACS-NSQIP) dataset, which contains preoperative, intraoperative, and 30-day postoperative data from 722 hospitals between 2011 and 2018. Using Current Procedural Terminology (CPT) codes, the data was filtered to include all hemodialysis access related interventional procedures. The data from 2011-2017 was divided into a training set (70%) and a 'contemporaneous' testing set (30%). The data from 2018 was used as a separate, 'non-contemporaneous' testing set. The 15 most relevant features to predicting each outcome were selected using Gini Importance. Two models, Random Forests and TabPFN, were trained and evaluated on our dataset, to compare performance. Random Forest Classifiers are ensemble models that fit multiple decision trees to the data and average over them to reduce overfitting and improve accuracy. TabPFN is a foundation model pre-trained on tabular datasets that outperforms ensemble methods on smaller datasets without further training. The primary outcomes were cardiac arrest, myocardial infarction, and 30-day mortality.

RESULTS

A total of 10839 cases were identified. Both models demonstrated strong performance in predicting cardiac arrest, myocardial infarction, and 30-day mortality. On the non-contemporaneous test set, Random Forest achieved accuracies of 76.69% (AUROC: 0.7695) for cardiac arrest, 73.27% (AUROC: 0.7013) for MI, and 78.47% (AUROC: 0.7763) for 30-day mortality. TabPFN performed slightly better for cardiac outcomes and comparably for mortality, with accuracies of 76.73% (AUROC: 0.8420) for cardiac arrest, 99.05% (AUROC: 0.7338) for MI, and 83.22% (AUROC: 0.7510) for 30-day mortality.

CONCLUSION

This AI-based approach using national surgical quality data achieved moderate discrimination in predicting early cardiac complications and 30-day mortality following dialysis-related IR procedures. TabPFN slightly outperformed conventional Random Forests across these outcomes.

CLINICAL RELEVANCE/APPLICATION

A validated dialysis-specific IR risk score has the potential to inform pre-operative counseling, anesthetic planning, and post-procedural monitoring. Subsequent work should target algorithm fine-tuning, conducting multicenter external validation, and piloting the tool within interventional radiology units.

S3B-SPIR-3 BILATERAL SUBCUTANEOUS RAT TUMOR MODEL SUPPLIED BY THE ILIOLUMBAR ARTERY: A SIMPLIFIED AND VERSATILE PLATFORM FOR TRANSARTERIAL THERAPY STUDIES

Takeshi Suzuki, MD, PhD (*Presenter*)
Kenkichi Michimoto (*Abstract Co-Author*)
Todd Graham (*Abstract Co-Author*)
Khashayar Farsad, MD, PhD (*Abstract Co-Author*)
Kentaro Yamada, MD, PhD (*Abstract Co-Author*)

PURPOSE

To determine the feasibility of a bilateral flank subcutaneous rat tumor model, perfused by the iliolumbar arteries (ILA), for pre-clinical trans-arterial therapy research.

METHODS AND MATERIALS

Eighteen male Lewis rats (body weight: 295 g [289-301], Median [IQR]) received bilateral flank implants of DSL-6A/C1 (pancreatic ductal cell adenocarcinoma cell line) tumor fragments (passaged 2-3 times) through a 14-G intravenous catheter at the iliac crest level. Tumors exceeding 8 mm in diameter were enrolled for angiography. Angiography procedures were performed via the tail artery approach using a 1.3 or 1.6-F microcatheter to select the ILA, followed by digital subtraction angiography (DSA) to assess tumor staining. Tumor engraftment rate, catheterization success and the procedural time from skin incision to DSA of the ILA were recorded. In one rat, Isosulfan Blue was injected from the ILA to confirm the tumor's vascular supply.

RESULTS

The time from tumor implantation to the angiography was 19 days in 17 rats and 20 days in 1 rat. At the time of the procedure, the body weight of the rats was 337 g [330-341], Median [IQR]. The tumor engraftment rate was 97.3% (35/36), with bilateral engraftment in 17 cases and unilateral engraftment in 1 case. No major complications, such as significant skin ulceration or hemorrhage were observed during tumor incubation period.ILA catheterization was technically successful in all 18 rats using the tail artery access technique with a procedural time from skin incision to angiography from the ILA of 20 min [15-25], Median [IQR]. All cases demonstrated tumor staining. In one case, Isosulfan Blue injection at the proximal portion of the iliolumbar artery resulted in macroscopically tumor staining, confirming the vascular supply to the tumor.

CONCLUSION

Bilateral flank tumors were consistently and exclusively supplied by the ILA. The model combined a high engraftment rate, straightforward monitoring, and technically simple catheterization of the ILA from the abdominal aorta, supporting its feasibility as a versatile platform for trans-arterial therapy studies and suggesting that it may be readily applied to various tumor models beyond pancreatic cancer. Bilateral implantation permitted one tumor to serve as an internal control or as a reserve when unilateral engraftment failed. These advantages suggested that this platform could further accelerate rat trans-arterial therapy research.

CLINICAL RELEVANCE/APPLICATION

This simplified, highly reproducible model enables uniform evaluation of intra-arterial therapeutics and standardized assessment of tumor microenvironments, potentially accelerating translation of novel trans-arterial treatments.

S3B-SPIR-4 MACROPHAGE PYROPTOSIS INHIBITION ALLEVIATES NEOINTIMAL FORMATION AND RESTENOSIS AFTER ENDOVASCULAR INTERVENTIONS

Zaixiong Ji, MD, PhD (*Presenter*)
Meijuan He (*Abstract Co-Author*)
Han Wang, MD, PhD (*Abstract Co-Author*)

PURPOSE

Clinically, the primary cause of long-term failure after endovascular interventions for cardiovascular diseases is restenosis. The commonly used therapeutic devices, including balloons or stents, are coated with non-specific antiproliferative agents, whose indiscriminate cytotoxicity exacerbates the underlying inflammation. Here, we explored the mechanisms of restenosis and devised a mechanism-based strategy against restenosis.

METHODS AND MATERIALS

Single-cell transcriptomic sequencing was employed to investigate cellular and gene changes in restenotic vessels. Macrophage-specific knockdown of GSDMD was performed, and disulfiram-coated balloon (DCB) is developed to deliver disulfiram (DSF) to the target vessel, blocking GSDMD-mediated pyroptosis. The effects of this strategy were validated through systematic in vivo and in vitro experiments.

RESULTS

Single-cell transcriptomic analysis demonstrates that macrophages are the key cell population undergoing pyroptosis in vessels with restenosis. Knockdown of specific macrophage GSDMD ameliorates inflammatory response and neointimal formation. DCB is specifically designed to precisely deliver DSF to the injured vessel wall, blocking GSDMD pore formation. Systematic in vivo and in vitro results con& 7;rm that DCB curbs macrophage pyroptosis and associated inflammation by inhibiting GSDMD, promoting functional re-endothelialization and suppressing neointimal hyperplasia, thereby superiorly preventing long-term vascular restenosis.

CONCLUSION

Collectively, our study shows that GSDMD-mediated macrophage pyroptosis plays a crucial role in the restenosis process following endovascular interventional injury. Based on this mechanism, the customed DCB targeting GSDMD to inhibit pyroptosis alleviates vascular restenosis, supporting the repurposing of FDA-approved disulfiram in proliferative cardiovascular diseases.

CLINICAL RELEVANCE/APPLICATION

In contrast to the status quo (drug-coated balloons and drug-eluting stents), DCB does not have cytotoxicity that exacerbates inflammation, providing a promising therapeutic strategy for restenosis prevention.

S3B-SPIR-5 PRE-PROCEDURE DESMOPRESSIN ADMINISTRATION REDUCES CLINICALLY SIGNIFICANT HEMORRHAGE AFTER NONFOCAL RENAL BIOPSY: RETROSPECTIVE COHORT ANALYSIS

Bradford Dugan, BS (*Presenter*)
Asif Rahman (*Abstract Co-Author*)
Michael V. Korona JR, MD (*Abstract Co-Author*)
Amy R. Deipolyi, MD, PhD (*Abstract Co-Author*)

PURPOSE

Ultrasound-guided nonfocal renal biopsy (NFRB) carries a bleeding risk of 1.5-14%. Desmopressin (DDAVP), a synthetic vasopressin analog, may reduce bleeding by promoting hemostasis. This study evaluated the safety and efficacy of pre-biopsy DDAVP administration to any patient undergoing NFRB regardless of pre-procedure renal function.

METHODS AND MATERIALS

A retrospective observational study was conducted at a single institution starting before and continuing after implementation of a DDAVP protocol for all NFRBs. The cohort included 150 patients undergoing 150 NFRBs from 3/2022-4/2025. Starting 7/2023, all patients received 0.3 mcg/kg IV DDAVP immediately prior to biopsy. All procedures used 17-gauge guiding needles to obtain 18-gauge cores. Patients who did and did not receive DDAVP were compared using Welch t-tests and Fisher's exact tests (a=0.05).

RESULTS

Of 150 patients, 71 (33 women, 38 men) received DDAVP and 79 (41 women, 38 men) did not (p=0.52). Patients who received DDAVP were younger (53±14 v. 59±18 y; p=0.02). Maximal systolic blood pressure was similar between groups (121±16 v. 124±13 y; p=0.21). There were no significant differences between the DDAVP and no DDAVP groups in the change in pre- and post- procedure hemoglobin (-3.5±14.4% v. -0.9±9.5%; p=24) or sodium levels (-0.3±2.0% v. 0.1±2.3%; p=30). The rates of blood transfusion were similar (8/79 v. 8/71; p=1). However, 6/79 (8%) patients without DDAVP required unplanned admission and/or angiography within 1 week, compared to 0/71 in the DDAVP group (p=0.03). No patients required surgery or died after NFRB. Thromboembolic events occurred in 2/79 (2.5%) without DDAVP and 3/71 (4.2%) with DDAVP (P=0.67). All 5 thromboembolic events occurred in patients on antiplatelet/anticoagulant agents held per Society of Interventional Radiology guidelines.

CONCLUSION

DDAVP administration prior to NFRB was associated with significantly fewer unplanned admissions or angiography/embolization procedures, without an increase in thromboembolic events. Pre-procedure DDAVP may reduce clinically significant hemorrhage following NFRB.

CLINICAL RELEVANCE/APPLICATION

Routine pre-procedure DDAVP administration to all patients undergoing NFRB may improve patient safety by reducing post-procedural bleeding and need for urgent interventions.

S3B-SPIR-6 LIVER RF ABLATION INDUCES DIFFUSE PRO-IMMUNOGENIC AND PRO-TUMORIGENIC PATHWAY ACTIVATION REVEALED BY MULTI-OMIC PROFILING

Lukas Salvermoser, MD (*Presenter*)
Lorenzo Sperlich (*Abstract Co-Author*)
Daniel David Khademi (*Abstract Co-Author*)

Matthias M. Stechele, MD (*Abstract Co-Author*)
Jens Ricke, MD, PhD (*Abstract Co-Author*)
S. Nahum Goldberg, MD (*Abstract Co-Author*)

PURPOSE

To investigate pro-immunogenic and pro-tumorigenic potential of hepatic RFA.

METHODS AND MATERIALS

Standardized Radiofrequency ablation (RFA) (70°Cx5min) of healthy normal liver tissue was performed on 15 male 8-10w C57/Bl6 mice. Evidence of increased transcription among 16,000 genes (FC>2 in any of 10 major cell populations) was obtained by Single cell RNA sequencing (scRNAseq) of normal distant liver from controls and at 1 and 7d post-RFA. Increased translational expression (>25% over shams) was assessed using Affymetrix proteinomics comparing 1,300 proteins between shams, 3 and 6d post-RFA pooled tissue homogenates. These genes were further evaluated by string-db pathway analysis (https://string-db.org/) including MCL clustering methodology to define common key active pathways. Thirty moderately sized (i.e. 49-545 proteins) pathways with high signal (>5) and a false discovery rate (FDR) of <10e-10 on the corresponding scRNA and proteinomic string clusters (i.e., combined cytokine/immune, growth factor, and collagen production) were further analyzed including: 17 GO Biology, 10 murine Reactome, and 3 Wikipathway databases. For each pathway, the signal and FDR were analyzed using the string website with odds ratios (OR) calculated using Enrichr (https://maayanlab.cloud/Enrichr).

RESULTS

443 genes and 427 proteins showed increased expression, with 73 of 228 identical proteins (32%) showing overlap. All 30 selected pathways had marked protein enrichment (signal=13; FDR=1.7e-41) on both the transcriptional (RNA) and translational (protein) level with 31±9% of possible pathway genes identified. Key immunogenic pathways with significant increase in both transcription and translation included “Regulation of IL-10 production”, “Chemokine-Mediated Signaling Pathway”, and “Regulation of T-Cell Proliferation” (OR=28.4, 27.8, 18.8, respectively). Multiple growth factor and tyrosine kinase pathways were similarly enriched, with markedly increased activation of angiogenesis and endothelial, epithelial, and fibroblast proliferation (OR>12).

CONCLUSION

RFA broadly activates both pro-immunogenic and pro-tumorigenic pathways. This suggests the potential beneficial use of adjuvant immunotherapy and that combination therapies will be essential, highlighting the need for deeper investigation into the interplay between these pathways.

CLINICAL RELEVANCE/APPLICATION

Focal hepatic ablation has both immunogenic and tumorigenic potential implying that combined adjuvant therapy may be required for optimal results in future clinical trials of tumor ablation and immunotherapy.

S3B-SPMK-1 DIFFERENTIATING BENIGN FROM MALIGNANT BONE AND SOFT TISSUE TUMORS AND ASSESSING KI-67 EXPRESSION USING APT AND DWI TOOLS

Xinxin Liu (*Presenter*)
Pengxiang Li (*Abstract Co-Author*)
Pan Shang (*Abstract Co-Author*)
Jing Lu (*Abstract Co-Author*)
Kai Ai (*Abstract Co-Author*)
Xiaowen Ma (*Abstract Co-Author*)

PURPOSE

This study aimed to investigate the use of Amide proton transfer (APT) imaging and diffusion-weighted imaging (DWI) in distinguishing benign from malignant bone and soft tissue tumors. We also assessed the correlation among APT, DWI, and Ki-67 expression.

METHODS AND MATERIALS

The study enrolled 49 patients from June 2023 to January 2024, and 29 patients were malignant tumors. The site were upper and lower extremities. They underwent MR scanning, and the diagnosis was confirmed by pathology. The APT, apparent diffusion coefficient (ADC), and exponential apparent diffusion coefficient (EADC) values were measured. We used APT and DWI to distinguish benign from malignant tumors, and analyzed the correlation among APT, ADC, EADC, and Ki-67 expression. The diagnostic efficiencies were evaluated using the receiver operating characteristic (ROC) curve. We used intraclass correlation coefficient (ICC) to obtain the interobserver reprehensibility.

RESULTS

The ICC was 0.848. The APT value was 2.26% ± 1.07%, 4.62% ± 1.43%; ADC value was 1.33% ± 0.4 ×10 -3 mm 2 /s, 1.01% ± 0.55 ×10 -3 mm 2 /s; EADC value was 0.29 ± 0.13, 0.40 ± 0.17 in benign and malignant tumors, respectively. Statistical differences were observed between benign and malignant tumors in APT (P <.001), ADC (P =.0032), and EADC (P =.019). APT exhibited a positive correlation with Ki-67 [r = 0.546, 95% confidence interval (CI): 0.217-0.762, P =.002]. In the ROC curve analysis for differentiating benign from malignant tumors, the sensitivity and specificity were respectively 72.41% and 95%, with APT value of 3.6%;79.31% and 85%, with ADC value of 1.047×10 -3 mm 2 /s; and 72.41% and 85%, with EADC value of 0.34. Combining APT, ADC, and EADC, the sensitivity and specificity were 72.41% and 95%, respectively. The sensitivity and specificity were respectively 100% and 57.14% (P <.0001), with an AUC value of 0.794, for APT in assessing the Ki-67 expression.

CONCLUSION

APT image exhibited an improved qualitative diagnostic efficiency in differentiating between benign and malignant bone and soft tissue tumors. APT value was higher in malignant than benign tumors. When APT value more than 3.6%, the tumor was prone to be malignant, and the sensitivity and specificity were high. Combining APT, ADC, and EADC had a higher specificity, and was more beneficial in distinguishing benign from malignant tumors. In addition, APT value exhibited a notable correlation with Ki-67 expression.

CLINICAL RELEVANCE/APPLICATION

APT image could help the surgeon to define tumor boundaries and improve the long-term prognosis.It’s helpful for predicting proliferative activity and recurrence after surgery.

S3B-SPMK-3 THE VALUE OF SPECTRAL CT IN PREOPERATIVE EVALUATION OF SELECTIVE POSTERIOR RHIZOTOMY IN CHILDREN WITH SPASTIC CEREBRAL PALSY

Juan Liu (*Presenter*)
Xiaoyue Zhang (*Abstract Co-Author*)

PURPOSE

To explore the clinical application value of spectral CT multi-parameter imaging technology in preoperative nerve root imaging of selective posterior spinal nerve root resection (SPR) in children with spastic cerebral palsy (CP).

METHODS AND MATERIALS

The lumbar spectral CT examination data of 27 children with spastic cerebral palsy who underwent SPR were retrospectively included. A double-blind method was adopted. Two radiologists respectively conducted subjective quality scoring (on a 5-point scale) for images in three modes: conventional CT (SC), calcium suppression (VNCa), and electron density (ED). The Kruskal-Wallis test was applied to compare the differences between groups. The intraclass correlation coefficient (ICC) was used to assess the consistency among raters (ICC>0.75 was considered highly consistent). In terms of objective quantitative analysis, the CT values (HU), standard deviation (SD), signal-to-noise ratio (SNR), and contrast-to-noise ratio (CNR) of the nerve roots and adjacent muscle tissues were measured at the opening level of the L5/S1 nerve roots, and the ED values (with water as the reference, %EDW) were calculated. Independent sample t-tests were used to compare the differences in SNR/CNR between SC and VNCa images, and paired t-tests were used to analyze the differences in ED values between nerve roots and muscle tissues.

RESULTS

The ED image quality score (4.6±0.5) was significantly higher than that of the SC (3.2±0.8) and VNCa (3.8±0.7) modes (P<0.01), and the ICC values of the scores of the two physicians reached 0.82. The SNR (1.7±2.5 vs 1.4±1.8, P=0.003) and CNR (5.4±12.5 vs 4.9±6.9, P=0.002) of the VNCa model were both superior to those of the traditional SC model. The ED value of nerve roots (99.8±2.3%EDW) was significantly lower than that of muscle tissues (105.2±0.2%EDW, P<0.001), and the difference was statistically significant.

CONCLUSION

Spectral CT significantly improves the imaging quality of nerve roots through multi-parameter imaging technology. Among them, the ED mode performs the best in soft tissue resolution, and the VNCa mode has an advantage in improving the signal-to-noise ratio.

CLINICAL RELEVANCE/APPLICATION

This technology can accurately quantify the density difference between nerve roots and surrounding tissues, providing a three-dimensional visualization basis for preoperative nerve root localization in SPR. It is expected to optimize the surgical path planning and shorten the intraoperative exploration time, and has important clinical application value.

S3B-SPMK-4 STATIN INITIATION AND LONGITUDINAL CHANGES IN CT-DERIVED VOLUMETRIC VERTEBRAL BONE MINERAL DENSITY: AN EMULATED TARGET TRIAL FROM THE MULTI-ETHNIC STUDY OF ATHEROSCLEROSIS

Roham Hadidchi, BS (*Presenter*)
Elena Ghotbi, MD (*Abstract Co-Author*)
Quincy A. Hathaway, MD, PhD (*Abstract Co-Author*)
Michael Bancks (*Abstract Co-Author*)
David A. Bluemke, MD, PhD (*Abstract Co-Author*)
R. Graham Barr (*Abstract Co-Author*)
Wendy Post (*Abstract Co-Author*)
Matthew J. Budoff, MD (*Abstract Co-Author*)
Joao A. Lima, MD (*Abstract Co-Author*)
Shadpour Demehri, MD (*Abstract Co-Author*)

PURPOSE

Opportunistic CT imaging enables extraction of clinically relevant data without added radiation or cost. Given the widespread use of thoracic and abdominal CT in the U.S., these scans represent an underutilized resource for secondary analyses such as bone assessment. Statins, prescribed to over 40 million U.S. adults (221 million prescriptions), are first-line therapy for hyperlipidemia and cardiovascular prevention. However, evidence regarding their effect on bone health is conflicting. We evaluated the association between statin initiation and longitudinal changes in multilevel vertebral bone mineral density (BMD) over six years.

METHODS AND MATERIALS

This emulated target trial is a secondary analysis of the Multi-Ethnic Study of Atherosclerosis (MESA). Participants underwent noncontrast chest CT with and without a phantom. TotalSegmentator v2, a nnU-Net algorithm, provided 3D vertebral body segmentation of T1-T10, followed by postprocessing to remove cortical bone. Vertebral BMD was computed using phantom HU values (0, 50, 100, 200 mg/cm³). Adults with 10-year ASCVD risk =7.5% at Exam 4 or 5 and no prior statin use were included. Statin initiators were propensity score-matched to non-initiators. Vertebral BMD was measured at baseline and six-year follow-up using chest CT. Linear mixed-effects models evaluated longitudinal BMD change, adjusting for scanner type. Prespecified subgroup analyses were conducted by age, sex, race/ethnicity, BMI, hs-CRP, physical activity, diabetes, smoking, and alcohol use. Sensitivity analysis using the array approach assessed the potential impact of unmeasured confounding.

RESULTS

DL-derived 3D segmentations correlated with manual axial (Dice score, 0.93; 95% CI: 0.92-0.95) and sagittal (0.91; 95% CI: 0.88-0.93) segmentations. A total of 384 participants (173 initiators; 211 non-initiators) were included in the per-protocol analysis. Statin initiation was associated with a slower decline in vertebral BMD compared with no initiation (ß = 1.00 g/cm³/year; 95% CI: 0.65-1.35; $p < 0.001$), corresponding to a 0.47% slower annual decline. An unmeasured confounder with a 1% annual effect would need to be =3× more prevalent among initiators vs. noninitiators to nullify the observed association, which is clinically unlikely. Subgroup analyses suggested stronger protective effects among those with impaired fasting glucose or diabetes, low hs-CRP, or higher physical activity.

CONCLUSION

Using multilevel DL-based quantification of vertebral BMD from routine chest CT, statin initiation was associated with reduced bone loss.

CLINICAL RELEVANCE/APPLICATION

Findings support the potential value of opportunistic BMD monitoring for medication effects on bone health using chest CT in high-risk populations.

S3B-SPMK-6 PREOPERATIVE DIFFERENTIATION OF SPINAL MULTIPLE MYELOMA AND OSTEOLYTIC METASTASIS USING DIFFUSION-WEIGHTED IMAGING-BASED HABITAT

Jun Xu (*Presenter*)
Ning Lang, MD (*Abstract Co-Author*)

PURPOSE

Multiple myeloma (MM) and osteolytic metastases (OM) are difficult to distinguish due to similar radiographic features and clinical symptoms, yet they require different treatments. Bone marrow biopsy is a key tool for differential diagnosis, but it is invasive and risky. This study aims to develop a non-invasive, preoperative method to differentiate MM from OM using diffusion-weighted imaging (DWI) habitat imaging.

METHODS AND MATERIALS

132 MM and 120 OM patients were prospectively included and underwent multi-b DWI examinations. Tumors were segmented into three habitats based on the true diffusion coefficient (Dt), perfusion fraction (f), and mean kurtosis coefficient (MK). The volume fraction of each habitat was calculated. Logistic regression was applied to identify risk factors from habitat fractions and clinical variables. Using these risk factors, clinical, habitat, and combined nomogram models were developed. Diagnostic accuracy was measured by the area under the receiver operating characteristic curves (AUCs).

RESULTS

MM exhibited a significantly higher fraction of habitat 3 ($p = 0.002$) and a significantly lower fraction of habitat 2 ($p < 0.001$), which were selected as risk factors. Additionally, sex, T2WI signal uniformity and homogeneous enhanced appearance were included as risk factors for differential diagnosis. The nomogram model demonstrated the highest diagnostic performance (AUC = 0.881), followed by the habitat model (AUC = 0.814) and the clinical model (AUC = 0.706). Decision curve analysis indicated that the nomogram model offered more net benefit in compared to the clinical model.

CONCLUSION

DWI-based habitat imaging shows clinical potential for noninvasively and preoperatively differentiating between spine MM and OM.

CLINICAL RELEVANCE/APPLICATION

DWI-based habitat imaging offers a non-invasive method to improve the challenging preoperative differentiation between spinal multiple myeloma and osteolytic metastases, potentially reducing invasive biopsies and guiding more timely and appropriate treatment selection.

S3B-SPMK-7 EVALUATION OF THE IMPACT OF DEEP LEARNING-BASED RECONSTRUCTION ON T2 AND T2* MAPPING DATA FOR KNEE CARTILAGE QUANTIFICATION

Nagore Castro (*Presenter*)
Alicia Palomar Garcia (*Abstract Co-Author*)
Jordi Catala March, MD (*Abstract Co-Author*)

PURPOSE

T2 and T2* mapping are quantitative MRI techniques to assess articular cartilage integrity by detecting changes in tissue composition and structure. However, measurement accuracy can be affected by noise and image quality. Advanced Intelligent Clear-IQ Engine (AiCE) technology, based on deep learning, would improve image quality while keeping the reliability of T2 and T2* quantification. The goal is to assess the impact of AiCE on T2 and T2* quantification by comparing and correlating knee articular cartilage measurements with and without AiCE reconstruction.

METHODS AND MATERIALS

A cohort of 10 patients with suspected knee articular cartilage pathology was evaluated on a 3T Vantage Galan (Canon Medical Systems, Tochigi, Japan) using a 16-channel, multipurpose, flexible SPEEDER coil. The protocol included conventional sequences, plus T2 mapping (4-echo fast spin echo) with TE min/ TE step =20/20ms, TR=3850ms, pixel size=0.36x0.36mm 2 and duration=2:54min; and T2* mapping (6-echo field echo) with TE min /TE step =2.3/2.3ms, TR=35ms, pixel size=0.7x0.7mm 2 and duration=3:33min. T2 and T2* maps were generated with Olea Sphere® Relaxometry plug-in to quantitatively assess the integrity of knee cartilage. A total of 5 slices per patient were selected to facilitate the full delineation of the femorotibial cartilage. T2 and T2* relaxation times, with and without AiCE reconstruction, were compared using a paired t-test and their correlation was assessed with Pearson correlation coefficient.

RESULTS

Non-significant differences were found between measurements based on data with and without AiCE reconstruction in either of the two relaxation times, T2 and T2*. A moderate and significant positive correlation between T2 and T2* values was observed both with AiCE reconstruction ($r=0.68$; $p<0.0001$) and without AiCE ($r=0.66$; $p<0.0001$), but correlation strength was slightly improved when AiCE reconstruction was used.

CONCLUSION

The results show that using AiCE does not affect knee articular cartilage quantification, as both T2 and T2* relaxation times based on data reconstructed with and without AiCE are equivalent. Besides, a more robust and significant correlation between variables was found when data was reconstructed with AiCE, probably due to the image denoising and improved quality. Therefore, using AiCE could improve the diagnostic performance of T2 and T2* mapping on the assessment of knee cartilage.

CLINICAL RELEVANCE/APPLICATION

Evaluation of T2 and T2* relaxation times allows the early detection of abnormalities as osteoarthritis, by revealing early cartilage changes due to degeneration that are not visible on MRI. Besides, they are sensitive to disruption in collagen fibres, increased water content, and useful for postoperative follow-up.

S3B-SPMS-1 VOLUMETRIC ANALYSIS TO INCREASE SENSITIVITY OF RESPONSE ASSESSMENT FOR SOLID TUMOR EVALUATION LEVERAGING A PROMPTABLE SEGMENTATION MODEL, A PILOT STUDY

Leo Machado (*Presenter*)
Amaury Prat (*Abstract Co-Author*)
Korentin Le Floch (*Abstract Co-Author*)
Theo Danielou (*Abstract Co-Author*)
Maxime Ronot, MD, PhD (*Abstract Co-Author*)
Pierre Manceron (*Abstract Co-Author*)
Paul Herent, MD, MSc (*Abstract Co-Author*)
Daniel Tordjman (*Abstract Co-Author*)

PURPOSE

RECIST 1.1 is the standard methodology for the longitudinal follow-up of solid tumors. Linear measurements may not be as sensitive as volumetric ones to detect modifications of the lesion burden. This study investigates the benefits of using a promptable AI foundation segmentation model for volume-based longitudinal tumor response evaluation in a real-world cohort.

METHODS AND MATERIALS

We gathered a multicentric cohort of 28 patients monitored for oncological disease with 1 baseline and 2 follow-up CT scans. We compared the performance of volume vs RECIST diameters for disease status classification. We used the RECIST sum of diameters at the second follow-up as the ground truth, according to standard thresholds: -30% for Partial Response (PR), +20% for Progressive Disease (PD). For the volume, we used empirically derived thresholds of -50% for PR and +40% for PD, within the literature range (Goldmacher et al., 2012, Br J Clin Pharmacol; Hayes et al., 2016, Eur J Radiol). In total 79 target lesions (mostly lymph node, lung and liver lesions) were segmented in 3D and measured for RECIST diameters by 2 radiologists. For the semi-automated analysis, we used a segmentation model inspired by previous studies (Machado et al., 2025, NPJ Precis Oncol). We prompted the model with a bounding box around the tumor and up to 5 edit points to generate predicted segmentation masks, with a Dice score of 81% against the ground truth, indicating good segmentation performance.

RESULTS

At the first follow-up, the volume-based analysis identified 100% of the responders, compared to 40% with RECIST diameters, and 33% of the progressors vs 11%. At the second follow-up, 100% agreement was observed between volume-based response evaluation and RECIST diameters for PR (n=5) and PD (n=9). Among the 14 stable patients according to RECIST diameters at the second follow-up, volume-based analysis classified 4 as PD, 6 as stable, and 4 as PR. The absence of long-term clinical data limits the interpretation of these differences, possibly due to misclassification or early detection.

CONCLUSION

This study demonstrates the potential of a semi-automatic volumetry-based system for oncology based on a promptable AI segmentation model. This method enables early detection of progressors and responders, which could lead to essential modifications for patient care. This feasibility experiment calls for complementary studies with a prospective design and a priori selection of target lesions to demonstrate a clinically relevant impact for cancer patients.

CLINICAL RELEVANCE/APPLICATION

AI-driven volumetric analysis allows for earlier detection of tumor response and progression compared to RECIST 1.1, potentially enabling timely adjustments in patient care.

S3B-SPNMMI-1 A DIGITAL AI EXPERIMENT IN COLLIMATOR-LESS SPECT AND COINCIDENCE-FREE PET IMAGING

Nathan S. Lay, PhD (*Presenter*)
Michael V. Green, MS (*Abstract Co-Author*)
Jurgen Seidel (*Abstract Co-Author*)
Steve Adler, PhD (*Abstract Co-Author*)
Om Khanal (*Abstract Co-Author*)
Peter L. Choyke, MD (*Abstract Co-Author*)
Baris Turkbey, MD (*Abstract Co-Author*)

PURPOSE

Image formation in SPECT and PET requires collimation, mechanical and electronic, respectively. We tested the hypothesis that under ideal circumstances, 3D images of transparent gamma radiation emitting objects could be formed without collimation by allowing radiation from the entire object to illuminate the interior of a surrounding cylinder imagined to be tiled with perfect, thin radiation detectors. This 2D "projection image" contains all the information necessary to reconstruct the original source distribution if a suitable inverse algorithm can be identified. Here, we trained an AI algorithm to carry out this inversion for a cylindrical detector "imaging" a MOBY digital mouse labeled with a bone-seeking radiotracer that approximates 18 F-fluoride (a positron emitter) and 99m Tc-MDP.

METHODS AND MATERIALS

The MOBY mouse model (Duke University) is a high-resolution digital rendering of the major body organs and subsystems of the adult male animal that allows the amount of radioactivity in each to be varied by the user. Activity (1.85 MBq) was distributed such that, on average, 50% of the "dose" went to the mouse skeleton and 50% was distributed throughout the rest of the body. The model mouse was placed inside the cylinder (8 cm dia. x 10 cm length) and allowed to irradiate its inner surface for 10 s creating the projection image. A ResNet50/U-net AI algorithm was trained by pairing 32,000 MOBY ground truth (GT) tracer distributions with their corresponding projection images while randomly perturbing the amount of tracer in the skeleton and body by + 10% around their means, and with other perturbations, e.g., statistical fluctuations. The AI was designed such that when shown a projection image from a never-before seen MOBY source distribution, the AI would produce the best match to its GT counterpart, the equivalent of a 3D SPECT or PET image stack.

RESULTS

AI reconstructions of the bone/body tracer distribution closely mimicked the anatomy and concentrations present in the GT distributions. Spatial resolution (FWHM) in the reconstructions was < 0.6 mm (GT images, 0.2 mm) and concentrations differed < 20% in the skeleton.

CONCLUSION

It appears possible to reconstruct a 3D gamma ray source distribution from its projection onto an uncollimated 2D surface using a suitably trained AI for reconstruction. Disadvantages of this method are whole-body imaging and the very large number of a priori training sets needed to span the large spatial and concentration parameter space.

CLINICAL RELEVANCE/APPLICATION

If practicable, clinical tracer doses could be reduced for SPECT (>100) and PET (>3) with the potential for improved spatial resolution and simplification of imaging system design.

S3B-SPNMMI-2 IMPACT OF PENALISED LIKELIHOOD RECONSTRUCTION ON RESPONSE ASSESSMENT FDG PET-CT CATEGORISATION IN SOLID TUMOURS AND HODGKIN LYMPHOMA

James Cairns, MSc, BMBS (*Presenter*)
Rachel J. Gravell I, MBChB, MSc (*Abstract Co-Author*)
Uzair Ali, MD, MBBCh (*Abstract Co-Author*)
Russell Frood, MBChB, FRCR (*Abstract Co-Author*)
Chirag Patel, FRCR (*Abstract Co-Author*)
Andrew F. Scarsbrook, BMBS, FRCR (*Abstract Co-Author*)

PURPOSE

FDG PET-CT response assessment is widely used, frequently influencing patient management and is based on studies using standard PET reconstructions. Newer penalised likelihood (PL) PET reconstruction algorithms increase the degree of tracer uptake particularly in smaller lesions on visual and semi-quantitative assessments by suppressing image noise and improving signal-to-noise ratio. The study aim was to evaluate clinical impact of standard versus PL reconstruction response assessment categorisation, in patients with Hodgkin Lymphoma (HL), head and neck, anal and cervical cancers.

METHODS AND MATERIALS

Consecutive patients undergoing post treatment FDG PET-CT with standard time of flight (TOF) and PL reconstruction between November 2023 and May 2024 were retrospectively analysed at a high-volume cancer centre. Cases were evaluated qualitatively and semi-quantitatively for residual tumour uptake/nodal disease on TOF and PL reconstructions. In the solid tumour group, cases were categorised as positive or negative based on activity above or below background liver uptake. Deauville Score (DS) was assigned for HL patients, where DS1-3 was considered negative, and DS4-5 considered positive for residual disease. Disease status at 12-month clinical follow-up was confirmed by case note review.

RESULTS

98 patients were included, 48 were solid tumour (27 head and neck (H&N); 15 anal and 6 cervical) and 50 HL. In the H&N group, two patients (7.4%) were upgraded to positive when using PL recons. One patient was upgraded within the anal group (6.7%), and none within the cervical group. In the HL group, DS, changed in ten scans

(20%) using PL recons. Three scans remained categorised as negative (DS1-3) and four positive (D4-5). However, three scans (6%) changed the outcome from negative (DS3) to positive (DS4). Most cases with negative to positive change on PL recon (5/6 patients, 83%) had no evidence of disease at the relevant site 12 months post therapy, one patient (17%) had subsequently confirmed disease relapse.

CONCLUSION

PL reconstruction enhances small lesion conspicuity. However, this increased sensitivity might lead to overestimation and potential response assessment misclassification in a minority of cases, warranting cautious interpretation in clinical practice.

CLINICAL RELEVANCE/APPLICATION

New PET reconstruction algorithms enhance lesion detection. Use in response assessment requires interpretative vigilance and consideration of follow-up imaging in select cases to avoid over treatment.

S3B-SPNPM-1 WORK-RELATED INJURIES IN RADIOLOGY

Amy L. Schranz, PhD, MBBCh (*Presenter*)
Ammar Alam (*Abstract Co-Author*)
Paula N. Patino, MD (*Abstract Co-Author*)
Susan Peddle (*Abstract Co-Author*)
Nathalie Fleming (*Abstract Co-Author*)
Mukesh G. Harisinghani, MD (*Abstract Co-Author*)
Marlise P. dos Santos, MD,MPH (*Abstract Co-Author*)

PURPOSE

Ergonomic optimisation of radiology reading rooms remains unaddressed in many departments. Poor workstation ergonomics including suboptimal monitors, chairs, desks, lighting, and input devices can increase the risk of repetitive stress injuries (RSIs) and contribute to adverse outcomes such as musculoskeletal pain, eye strain, and headaches. This study aimed to (1) determine the prevalence and types of RSIs among PACS workstation users in our department, (2) identify specific ergonomic deficiencies, and (3) explore the association between workstation ergonomics and physician burnout. We hypothesise that a higher burden of RSIs would correlate with increased burnout symptoms.

METHODS AND MATERIALS

Data was collected through an REB-approved electronic survey distributed to faculty, residents, and fellows in our radiology department (Collection period March 01-May 30, 2025). The anonymous survey collected data on RSI prevalence, ergonomic shortcomings, and perceived effects on work performance and burnout. Validated instruments used included the Cornell Musculoskeletal Discomfort Questionnaire (CMDQ) and the abbreviated Maslach Burnout Inventory (aMBI).

RESULTS

To date, RSIs have been reported by 82% of participants (n=42/49; M:F=31:18), with neck (70%) and upper back (60%) pain being most common. Of those affected, 68% stated that their injury impaired work performance, and 53% believed their workstation worsened their condition. Additionally, 82% noted a component of their hospital workstation had been broken in the past year, while 88% had never received formal ergonomic training. Notably, 33% felt that their RSI contributed to burnout. Preliminary analysis demonstrated a trend ($p < 0.1$) linking higher RSI frequency and severity with increased emotional exhaustion.

CONCLUSION

Preliminary data indicate a high prevalence of RSIs among radiology PACS users, driven in part by inadequate ergonomics, broken equipment, and lack of training. These factors may play a significant role in contributing to physician burnout.

CLINICAL RELEVANCE/APPLICATION

Repetitive stress injuries can diminish concentration, reduce efficiency, and impair job performance, ultimately affecting the quality and safety of patient care. Evidence suggests that improving workstation ergonomics can reduce injury rates, enhance productivity, and mitigate burnout. Proactive ergonomic interventions may therefore promote clinician well-being and improve patient outcomes.

S3B-SPNR-1 REPEATED NEUROMODULATION WITH LOW-INTENSITY FOCUSED ULTRASOUND IN PATIENTS WITH ALZHEIMER'S DISEASE

Yong-An Chung, MD, PhD (*Presenter*)
In Uk Song (*Abstract Co-Author*)

PURPOSE

This pilot study evaluated the safety and potential to improve cognition and functional connectivity following repeated LIFU treatment in AD patients.

METHODS AND MATERIALS

Ten early-stage AD patients underwent six sessions of neuronavigation-guided LIFU targeting the left dorsolateral prefrontal cortex (DLPFC) within 2-3 weeks, alongside ongoing standard pharmacotherapy. Neuropsychological assessments and resting-state functional magnetic resonance imaging were performed at baseline and eight weeks post-treatment.

RESULTS

Memory performance ($p = 0.02$) and functional connectivity between the left DLPFC and both the left perirhinal cortex and left dorsomedial prefrontal cortex (corrected $p < 0.05$) significantly improved from baseline. Additionally, enhancements in memory performance were positively correlated with increases in functional connectivity of the left DLPFC with the left perirhinal cortex (Kendall's tau = 0.56, $p = 0.03$). No adverse events were reported during the LIFU treatments or at the subsequent follow-up.

CONCLUSION

LIFU may have the therapeutic potential to enhance both brain network connectivity and memory functions in AD patients. Our results provide a basis for further research, including randomized sham-controlled trials and optimization of stimulation protocols, on LIFU as a supplementary or alternative treatment option for AD.

CLINICAL RELEVANCE/APPLICATION

The results showed significant improvements in memory performance and functional connectivity between the left DLPFC and both the left perirhinal cortex and the left dorsomedial prefrontal cortex, with no adverse events reported. Additionally, we found a positive correlation between changes in memory function and changes in functional connectivity. These findings suggest that LIFU may have therapeutic potential for AD patients.

S3B-SPNR-2 FAST SCREENING OF SPINAL DURAL ARTERIOVENOUS FISTULA AND AUTOMATIC IDENTIFICATION OF FISTULAS USING DEEP LEARNING: AN INNOVATIVE AI-DRIVEN 3D-CNN SYSTEM FOR ENHANCING CLINICAL WORKFLOW

Fei Zheng (*Presenter*)
Nan Hong, MD (*Abstract Co-Author*)

PURPOSE

Manual post-processing of computed tomography angiography (CTA) images, performed by technicians, is labor-intensive and prone to errors. We propose an AI-based reconstruction system using a three-dimensional convolutional neural network (3D-CNN) integrated with physiological anatomical knowledge to automatically detect spinal dural arteriovenous fistula (SDAVF) and localize its fistula position.

METHODS AND MATERIALS

This study involved 309 patients (371,737 images) diagnosed with SDAVF through digital subtraction angiography (DSA) and surgery, conducted from July 2018 to January 2025. The process was divided into a training set, validation set, and two independent test sets (one prospective). Four segmentation and recognition models were developed using ResU-net, and a fistula identification model was built with DenseNet. Initially, ResUnet1 segmented the spinal cord, followed by dilation to obtain the spinal canal region. ResUnet2 automatically segmented malformed vascular clusters within this region. ResUnet3 identified the centroids of vertebral bodies from T1 to L5, using a connected domain algorithm to label vertebrae. The highest and lowest points of malformed vessels were identified, and the region was cropped accordingly. The intervertebral foramina were then detected, and DenseNet assessed the presence of a fistula in each intervertebral foramen. Performance evaluation of each model was carried out using two independent test sets, with accuracy analysis used to validate the model's reliability.

RESULTS

The ResUnet2 model, using a 33.5 threshold for segmenting malformed vascular clusters, accurately distinguished patients with and without arteriovenous fistulas. In the first test set, the accuracy, precision, recall, and F1-score were 0.930, 0.871, 1.000, and 0.931, respectively, and in the second test set, 0.964, 1.000, 0.923, and 0.960, respectively. The DenseNet-based fistula identification model achieved accuracies of 0.903, 0.926, and 0.846 in the validation and test sets. Compared to technicians, this system reduced time consumption from 40.75 ± 11.57 minutes to 1.05 ± 0.29 minutes, and the number of clicks from 761.80 ± 202.05 to 9.68 ± 2.12. These improvements streamline the clinical workflow.

CONCLUSION

We developed an AI-based imaging recognition system, utilizing anatomical knowledge and 3D-CNNs, to diagnose SDAVF and localize fistula orifices. This system aids technicians and establishes a time-saving workflow in clinical settings.

CLINICAL RELEVANCE/APPLICATION

Our system has the potential to become a standard tool in radiological workflows, supporting faster diagnoses and enhancing communication with patients, ultimately improving patient care and efficiency.

S3B-SPNR-3 Zhiming Zhou (*Presenter*)

PREDICTION OF RUPTURE RISK IN INTRACRANIAL ANEURYSM: A HIGH-RESOLUTION VESSEL WALL IMAGING BASED RADIOMICS ANALYSIS

PURPOSE

This study aimed to develop and validate a novel prediction model to assess the risk of IA rupture by integrating high-resolution vessel wall imaging (HR-VWI) with radiomics.

METHODS AND MATERIALS

A total of 446 patients with IAs from two centers were included in this retrospective study. HR-VWI images were preprocessed to extract regions of interest from IA and parent artery (PA) walls. Using Pyradiomics, 851 radiomic features were extracted. Key features were selected through variance analysis, t-tests, and ElasticNet regularization. Based on these features, three radiomics score (Radscore) models were developed: Radscore_IA (for the IA), Radscore_PA (for the PA), and Radscore_IA_PA (a combined model). Moreover, aneurysm location (LOC), as a morphological predictor, was incorporated into new models: Radscore_LOC_IA, Radscore_LOC_PA, and Radscore_LOC_IA_PA. The performance of these models was evaluated using receiver operating characteristic (ROC) curves, with the ELAPSS score serving as a benchmark.

RESULTS

In the derivation cohort, AUC values for IA rupture prediction were as follows: ELAPSS (0.676), Radscore_IA (0.846), Radscore_PA (0.822), Radscore_IA_PA (0.878), Radscore_LOC_IA (0.864), Radscore_LOC_PA (0.836), and Radscore_LOC_IA_PA (0.888). In the validation cohort, AUC values were as follows: ELAPSS (0.617), Radscore_IA (0.837), Radscore_PA (0.820), Radscore_IA_PA (0.878), Radscore_LOC_IA (0.852), Radscore_LOC_PA (0.842), and Radscore_LOC_IA_PA (0.888). The Radscore_LOC_IA_PA model exhibited the highest predictive performance, significantly outperforming other models ($P < 0.05$). Calibration and decision curve analyses confirmed the robustness and clinical application of all models.

CONCLUSION

This study presents an innovative HR-VWI radiomics-based prediction model, Radscore_LOC_IA_PA, which combines radiomics features from the IA wall and PA wall along with the aneurysm location. This model significantly enhances the prediction of IA rupture risk compared to traditional methods, providing accurate risk stratification and clinical management of patients with IAs.

CLINICAL RELEVANCE/APPLICATION

Our study presents a groundbreaking HR-VWI radiomics-based prediction model, Radscore_LOC_IA_PA, which integrates 3D radiomics features from the IA wall and PA wall, along with aneurysm location.

S3B-SPNR-4 INTEGRATION OF RADIOMICS AND CLINICAL BIOMARKERS IMPROVES IDENTIFICATION OF INTRAPLAQUE HEMORRHAGE IN INTRACRANIAL ATHEROSCLEROSIS: A 3D HRMR-VWI STUDY

Xuan Chen (*Presenter*)

PURPOSE

To investigate the diagnostic value of radiomics analysis based on HRMR-VWI in detecting intraplaque hemorrhage (IPH) among symptomatic intracranial atherosclerotic disease (ICAD) patients.

METHODS AND MATERIALS

This retrospective study analyzed 144 intracranial atherosclerotic plaques from 169 patients with ICAD admitted between April 2020 and April 2022. Plaques were classified into IPH-positive (n=56) and IPH-negative (n=88) groups using HRMR-VWI. Clinical parameters, serum biomarkers, and conventional imaging features were collected. Univariate analyses (independent t-test, Mann-Whitney U test, chi-square test) identified significant predictors of IPH, followed by multivariate logistic regression to establish a traditional model. Plaques were stratified into training (n=115) and testing (n=29) cohorts using 8:2 stratified randomization. Radiomic features extracted from 3D-T1WI underwent least absolute shrinkage and selection operator algorithm for model construction in the training cohort, with subsequent validation in the testing cohort. A combined model integrating traditional and radiomic predictors was developed. Diagnostic performance was evaluated using the ROC curves, AUC, and DeLong's test.

RESULTS

Significant intergroup differences were observed in hypertension prevalence, Hcy, C-CRP, TC, LDL-C, stenosis rate, EI, and NWI, all $P <0.05$. Multivariate analysis identified CRP (OR=1.060, 95%CI 1.009-1.112, P = 0.019), LDL-C (OR=1.956, 95%CI 1.036-3.692, P = 0.039), and EI (OR=1.468, 95%CI 1.015-2.123, P = 0.041) as independent IPH predictors. The traditional model incorporating CRP, LDL-C, and eccentric index demonstrated AUC values of 0.710 and 0.707 in identifying IPH within the training and testing cohorts, respectively. By integrating radiomic features from 3D T1WI, improved diagnostic performance was achieved in both training and testing cohorts (AUC: 0.901 and 0.828). In the training cohort, the combined model showed significantly superior AUC in predicting IPH compared to the traditional model ($Z=3.946$, $P <0.001$). No statistically significant difference in AUC was observed between the radiomics model and the combined model ($Z=1.230$, $P >0.05$). The combined model achieved optimal performance (AUC=0.901; sensitivity=86.7%, specificity=85.7%, accuracy=81.7%).

CONCLUSION

The radiomics method based on 3D HRMR-VWI has demonstrates clinical utility in identifying IPH in symptomatic ICAD patients.

CLINICAL RELEVANCE/APPLICATION

Radiomics analysis combined with HRMR-VWI enhances non-invasive detection of intraplaque hemorrhage in symptomatic ICAD patients, improving risk stratification and guiding targeted therapies to reduce stroke recurrence through high diagnostic accuracy.

S3B-SPNR-6 PERFORMANCE OF GADOPICLENOL IN DYNAMIC SUSCEPTIBILITY CONTRAST MAGNETIC RESONANCE IMAGING (DSC-MRI) PERFUSION OF BRAIN GLIOMAS

Simona Gaudino (*Presenter*)
Anna Pichiecchio, MD (*Abstract Co-Author*)
Katarzyna Dziadziuszko, MD (*Abstract Co-Author*)
Simonetta Gerevini, MD (*Abstract Co-Author*)

PURPOSE

To demonstrate the non-inferiority of DSC-MRI perfusion using gadopiclenol (EluciremTM) at 0.05 mmol/kg compared to gadoterate meglumine (Dotarem®) at 0.1 mmol/kg in terms of diagnostic quality of Cerebral Blood Volume (CBV) perfusion map

METHODS AND MATERIALS

In this multicenter randomized controlled trial, 138 adult patients with naive or recurrent primary glial tumor scheduled for a follow-up DSC-MRI were randomized to receive either gadopiclenol at 0.05 mmol/kg or gadoterate meglumine at 0.1 mmol/kg, with stratification on glioma grade (low, high). CBV maps were generated through a post-processing software. The primary outcome was the CBV map diagnostic quality assessed by two independent blinded readers, using a 4-point scale (poor, fair, good, excellent). Secondary outcomes included differentiation of glioma grade by relative CBV (rCBV) quantification, and safety. Non-inferiority was defined as proportion of patients with excellent or good diagnostic quality images for gadopiclenol of no more than 12% below that for gadoterate meglumine

RESULTS

A total of 136 patients underwent an MRI with gadopiclenol or gadoterate meglumine, of whom 129 patients had diagnostic images. Finally, 124 patients without protocol major deviation were included in the per-protocol analysis: 60 with gadopiclenol and 64 with gadoterate meglumine. Gadopiclenol was non-inferior to gadoterate meglumine on CBV perfusion map diagnostic quality. The proportion of patients with CBV map images assessed as "excellent or good" was 96.7% and 98.4%, respectively, with a difference of -1.8% [two-sided 95% CI: -8.9% to 5.3%]. Overall, rCBV values were significantly different between high-grade and low-grade gliomas with both contrast agents, with a median of 3.11 vs 1.51 ($p = 0.003$) for gadopiclenol and 2.47 vs 1.41 ($p < 0.001$) for gadoterate meglumine. There was no difference between the two agents for grade differentiation ($p = 0.35$). Five patients (3.7%) experienced non-serious adverse events: 3 in the gadopiclenol group (incorrect dose administered for 2 patients, gastrointestinal disorders for one) and 2 in the gadoterate meglumine group (incorrect dose administered for one and headache for the other). All adverse events were of mild intensity and resolved spontaneously. None was considered related to the contrast agent

CONCLUSION

DSC-MRI perfusion using gadopiclenol at 0.05 mmol/kg was non-inferior to gadoterate meglumine at 0.1 mmol/kg on diagnostic quality of CBV perfusion map and both enabled tumor grade differentiation in patients with brain glioma. This study additionally confirmed the safety profile of gadopiclenol

CLINICAL RELEVANCE/APPLICATION

Half-dose of gadopiclenol (0.05 mmol/kg) can be used in DSC-MRI perfusion for brain gliomas

S3B-SPNR-7 PLASMA NEUROFILAMENT LIGHT REFLECTS BRAIN TISSUE LOSS, VENTRICULAR ENLARGEMENT, AND VASCULAR-MEDIATED NEURODEGENERATION

Khalid Saifullah, BSc (*Presenter*)
Gulam Mahfuz Chowdhury, BEng (*Abstract Co-Author*)
Arnold M. Evia JR, PhD (*Abstract Co-Author*)
David A. Bennett, MD (*Abstract Co-Author*)
Julie A. Schneider, MD (*Abstract Co-Author*)
Konstantinos Arfanakis, PhD (*Abstract Co-Author*)

PURPOSE

Neurofilament light chain (NfL), has gained attention as a blood-based indicator of neurodegeneration and brain structural changes. Despite its growing use, the association between NfL and white matter hyperintensities (WMH) - a hallmark of small vessel disease - along with measures of neurodegeneration using deformation-based morphometry (DBM), remains poorly understood in older adults without dementia. This study investigates the interconnections among NfL, WMH, and neurodegeneration, with particular emphasis on the mediating role of vascular pathology.

METHODS AND MATERIALS

Participants and Data We analyzed data from 202 non-demented, community-based older adults enrolled in four longitudinal studies: MAP, ROS, MARS, and AA. Fasting blood samples were collected and quantified by the NCRAD. Structural MRI scans (3D T1-weighted MPRAGE) were registered to the MIITRA atlas to generate log Jacobian (LogJ) maps reflecting local brain volume differences. WMH volume, segmented from T2w FLAIR and T1w images, was expressed as a percentage of intracranial volume and log-transformed. Statistical analysis Voxel-wise linear regression was used to assess the association between plasma NfL levels and LogJ-based neurodegeneration. Similar analyses were conducted to assess the relationship between WMH burden and LogJ maps. The link between NfL levels and WMH burden was also evaluated. To explore potential mediation, we assessed whether WMH burden accounted for the effect of NfL on neurodegeneration. All statistical models included covariate adjustments for age, sex, education, MRI-to-blood draw interval, and scanner type. Voxel-wise analyses were performed using FSL PALM, incorporating 5000 permutations, family-wise error rate correction ($p < 0.05$).

RESULTS

Higher plasma NfL levels were linked to greater neurodegeneration, as indicated by reduced brain volume and expanded ventricular spaces. NfL also showed a significant positive relationship with WMH volume ($\beta = 0.0798$, $SE = 0.0436$, $p = 0.0344$). Additionally, WMH burden demonstrated a strong association with brain tissue loss. Importantly, when WMH was accounted for in the model, the previously observed association between NfL and neurodegeneration was attenuated, suggesting that WMH may play a mediating role in this relationship.

CONCLUSION

Our results underscore the potential of NfL as an indicator of both neurodegeneration and vascular contributions to brain aging, with vascular pathology possibly driving neurodegeneration.

CLINICAL RELEVANCE/APPLICATION

These findings highlight plasma NfL as a non-invasive marker of neurodegeneration and vascular injury, aiding early risk detection for cognitive decline.

S3B-SPNR-8 HIGHER ARTS SCORE IS ASSOCIATED WITH HIGHER LEVELS OF NFL BUT NOT WITH P-TAU217

Gulam Mahfuz Chowdhury, BEng (*Presenter*)
Khalid Saifullah, BSc (*Abstract Co-Author*)
Arnold M. Evia JR, PhD (*Abstract Co-Author*)
David A. Bennett, MD (*Abstract Co-Author*)
Julie A. Schneider, MD (*Abstract Co-Author*)
Konstantinos Arfanakis, PhD (*Abstract Co-Author*)

PURPOSE

Intracranial arteriolosclerosis affects cerebrovascular health and cognition, with ARTS serving as its MRI-based marker. Its relationship to Alzheimer's pathology and neuronal damage remains unclear. We investigated the association between ARTS and blood biomarkers p-tau217 (Alzheimer's) and NfL (axonal damage).

METHODS AND MATERIALS

This study included 202 participants from four longitudinal, clinical-pathologic cohort studies of aging: MAP, ROS, MARS, and AACC of the Rush Alzheimer's Disease Research Center. This sample included only participants with no or mild cognitive impairment (NCI, MCI). None of the participants had dementia. All participants underwent in-vivo MRI on 3 Tesla MRI scanners using MPRAGE, FLAIR, and DTI sequences. The MRI data were used to calculate ARTS scores for all participants using the fully-automated, publicly available ARTS software. Blood was collected on all participants. plasma p-tau217 and NfL levels were measured at the National Centralized Repository for Alzheimer's Disease and Related Dementias (NCRAD) using established procedures. Both p-tau217 and NfL values were log transformed to normalize the distribution. Linear regression was used to test the association of ARTS score with levels of p-tau217 and NfL, separately, controlling for demographics (age at visit, sex, years of education), interval between blood draw and MRI scanning, and scanner. The FSL PALM tool with 10000 permutations and tail acceleration was used for the statistical analysis. Associations were considered significant at $p<0.05$ after family-wise error (FWE) correction.

RESULTS

No significant association of ARTS scores with levels of p-tau217 was detected ($\beta=0.0046$, $p=0.38$), underscoring that ARTS is independent of Alzheimer's pathology (Fig.2A). In contrast, a strong positive association of ARTS with NfL was observed ($\beta=0.0485$, $p=0.0011$), highlighting that ARTS is linked to CSVD-related axonal injury.

CONCLUSION

The present study in community-based older adults without dementia suggests that ARTS scores are not influenced by Alzheimer's pathology, which often co-occurs with arteriolosclerosis. Yet, higher ARTS scores are associated with more severe axonal injury assessed by means of higher NfL scores.

CLINICAL RELEVANCE/APPLICATION

The study showed that the ARTS marker of arteriolosclerosis is unrelated to p-tau217 but positively associated with NfL. This suggests ARTS is independent of Alzheimer's pathology, making it a valuable tool for identifying arteriolosclerosis even when both conditions co-exist. The link between ARTS and NfL supports its role in detecting vascular-related axonal injury, aligning with evidence that small vessel disease contributes to brain damage and cognitive decline.

S3B-SPNR-9 MRI CHARACTERISTICS AND IMPROVEMENT DETERMINATION OF THE TYPE OF PITUITARY SOMATOTROPH TUMOURS

Alexey Petryaikin, MD, PhD (*Presenter*)
Safi Tamaeva (*Abstract Co-Author*)
Anna Khoruzhaya (*Abstract Co-Author*)
Evgeny Pronin (*Abstract Co-Author*)
Vyacheslav Pronin (*Abstract Co-Author*)
Egor Syrkashev (*Abstract Co-Author*)
Mikhail Antsiferov (*Abstract Co-Author*)
Iurii Vasilev (*Abstract Co-Author*)

PURPOSE

The study aimed to enhance noninvasive differentiation between densely (DGST) and sparsely granulated somatotroph tumors (SGST) using MRI-derived relative signal intensity metrics by developing a composite index combining T2- and T1-weighted imaging (T2-T1) signals, the research sought to improve prognostication for responsiveness to first-generation somatostatin receptor ligands therapy.

METHODS AND MATERIALS

A retrospective analysis included 71 acromegaly patients (34 DGST, 37 SGST) diagnosed postoperatively via histopathology. Preoperative MRI (1.5 Tesla) was performed, acquiring T1- and T2-weighted images (WI). Relative signal intensity (S rel) was calculated as: S rel =(S tumor -S gm)/S gm ×100%, where S tumor = tumor signal, S gm = gray matter signal. Metrics included S rel (T2), S rel (T1), and a synthetic index S rel (T2-T1) = S rel (T2) - S rel (T1). Secondary parameters: tumor volume, invasion index (Knosp + Hardy grading). Statistical analysis used Mann-Whitney U tests and ROC AUC test.

RESULTS

DGST exhibited significantly lower T2-WI signal intensity (S rel = -14.9% [-25.7; -0.6]) compared to SGST (+10.6% [1.7; 25.4], p<0.001), while T1-WI signals were higher in DGST (8.2% [3.7; 11.4]) versus SGST (-0.4% [-6.9; -3.9], p<0.001). The synthetic S rel (T2-T1) index demonstrated the largest intergroup difference (-21.5% [-44.7; -7.2] for DGST vs. +7.2% [-3.2; 31.5] for SGST, p<0.001) with superior diagnostic accuracy (AUC=0.864). ROC analysis identified optimal cutoffs at -6.0% for T2-WI (AUC=0.847, sensitivity=91.9%, specificity=70.6%) and -3.5% for S rel (T2-T1) (AUC=0.864, sensitivity=81.1%, specificity=82.4%). SGST tumors were larger in volume (3.1 vs. 2.1 mL, p=0.041), while invasion indices (7 vs. 7, p=0.337) and contrast enhancement (40.6% vs. 41.1%, p=0.290) showed no significant differences.

CONCLUSION

The composite S rel (T2-T1) index can improve preoperative differentiation of pituitary DGST and SGST in addition to the standard T2-based criterion, achieving high diagnostic accuracy (AUC=0.864). While tumor volume helps differentiation; invasion indices and contrast enhancement have no discriminatory power. Limitations include the retrospective design and unreported borderline cases near the cutoff values.

CLINICAL RELEVANCE/APPLICATION

Noninvasive MRI differentiation of pituitary DGST and SGST using the S rel (T2-T1) index in addition to the standard T2-based index allows timely planning of personalized treatment. Favorable DGST response to first-generation somatostatin receptor ligands highlights the clinical value of preoperative identification. This approach improves prognosis, optimizes treatment costs, therapeutic strategies and supports precision medicine in the treatment of acromegaly.

S3B-SPNR-10 SPATIAL HETEROGENEITY MODELING IN ACUTE ISCHEMIC STROKE: A MULTI-MODAL MRI-DERIVED CLUSTERING APPROACH FOR PROGNOSTIC STRATIFICATION

Mentian Ma (*Presenter*)
Weiyin V. Liu (*Abstract Co-Author*)
Suping Chen (*Abstract Co-Author*)
Kun Zhang, MD (*Abstract Co-Author*)

PURPOSE

Stroke remains a major cause of adult disability and death. While infarct volume and location are conventionally imaging biomarkers, recent radiomics and neuroimaging have revealed complex spatial heterogeneity in ischemic tissue beyond visible infarct zones. Inspired by spatial genomics and network neuroscience, this study aimed to delineate MRI-based spatial subgroups in ischemic stroke and assess their value in predicting disease-free survival (DFS) and 90-day outcomes.

METHODS AND MATERIALS

We retrospectively enrolled 287 patients with DWI-confirmed acute ischemic infarction who underwent T1-weighted, T2-weighted, and DWI scans. After preprocessing and co-registration, a two-step clustering approach was applied. First, first-order spatial features were extracted from infarct regions of interest (ROIs), followed by superpixel segmentation. Subsequently, the Leiden algorithm was used to cluster six representative spatial subregions. To enhance robustness, consensus clustering based on multi-region spatial interaction (MSI) matrices was performed, identifying two clusters: Cluster1 (n=190) and Cluster2 (n=97). DFS, 90-day modified Rankin Scale (mRS), and time-dependent AUCs at 1, 2, and 4 years were compared using Patti's model as a reference. Kaplan-Meier survival curves were

RESULTS

DFS was significantly longer in Cluster1 than Cluster2 (Log-rank P = 0.019). When dichotomizing 90-day mRS scores into favorable (0-2) and unfavorable (3-6) outcomes, Cluster1 showed a higher proportion of favorable prognosis (P = 0.030). Time-dependent AUCs for the Habbita Cluster model were 0.593 (0.528-0.658) at 1 year, 0.536 (0.460-0.611) at 2 years, and 0.665 (0.314-1.000) at 4 years-exceeding Patti's model values of 0.517 (0.489-0.545), 0.513 (0.495-0.530), and 0.506 (0.497-0.515), respectively. Kaplan-Meier analysis based on Patti's model showed no significant DFS stratification (P = 0.080).

CONCLUSION

The Habbita Cluster model, derived from multi-modal MRI fusion, effectively captures brain tissue spatial heterogeneity in ischemic stroke and improves prognostic stratification. Its superior predictive performance over conventional models indicates its value as an imaging biomarker to inform individualized management

CLINICAL RELEVANCE/APPLICATION

By enabling early and precise risk stratification, the Habbita Cluster model supported tailored clinical decisions-such as adjusting rehabilitation intensity and guiding secondary prevention—thereby optimizing therapeutic outcomes in stroke care.

S3B-SPNR-11 DETECTION OF TERT PROMOTER MUTATIONS IN GLIOMAS USING TIME-DEPENDENT DIFFUSION MRI-BASED MICROSTRUCTURE MAPPING

Jue Lu (*Presenter*)
Jing Wang (*Abstract Co-Author*)

PURPOSE

This study aimed to explore the utility of time-dependent diffusion MRI (t d -MRI) in quantitatively characterizing tumor microstructural features in vivo and evaluate the discriminatory efficacy of its derived parameters for the telomerase reverse transcriptase (TERT) promoter mutation status.

METHODS AND MATERIALS

This prospective study included 91 patients diagnosed with adult-type diffuse gliomas through pathology (mean age: 45.4 ± 12.3 years). They underwent t d -MRI with pulse and oscillating gradient diffusion sequences on a 3T scanner. Diffusion MRI data collected at different effective diffusion times were fitted into the limited spectrally edited diffusion model (IMPULSED) to obtain parameters such as intracellular fraction (V in), cell diameter, cellularity, and extracellular diffusivity(D ex).

RESULTS

In the IDH-mutant glioma subgroup (n = 33), the TERT-mutant group (n = 13) demonstrated significantly higher V in (0.14 ± 0.10 vs. 0.08 ± 0.05, p = 0.005) and cellularity (1.13 ± 1.06 vs. 0.53 ± 0.38, p = 0.002) compared to the TERT-wildtype group (n = 20), alongside smaller cell diameters (14.48 ± 1.47 μm vs. 15.84 ± 0.47 μm, p = 0.004) and lower D ex (1.50 ± 0.19 vs. 1.69 ± 0.24 $\mu m^2/ms$,p = 0.027). For molecular classification of TERT changes in gliomas, the area under the curve (AUC) for cellularity was the highest at 0.827, followed by V in at 0.792. In the T1 non-enhancement subgroup (n = 32), the AUC of cellularity further improved to 0.903, with V in reaching an AUC of 0.879. Notably, T1 contrast enhancement showed a strong positive correlation with tumor grade (r = 0.63, p<0.001).

CONCLUSION

The microstructural features based on t d -MRI provide supplementary information in the molecular classification of TERT mutations in adult-type diffuse gliomas. Cellularity and V in have good discriminative ability for identifying TERT changes.

CLINICAL RELEVANCE/APPLICATION

Gliomas are common malignant primary brain tumors, with adult-type diffuse glioma having the highest incidence. The telomerase reverse transcriptase (TERT) promoter mutation status is crucial for diagnosing adult-type diffuse gliomas for grading and determining patient prognosis.This study confirms the application value of microstructural mapping based on t d -MRI in molecular stratification of adult diffuse gliomas.

S3B-SPNR-16 ABNORMAL WHITE MATTER MICROSTRUCTURE IN THE AMYGDALA-RELATED FIBER TRACT PATHWAYS IN PATIENTS WITH TRIGEMINAL NEURALGIA: A MULTIVARIATE ANALYSIS

Zhang Chuan I, MD (*Presenter*)

PURPOSE

Trigeminal neuralgia (TN), a debilitating neuropathic disorder, is characterized by severe facial pain and heightened emotional comorbidities such as catastrophizing and anxiety. This study investigated whether microstructural abnormalities in amygdala-related white matter pathways mediate the relationship between psychological distress and pain severity in TN.

METHODS AND MATERIALS

A cross-sectional cohort of 46 TN patients (mean age: 57.6±10.2 years; ICHD-3 diagnosed) and 35 age-/sex-matched healthy controls underwent clinical assessments and 3T MRI. Pain intensity was quantified via the Penn Facial Pain Rating (PFPR) and McGill Pain Questionnaire (MPQ), while emotional distress was measured using the Pain Catastrophizing Scale (PCS) and Pain Anxiety Symptom Scale-20 (PASS-20). Diffusion tensor imaging (DTI) data were preprocessed using FSL v6.0 for eddy current/motion correction, followed by tensor estimation to derive fractional anisotropy (FA), mean diffusivity (MD), radial diffusivity (RD), and axial diffusivity (AD). Amygdala-related fiber pathways were reconstructed via seed-based fiber streamline (sFS) analysis in ExploreDTI, leveraging the Human Brainnetome Atlas for tract identification. Multivariate partial least squares correlation (PLSC) was employed to associate white matter metrics with clinical variables, validated through permutation/bootstrapping (5,000 iterations). Mediation analyses (SPSS Amos) tested whether amygdala-pathway microstructure explains the PCS-PFPR relationship, controlling for age/disease duration.

RESULTS

Our findings revealed a significant association between PCS and PFPR. Compared to HCs, TN patients exhibited abnormal white matter integrity in amygdala-related fiber pathways, mainly located at the splenium of the corpus callosum, bilateral anterior corona radiata, and bilateral external capsule. These white matter alterations were significantly associated with both pain severity (PFPR, MPQ) and emotional distress (PCS, PASS). Mediation analysis further showed that the fractional anisotropy values in amygdala-related white matter partially explained the link between catastrophizing and pain intensity.

CONCLUSION

These findings identify amygdala-prefrontal pathways as critical mediators of pain-emotion interactions in TN, suggesting that targeted neuromodulation of these circuits may disrupt the maladaptive pain-emotion cycle.

CLINICAL RELEVANCE/APPLICATION

This study suggests that pain catastrophizing may alter brain structure and contribute to chronic facial pain in trigeminal neuralgia patients. Early interventions targeting negative emotions could prevent further structural changes and improve clinical outcomes.

S3B-SPNR-17 QUANTITATIVE SUSCEPTIBILITY MAPPING REVEALS WHITE MATTER HYPERINTENSITY AND PERILESIONAL CHANGES RELATED TO COGNITIVE DECLINE IN CEREBRAL SMALL VESSEL DISEASE

Pengcheng Liang (*Presenter*)
Yilin Guo (*Abstract Co-Author*)
Changhu Liang, MD, PhD (*Abstract Co-Author*)
Lingfei Guo, MD (*Abstract Co-Author*)
Na Wang (*Abstract Co-Author*)
Yuanyuan Wang (*Abstract Co-Author*)

PURPOSE

White matter hyperintensities (WMHs) are a hallmark of cerebral small vessel disease (CSVD) and have been implicated in cognitive decline. However, the role of magnetic susceptibility changes within and around WMHs remains unclear. This study aimed to investigate the relationship between WMH and perilesional susceptibility values and cognitive performance in CSVD.

METHODS AND MATERIALS

We included 299 participants who underwent 3T MRI with QSM and DTI. WMHs were automatically segmented and manually corrected. Susceptibility values were extracted from WMHs and concentric perilesional white matter regions (0-2 mm, 2-4 mm, 4-6 mm). Diffusion parameters (FA, RD, AD, ADC) were computed. Cognitive

assessments included MoCA, AVLT, SDMT, SCWT, and TSUM. We analyzed group differences across CSVD severity (score 0, 1, =2), and conducted partial correlations adjusted for confounders.

RESULTS

WMH susceptibility values were significantly lower than NAWM (P < .001) and increased with CSVD severity (P < .001). A spatial gradient was observed in perilesional regions, with susceptibility values progressively approaching NAWM levels. MoCA scores were negatively associated with WMH susceptibility (r = -0.16, P = .045). DTI metrics confirmed white matter degeneration with increasing CSVD severity. WMH volume significantly increased across 42 white matter tracts, especially in severe CSVD.

CONCLUSION

Both WMH and perilesional susceptibility alterations are linked to CSVD severity and cognitive impairment. The spatial gradient suggests early microstructural changes beyond visible lesions.

CLINICAL RELEVANCE/APPLICATION

QSM-derived susceptibility values in and around WMHs provide novel imaging biomarkers for CSVD-related white matter injury and may aid in early detection of cognitive decline.

S3B-SPNR-18 MULTIMODAL ASSESSMENT OF ACUTE SLEEP DEPRIVATION EFFECTS IN HEALTHY ADULTS USING 7T MRI

Eric Einspaenner, MSc (*Presenter*)
Erelle Fuchs (*Abstract Co-Author*)
Hendrik Mattern (*Abstract Co-Author*)
Heiko Grossmann (*Abstract Co-Author*)
Eya Khadhraoui (*Abstract Co-Author*)
Sebastian Johannes Muller (*Abstract Co-Author*)
Daniel Behme (*Abstract Co-Author*)

PURPOSE

Sleep deprivation has been known to impair cognitive performance and alter brain physiology. This study investigates structural, physiological and cognitive changes before, directly after and three days post sleep deprivation using 7T MRI, blood biomarkers and reaction time testing.

METHODS AND MATERIALS

We enrolled 30 healthy subjects (age 20-38) who underwent an 7T MRI at baseline (day 0), after sleep deprivation of 24h (day 1) and post-recovery (day 4). Participants were supervised by medical staff to confirm that the participants were awake for all 24h. Blood samples were collected before each scan in 27 participants. Cognitive performance was assessed via NASA PVT (Psychomotor Vigilance Test) at 0h, 12h, 24h, and 96h. QSM maps were reconstructed from ASPIRE-based GRE sequences using QSMbox. MP2RAGE scans enabled whole-brain segmentation via FastSurferCNN, aligned to QSM using FSL FLIRT. ROI-based mean +/- SD values were extracted from QSM and T1 maps. Additionally, an automated pipeline using Frangi filtering and thresholding on MP2RAGE and T2-weighted images was developed for enhanced perivascular space (PVS) detection and calculation of volume.

RESULTS

Sleep deprivation induced a transient increase in mean reaction time, in the slowest and fastest 10% after 24h, with recovery to baseline by 96h (not significant). Reaction time variability also decreased over time, indicating a training effect, as shown by the reduced variability in reaction times. Blood biomarkers showed delayed myoglobin and cystatin C elevations at 96h, consistent with muscle and renal stress, while osteopontin decreased at 24h, suggesting early metabolic response. MMP-9 peaked at 24h and normalized by 96h, reflecting transient inflammatory activation. Quantitative MRI revealed a negative correlation between ventricular T1 and reaction time slowing, suggesting altered glymphatic clearance. Similarly, QSM changes in the ventral diencephalon correlated with cognitive performance. White matter PVS volume peaked at 24h and normalized by 96h, supporting a reversible sleep-loss-associated alteration in fluid dynamics or neuroinflammation.

CONCLUSION

Sleep deprivation induces reversible alterations in cognitive performance, brain fluid dynamics, and systemic biomarkers, suggesting transient disruption of glymphatic and inflammatory homeostasis. Multimodal imaging and biomarker integration offer novel insights into sleep-dependent brain clearance mechanisms.

CLINICAL RELEVANCE/APPLICATION

To identify morphologic (PVS volume) and functional (qT1) changes in individuals before and after sleep deprivation as a potential new biomarker for glymphatic system impairment.

S3B-SPOB-1 THE VALUE OF AMIDE PROTON TRANSFER-WEIGHTED IMAGING AND INTRAVOXEL INCOHERENT MOTION IMAGING IN OPTIMIZING RISK STRATIFICATION OF O-RADS MRI 4 LESIONS

Jinhui Huang (*Presenter*)
Mei-yu Sun (*Abstract Co-Author*)
Ying Han (*Abstract Co-Author*)
Yuqi Chen (*Abstract Co-Author*)

PURPOSE

Exploring the value of quantitative parameters of amide proton transfer-weighted imaging (APT) and intravoxel incoherent motion imaging (IVIM) in the differentiation of benign and malignant ovarian lesions classified as O-RADS MRI 4.

METHODS AND MATERIALS

This study retrospectively collected MRI image data from patients with ovarian mass confirmed by pathology at a certain hospital from November 2019 to October 2024. All masses are rated as O-RADS MRI score 4 , and the score is jointly decided by two observers. Among the 33 cases of O-RADS MRI category 4, there were 14 benign cases and 19 malignant cases. All patients underwent pelvic MRI scans on a 3.0T MRI scanner, including T1-weighted contrast-enhancement, IVIM and APTw imaging. Two physicians measured the APT values and standard apparent diffusion coefficient (ADC stand), slow diffusion coefficient (D slow), fast diffusion coefficient (D fast), and fast diffusion coefficient fraction (f) of the solid tissue of lesions. The intraclass correlation coefficient (ICC) was used to assess the consistency of measurements between two physicians. Compare the differences of various parameters between the benign and malignant groups,and build different diagnostic models.

RESULTS

The APT values, ADC stand , D slow , and f measured by the two physicians showed good consistency, with an ICC range of 0.874-0.915 (P <0.001).The consistency of D fast was moderate, with an ICC of 0.576 (P <0.001). In the differential analysis, the ADC stand of the benign group is higher than that of the malignant group[(0.853±0.19)×10 -3 mm 2 /s vs. (0.648±0.254)×10 -3 mm 2 /s, P =0.016], the f of the benign group is higher than that of the malignant group [0.854(0.172)vs. 0.553(0.362), P =0.007], the APT value of the benign group is lower than that of the malignant group[1.495(1.3)vs. 3.24(2.04), P =0.001], with statistically significant differences.Multivariate analysis indicated that f (OR =0.992, P =0.012) and APT value (OR =2.859, P =0.012) are independent predictors of ovarian malignancy. The AUC for predicting malignant lesions in O-RADS MRI category 4 using APT value and f were 0.831 and 0.776, respectively. By combining the APT value and f to construct a diagnostic model, the AUC for predicting malignant lesions in O-RADS MRI category 4 increased to 0.921. The AUC of the combined APT value and f was significantly higher than that of the f value alone, with a statistically significant difference (P =0.03).

CONCLUSION

The APT value of APTw and the f of IVIM are helpful in distinguishing the benign and malignant lesions of O-RADS MRI score 4.

CLINICAL RELEVANCE/APPLICATION

The APT value of APTw and the f of IVIM can optimize the risk stratification of O-RADS MRI category 4 lesions,which can provide some assistance for clinical decision-making.

S3B-SPOB-2 CORRELATION OF PLACENTAL ULTRASOUND ELASTOGRAPHY WITH PERINATAL OUTCOMES IN GESTATIONAL DIABETES MELLITUS

Neha Bagri, MD, MBBS (*Presenter*)
Sooraj Sukumaran, MBBS (*Abstract Co-Author*)
Ritu N. Misra, MD, MBBS (*Abstract Co-Author*)
Aanchal Bhayana, MBBS (*Abstract Co-Author*)

PURPOSE

To correlate placental ultrasound shear wave Elastography (SWE) values with perinatal outcomes in Gestational Diabetes Mellitus (GDM).

METHODS AND MATERIALS

The study included 160 pregnant women, comprising 80 GDM and 80 healthy controls. Ultrasound SWE was performed on the placenta, and mean SWE and velocity values were derived from six measurements. Both the cases and controls were followed to record Apgar scores and NICU admission. Statistical analysis was done, and the SWE values were compared to correlate these values with perinatal outcomes.

RESULTS

A moderate positive correlation was observed between SWE values and maternal fasting blood glucose (FBS) levels (rho = 0.32, p = 0.001), indicating that higher glucose levels are associated with increased placental stiffness. In the control group, the mean SWE was 5.5 kPa, while in the GDM group, it increased to 10.1 kPa, reflecting the impact of a diabetic environment on placental stiffness. The mean velocity was also higher in the GDM group (1.6 m/s) as compared to the control group (mean = 1.3 m/s). A moderate negative correlation between APGAR (1-min) and mean SWE was found at <32 weeks of gestation (rho = -0.48, p = 0.017). No significant correlation was found with NICU admissions.

CONCLUSION

Placental stiffness differs significantly between GDM and controls, with higher values in GDM. Ultrasound SWE can substantially contribute to the management of GDM and improve the outcomes. A negative correlation between SWE and 1-min APGAR score at <32 weeks of gestation highlights the adverse impact of increased placental stiffness on perinatal outcomes.

CLINICAL RELEVANCE/APPLICATION

Any degree of glucose tolerance in pregnancy is associated with adverse maternal and fetal outcomes. Metabolic insult in GDM may lead to short-term changes in various molecules, including the placental cells, resulting in the increased production of inflammatory cytokines, eventually increasing placental stiffness. The placenta may be considered a metabolic mirror reflecting the fetus's and the mother's health status. Ultrasound Elastography is a modality used to measure tissue shear wave velocity, a quantitative measure of the elastic properties of the soft tissue. Placental Elastography studies in the existing literature have shown evidence of higher tissue stiffness in women with preeclampsia and fetal growth restriction. However, there is a paucity of information regarding placental Elastography in women with gestational diabetes mellitus and its significance in the prediction of maternal and neonatal risks in terms of APGAR score and the requirement of NICU admission.

S3B-SPOB-3 ASSOCIATION OF FETAL PULMONARY ARTERY DOPPLER INDICES AND FETAL LUNG MATURITY IN SINGLETON PREGNANCIES

Priyanka Panda, MBBS, MD (*Presenter*)

PURPOSE

Respiratory distress syndrome (RDS) in newborns is one of the leading causes of neonatal mortality so accurately assessing fetal lung maturity is crucial in determining the best time for pregnancy termination to help reduce the incidence of respiratory distress syndrome. Non-invasive antenatal assessment of fetal lung maturity is important so that invasive procedures like amniocentesis can be avoided.

METHODS AND MATERIALS

This study was done on 84 pregnant women attending the hospital in active labor and fetuses delivered within 48 hours of ultrasound scan. Color Doppler examination was performed for obtaining fetal main pulmonary artery resistance index (RI), pulsatility index (PI) and the acceleration/ejection time (AT/ET) ratio. After delivery neonate was observed for the clinical signs of respiratory distress, need for exogenous surfactant administration and NICU admission. Cutoffs were determined for fetal main pulmonary artery doppler indices like PI, RI and AT/ET ratio for predicting fetal lung maturity.

RESULTS

If the AT/ET ratio is below the cutoff value (0.30), neonatal requirement of surfactant could be predicted with Sensitivity=91.7% and Specificity=96.7%. Similarly, If RI is higher than the cutoff value (0.82) neonatal surfactant requirement could be predicted with Sensitivity=75% and Specificity=95% while if PI is more that cutoff value (2.14), it could be predicted with Sensitivity=95.83% and Specificity=61.67% that there is fetal lung immaturity.

CONCLUSION

Fetuses having AT/ET ratio = 0.30, PI < 2.14 and RI < 0.82 were unlikely to develop respiratory distress and did not require exogenous surfactant administration postnatally while the fetuses who had AT/ET ratio = 0.30, PI > 2.14 and RI > 0.82 were more predisposed to develop respiratory distress post-delivery and required exogenous surfactant administration, admission to NICU. Thus, these values can help distinguish between mature and immature lung of fetus antenatally.

CLINICAL RELEVANCE/APPLICATION

Based on findings of current study, it may be concluded that Doppler ultrasound may be a useful tool in the diagnosis of fetal lung maturity. It was found that elevated PI and RI values and low acceleration- time/ejection-time ratio(AT/ET ratio) can accurately predict the development of neonatal respiratory distress syndrome in females with singleton pregnancies who had no other associated comorbidities. Ultrasound doppler is a fast, low-cost technique that can be carried out in smaller centres to evaluate the lung maturity in fetuses antenatally. This could lead to better preparedness of obstetricians and neonatologists prior to delivery and could aid in triaging patients for referral to higher centres which are better equipped with neonatal care facilities.

S3B-SPPD-1 ASSESSMENT OF TECHNICAL PRECISION OF PEDIATRIC LIVER FAT QUANTIFICATION WITH MRI AND ULTRASOUND

Jiayi Tang, MSc (*Presenter*)
Lizbeth Ayala-Dominguez, PhD (*Abstract Co-Author*)
Amber Possell, RDMS, RVT, BS, RT (*Abstract Co-Author*)
Gabrielle Hoffmann (*Abstract Co-Author*)
Jitka Starekova, MD (*Abstract Co-Author*)
Alexandra Anagnostopoulos (*Abstract Co-Author*)
Daiki Tamada, PhD (*Abstract Co-Author*)
Garrett Fullerton, MS (*Abstract Co-Author*)
Andrew L. Wentland, MD,PhD (*Abstract Co-Author*)
Aaron Carrel (*Abstract Co-Author*)
Ivan Rosado-Mendez, PHD (*Abstract Co-Author*)
Diego Hernando, PhD (*Abstract Co-Author*)

PURPOSE

Metabolic dysfunction-associated steatotic liver disease (MASLD) is prevalent in children, especially those with obesity, highlighting the need for accessible, noninvasive fat quantification. While 3D chemical-shift-encoded (3D-CSE) MRI is the standard for proton-density fat fraction (PDFF) quantification, its ~20s breath-hold (BH) limits accessibility to children. Alternative MRI methods may improve accessibility by avoiding BH, while ultrasound (US) offers lower cost and wider equipment availability. This work evaluates the bias and repeatability of two methods that improve accessibility to noninvasive fat quantification: 2D free-breathing (FB) CSE-MRI with short per-slice temporal aperture and flip angle modulation (2D-FAM), and US-derived fat fraction (UDFF).

METHODS AND MATERIALS

In this IRB-approved prospective study, children were imaged with BH 3D-CSE, FB 2D-FAM, and BH (~10s) US in a single visit, using a 3.0T GE Signa Premier MR system and a Siemens ACUSON Seqouia US system. US was acquired by one sonographer, in the intercostal view, with a 9C2 transducer. For CSE-MRI, whole-liver PDFF maps were reconstructed, and ROIs were placed on the 5th Couinaud liver segment for approximate colocalization with US. UDFF was computed with the vendor's algorithm after image quality was verified by the sonographer. 2D-FAM and UDFF were compared to 3D-CSE to assess bias. Test-retest acquisitions were obtained and assessed via Bland-Altman analysis.

RESULTS

22 children (ages 10-14; 11 male/11 female; 12 with >95th percentile BMI and 10 with normal BMI) were imaged in test-retest (44 exams). 32/44 US exams had =3 frames of sufficient quality and were included, while all CSE-MRI PDFF maps were of diagnostic quality. 3D-CSE and 2D-FAM showed good agreement (mean bias=-0.3±0.5% PDFF, 95% limits of agreement, LoA=3.3±0.9%). 2D-FAM somewhat underestimated PDFF at high fat vs 3D-CSE (slope=0.83±0.07, intercept=0.5±0.6%), which may be partly due to T1-bias in 3D-CSE. UDFF showed moderate agreement with 3D-CSE (mean bias=0.7±1.4%, 95% LoA=7.5±2.4%) and overestimated at low fat and underestimated at high fat (slope=0.68±0.18, intercept=2.4±1.5%). The repeatability coefficients for 3D-CSE, 2D-FAM, and UDFF were 4.5±1.8, 2.1±0.8, and 7.0±3.8% respectively.

CONCLUSION

FB 2D-FAM may improve repeatability (ie. precision) of PDFF measurements in children, while maintaining low bias compared to BH 3D-CSE. UDFF shows promise in accessible fat quantification, and bias and precision may be improved via new postprocessing methods.

CLINICAL RELEVANCE/APPLICATION

MR/US-based fat quantification methods with improved accessibility, bias, and precision may enable widespread screening and staging of MASLD in children.

S3B-SPPD-2 HIP MORPHOLOGY OF EHLERS-DANLOS/HYPERMOBILITY SYNDROME PATIENTS UNDERGOING PERIACETABULAR OSTEOTOMY

Pedro Henrique Caldeira Brant Faria, MD (*Presenter*)
Jade Iwasaka-Neder, MD, MPH (*Abstract Co-Author*)
Ani Maroyan (*Abstract Co-Author*)
Andy Tsai, MD, PhD (*Abstract Co-Author*)
Michael B. Millis, MD (*Abstract Co-Author*)
Sarah D. Bixby, MD, MBA (*Abstract Co-Author*)

PURPOSE

Patients with Ehlers-Danlos Syndrome or Joint Hypermobility Syndrome (EDS/JHS) often experience hip instability. Some are treated with periacetabular osteotomy (PAO), a surgery traditionally reserved for acetabular deficiency in developmental dysplasia of the hip (DDH) in the setting of reduced lateral center-edge angle (LCEA) and other osseous abnormalities. It remains unclear whether instability in EDS/JHS is a clue to underlying osseous dysplasia or solely due to ligamentous laxity. This study (1) compared acetabular coverage in EDS/JHS patients undergoing PAO to non-EDS/JHS controls to assess the prevalence of radiographic dysplasia, and (2) reviewed surgical indications to evaluate potential mismatch between clinical and radiographic findings.

METHODS AND MATERIALS

Cases comprised pediatric patients (<21 years) with EDS/JHS and pre-operative hip radiographs who underwent PAO at our large tertiary children's hospital (1/2000-5/2024). EDS/JHS was defined as Beighton score =6 and reported history of ligamentous laxity. Matched controls included patients with DDH who underwent PAO with no history of EDS/JHS. Surgical indications were extracted from operative notes. Two readers measured LCEA, anterior center-edge angle (ACEA), Tönnis angle (TA), and Sharp angle (SA) independently. Statistical analysis included Wilcoxon rank-sum test and intraclass correlation (ICC).

RESULTS

The study included 36 EDS/JHS patients (all females; age = 17.6, range = 13-20 years) and 36 controls. Despite 97.2% (35/36) of EDS/JHS patients carrying a surgical diagnosis of dysplasia, 58.3% had normal LCEA (=25°) and 51% had normal ACEA (=20°), indicating normal acetabular coverage in over half the cases. Compared to controls, EDS/JHS patients had higher LCEA (26° vs. 16°, P=.001) and ACEA (25° vs. 14.5°, P=.001), and lower Tönnis (8.5° vs. 17.2°, P=.001) and Sharp angles (42.4° vs. 48°, P=.001). Inter-reader ICCs were good to excellent in both groups (0.88-0.93).

CONCLUSION

Many EDS/JHS patients undergoing PAO lack radiographic features of DDH. Hip instability in EDS/JHS patients may stem from soft tissue laxity rather than acetabular deficiency. We suggest that the term "acetabular dysplasia" may be inappropriate to describe EDS/JHS patients unless there is true acetabular deficiency. Further research is needed to assess their surgical outcomes and identify reliable imaging parameters to optimize treatment selection.

CLINICAL RELEVANCE/APPLICATION

This study highlights a misalignment between radiographic and pre-operative diagnoses in EDS/JHS patients undergoing PAO. Refining terminology in patients with instability without osseous deficiency may improve understanding of the underlying pathology and support surgical decision-making.

S3B-SPPD-3 DEEP LEARNING-ACCELERATED AUTOMATED SEGMENTATION OF PLEXIFORM NEUROFIBROMA IN PATIENTS WITH NEUROFIBROMATOSIS TYPE 1

Jeong Min Song, MD (*Presenter*)
Wonkeun Jo (*Abstract Co-Author*)
Hee Mang Yoon, MD, PhD (*Abstract Co-Author*)
Yu Sub Sung (*Abstract Co-Author*)
Pyeong Hwa Kim (*Abstract Co-Author*)
Ah Young Jung, MD (*Abstract Co-Author*)

PURPOSE

While 3D volumetric analysis of plexiform neurofibromas (PNs) is crucial to evaluate treatment response in patients with neurofibromatosis type 1 (NF1), particularly to selumetinib, manual segmentation is labor-intensive and time-consuming. This study aims to develop a deep learning model to assist with the automated segmentation of PNs in patients with NF1.

METHODS AND MATERIALS

We retrospectively collected MRI examinations of pediatric and adult NF1 patients enrolled in a selumetinib clinical trial between May 2019 and December 2023. For model development, axial T2-weighted fat-suppressed images with a slice thickness of 3-7 mm and no interslice gap were used. To overcome the small dataset size, we employed 5-fold cross-validation to train a Cascade Mask R-CNN, using an ensemble of the resulting models for inference. As the reference standard, we used PN segmentation labels created by image analysts under radiologist supervision. Given the clinical importance of target PN volume measurement in treatment response evaluation, the model's performance was assessed separately for whole PN and target PN volume segmentation. For model testing, MRI examinations of NF1 patients with measurable PNs, not enrolled in the clinical trial, were retrospectively collected from a single institution between January and July 2024. Segmentation performance of the model was evaluated using Intersection over Union (IoU), F1 score, precision, and recall.

RESULTS

A total of 80 MRI examinations from 62 patients (median age, 12.5 years; 38 males) were used for model development, with 73 examinations used for training and 7 for tuning. For model testing, 10 MRI examinations from 10 NF1 patients were used. In the model development dataset, target PNs were most common in the pelvis (19 of 80 PNs), followed by the neck, chest, and other regions. In the test dataset, target PNs were most common in the neck (5 of 10 PNs). For whole PN volume segmentation, the model achieved an IoU of 0.45, F1 score of 0.59, precision of 0.55, and recall of 0.70. For target PN volume segmentation, the IoU, F1 score, precision, and recall were 0.07, 0.13, 0.08, and 0.93, respectively. The model's inference time was under one minute for all cases.

CONCLUSION

We developed and internally validated an automated segmentation assistance deep learning model for PNs in NF1 patients. The proposed model demonstrated a high recall of 0.93 for segmentation of target PNs, suggesting that simple post-processing of the predicted segments may be sufficient for accurate evaluation of 3D volumetric analysis of target PNs.

CLINICAL RELEVANCE/APPLICATION

Following model inference, clinicians can efficiently correct minor segmentation errors, enabling a streamlined PN segmentation workflow and reducing expert workload.

S3B-SPPH-1 3D FLUID ATTENUATED INVERSION RECOVERY WITH A GENERALIZED PREPARATION PULSE

Christina Graf, PhD (*Presenter*)
Alexander Jaffray (*Abstract Co-Author*)
Armin Rund (*Abstract Co-Author*)
Stefan Steinerberger (*Abstract Co-Author*)
Alexander Rauscher, PhD, MSc (*Abstract Co-Author*)

PURPOSE

Preparation pulses are widely used in magnetic resonance imaging (MRI), with fluid attenuated inversion recovery (FLAIR) being a prominent example. In FLAIR, the signal is prepared with an 180 degree inversion pulse, with the aim to suppress signal from cerebrospinal fluid (CSF) in the subsequent imaging sequence. The inversion is almost always realized with an adiabatic full passage pulse (i.e. 180 degrees), which has good robustness to inhomogeneities in the radiofrequency field. Smaller flip angles for the preparation pulse may have advantages in certain applications. The purpose of our study was to develop a generalized preparation pulse with a flip angle of 140 degrees, and to test the pulse in a FLAIR sequence.

METHODS AND MATERIALS

The preparation pulse was designed using optimal control, incorporating robustness against field inhomogeneities directly into the cost function for pulse optimization, with a target flip angle of 140 degrees. In addition, maximum dephasing of the transverse magnetization was imposed so that purely a z-magnetization remains after preparation. The pulse replaced the inversion pulse of a 3D FLAIR sequence. Experimental data were acquired at 3 T in a human volunteer. The 140-degree preparation resulted in an inverson time of 1600 ms. Other scan parameters were 1 cubic mm isotropic resolution, repetition time (TR) = 6000 ms, effective echo time (TE) = 300 ms, scan duration = 3 min 48 s. For comparison, data were acquired with 180 degree inversion, the same spatial resolution, echo time and duration, resulting in a TI of 2000 ms at a TR of 6000 ms, and the same scan duration of 3 min 48 s.

RESULTS

The FLAIR scan with 140 degree preparation shows improved CSF suppression compared to the conventional FLAIR scan. Image contrast is similar for the two scans.

CONCLUSION

Non-180 degree preparation pulses are feasible. FLAIR with a 140 degree preparation pulse shows favourable CSF suppression compared to a conventional FLAIR with the same scan duration.

CLINICAL RELEVANCE/APPLICATION

The preparation pulse can be easily adopted into routine MRI, without any hardware modifications, facilitating direct clinical impact.

S3B-SPPH-2 DEVELOPING AN ATTENTION-BASED BREAST DENSE TISSUE SEGMENTATION ALGORITHM FOR MULTI-CENTER, MULTI-VENDOR DATA

Razieh Ganjee (*Presenter*)
Tamerlan Mustafaev, MD (*Abstract Co-Author*)
Belayat Hossain, PhD (*Abstract Co-Author*)
Margarita L. Zuley, MD (*Abstract Co-Author*)
Juhun Lee, PhD (*Abstract Co-Author*)

PURPOSE

Breast density, defined as the proportion of glandular (dense) to fatty tissue, is one of key risk factors for breast cancer. Reliable density assessment can be possible through accurate dense tissue segmentation from mammograms. However, variations in tissue appearance and texture, particularly across images from different vendors, pose challenges to robust segmentation of dense tissue. This study presents a deep network model incorporating global contextual information to improve dense tissue segmentation in multi-vendor and multi-center mammogram data.

METHODS AND MATERIALS

We developed a hierarchical encoder-decoder architecture with adaptive spatial and channel-wise attention mechanisms integrated into the skip connections. This dual-attention framework enables the model to capture long-range feature dependencies and account for intra-class variation in tissue appearance. We used 1,500 "for-presentation" mammograms of 606 women from three independent sources, each comprising 500 mammograms. These mammograms were acquired at various centers using different imaging vendors, including one from Asia with Siemens (Set1), and two from United States with Hologic (Set2,3). Using radiologist-validated dense tissue masks as ground truth, we trained and evaluated our algorithm's segmentation performance using 5-fold cross-validation. We then computed percent density (PD) using the segmentation outcomes and used it to evaluate the algorithm's ability to classify each mammogram into dense (BI-RADS density C-D) and fatty (BI-RADS density A-B) groups.

RESULTS

The proposed model achieved strong agreement with the ground truth, with an overall average Dice score of 0.72 ± 0.17 for 5 fold CV. It performed best on dense breast cases, with Dice scores of 0.84 ± 0.10 (Set1), 0.83 ± 0.11 (Set2), and 0.80 ± 0.10 (Set3). In the classification task of fatty vs. dense using PD, our model achieved an AUC of 0.96. While this was statistically lower than the ground truth-based PD (AUC = 0.98; DeLong's p = 0.004), the performance was comparable.

CONCLUSION

Our deep learning model demonstrated effectiveness in segmenting dense breast tissue across clinical centers and imaging vendors by leveraging spatial and channel-wise attention to capture appearance variations in features of the same tissue type, regardless of their location in the image.

CLINICAL RELEVANCE/APPLICATION

Breast dense tissue is a critical risk factor for breast cancer. The proposed algorithm may enable reliable segmentation of dense tissue over different clinical centers and imaging vendors, which can facilitate the evaluation process of breast density.

S3B-SPPH-3 COMPARATIVE ASSESSMENT OF RECONSTRUCTION METHODS FOR PULMONARY NODULE DETECTION IN ULTRA-LOW-DOSE CT

Siqi Qu (*Presenter*)
Zhiming Xiang (*Abstract Co-Author*)
Qiuxing Chen (*Abstract Co-Author*)
Kun Ma (*Abstract Co-Author*)

PURPOSE

To compare deep learning image reconstruction (DLIR) with adaptive statistical iterative reconstruction-Veo (ASIR-V) in ultra-low-dose chest CT (ULDCT) and evaluate their effects on image quality and quantitative assessment of pulmonary nodules.

METHODS AND MATERIALS

This prospective study included 98 patients with pulmonary nodules who underwent both standard-dose CT (SDCT) and ULDCT. ULDCT scanning parameters were adjusted based on body mass index (BMI) and categorized into four subgroups: L (<18.5 kg/m²), M (18.5-23.9 kg/m²), H (24-27.9 kg/m²), and F (=28 kg/m²). SDCT images were reconstructed using ASIR-V at 50% blending (ASIR-V 50%) and served as the reference standard. ULDCT images were reconstructed using ASIR-V 50%, DLIR at medium strength (DLIR-M), and DLIR at high strength (DLIR-H). Pulmonary nodule detection rates were calculated using SDCT as the reference. Nodule size (diameter and volume) was measured across all reconstructions. Standard deviation (SD) of CT attenuation values in lung parenchyma and subcutaneous fat at the same axial level as the nodules was used to assess image noise. Signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) were computed to evaluate image quality.

RESULTS

A total of 668 pulmonary nodules were identified on SDCT. Detection rates on ULDCT were 97.46% (651/668) with ASIR-V 50%, 97.90% (654/668) with DLIR-M, and 98.35% (657/668) with DLIR-H. The effective dose (ED) for SDCT was 3.74 ± 1.55 mSv, compared to 0.48 ± 0.11 mSv for ULDCT. Among ULDCT reconstructions, image noise—as measured by SD—was lowest in DLIR-H, followed by DLIR-M and ASIR-V 50%, while SNR and CNR followed the reverse trend ($P < 0.001$). No significant differences in nodule diameter or volume were found between ULDCT and SDCT reconstructions ($P > 0.001$). Nodule size and volume measurements from ASIR-V 50%, DLIR-M, and DLIR-H reconstructions were all highly consistent with those from SDCT, with ? values for diameter of 0.992, 0.995, and 0.991, and for volume of 0.992, 0.991, and 0.992, respectively. No statistically significant differences were observed among the three reconstruction techniques ($P > 0.001$).

CONCLUSION

DLIR enhanced image quality and improved nodule detection on ULDCT compared with ASIR-V50%. Nodule size measurements on ULDCT reconstructed with ASIR-V50%, DLIR-M, and DLIR-H showed high agreement with those on SDCT in both diameter and volume.

CLINICAL RELEVANCE/APPLICATION

DLIR improves image quality in ULDCT while preserving diagnostic accuracy for pulmonary nodule detection and quantification. By enabling substantial radiation dose reduction without compromising diagnostic performance, DLIR offers meaningful clinical value for routine lung cancer screening.

S3B-SPPH-5 IMPROVING CT IMAGE QUALITY OF THE LEFT ATRIAL APPENDAGE AFTER PERCUTANEOUS CLOSURE USING A SECOND-GENERATION WHOLE-HEART MOTION CORRECTION ALGORITHM

Yanan Li (*Presenter*)

PURPOSE

To demonstrate the ability of a whole-heart motion correction algorithm (snapshot freeze, SSF2) to improve the cardiac computed tomography (CT) image quality of the left atrial appendage (LAA) after percutaneous closure.

METHODS AND MATERIALS

A total of 38 patients after percutaneous closure of LAA underwent single-heartbeat cardiac CT on a 16cm detector CT scanner. Images were reconstructed with no motion correction (STD), first-generation snapshot freeze (SSF1) and SSF2. The motion artifact, LAA visualization and overall image quality for the LAA closure (proximal, central, and distal) were assessed by two experienced radiologists using a five-point scale as shown in Table 1. The regions of interest were placed in three areas with heavy artifacts at the middle level of the LAA closure to measure the standard deviation (SD). The Friedman test with a post-hoc test was performed to compare objective and subjective results.

RESULTS
